Message from the 23rd USENIX Security Symposium Program Chair

Welcome to the 23rd USENIX Security Symposium in San Diego, CA! If I were to pick one phrase to describe this year, it would be "record-breaking" with "server-breaking" as a close second. This year's program will literally knock your socks off, especially the session on transparency. The Program Committee received 350 submissions, a whopping 26% increase over last year. After careful deliberation with an emphasis on positive and constructive reviewing, we accepted 67 papers. I'd like to thank the authors, the invited speakers, the Program Committee members and other organizers, the external reviewers, the sponsors, the USENIX staff, and the attendees for continuing to make USENIX Security a premier venue for security and privacy research. I'd also like to welcome our newcomers—be they students or seasoned researchers—to make the most of our technical sessions and evening events.

The USENIX Security Program Committee has followed a procedure that has changed little since the late 1990s, even as the number of submissions has grown from several dozen to hundreds. I evaluated the attendee survey of the previous year, interviewed both elders and newcomers, and performed a linear regression on paper submission statistics collected over the last 15 years. As a result, I instituted a number of changes to cope with the growth and maturation of our field. The changes include: introducing the light/heavy PC model to USENIX Security, the shadow PC concept, a hybrid unblinding process during the final stages of reviewing, a Doctoral Colloquium for career building, a Lightning Talks session of short videos, and enforcement of positive and constructive reviewing methodologies during deliberation.

I initially invited 56 Program Committee members (in honor of DES) to cover the advertised topics while attempting to increase diversity across dimensions of country, gender, geography, institution, and seniority. Each paper reaching the discussion phase had multiple reviewers who could speak at the PC meeting having read the paper. The authors of submissions were not revealed to the reviewers until late in the decision-making phase, and every paper was reviewed by at least two reviewers. The median number of reviews per paper was five. The heavy Program Committee met to discuss the submissions in May at the University of Michigan in Ann Arbor, Michigan. Attendees enjoyed quintessential and memorable Ann Arbor cuisine, including NSA-themed cocktails provided by Duo Security. Ahead of the meeting, each paper was assigned a discussion lead. We used punch cards and the "meeting tracker" feature of the HotCRP software so that each paper received ten minutes of discussion in an order planned ahead of time to ensure efficient and fairly allocated deliberation time. We finished exactly on schedule after two days.

The entire Program Committee invested a tremendous effort in reviewing and discussing these papers. PC members submitted on average 23 reviews. They received no tangible rewards other than a complimentary webcam privacy lens cap. So please, thank the all-volunteer PC members and external reviewers for their countless hours of work.

I would like to thank Patrick Traynor for chairing the Invited Talks Committee that selected a thought-provoking set of invited talks. The Poster and Works-in-Progress sessions are also "can't miss" events for glimpses of cutting-edge and emerging research activities. I would like to thank Franziska Roesner for serving as the Poster Session Chair, and Tadayoshi Kohno for serving as both the WiPs Chair and Shadow PC Coordinator.

I am especially appreciative of Jaeyeon Jung for accepting the responsibilities of Deputy PC Chair after I had to deal with an unexpected disaster and relocation of my children after our house collapsed. When evaluating excuses for late reviews, I would consider whether the PC member's house had recently collapsed. I also thank the USENIX Security Steering Committee and Niels Provos in particular for serving as USENIX Liaison. Eddie Kohler earns MVP status for his fast responses to various HotCRP questions. Finally, I would like to thank all of the authors who submitted their research for consideration. Our community is in its prime, so please enjoy the 23rd USENIX Security Symposium!

Privee: An Architecture for Automatically Analyzing Web Privacy Policies

Sebastian Zimmeck and Steven M. Bellovin

Department of Computer Science, Columbia University
{*sebastian,smb*}*@cs.columbia.edu*

Abstract

Privacy policies on websites are based on the notice-and-choice principle. They notify Web users of their privacy choices. However, many users do not read privacy policies or have difficulties understanding them. In order to increase privacy transparency we propose Privee—a software architecture for analyzing essential policy terms based on crowdsourcing and automatic classification techniques. We implement Privee in a proof of concept browser extension that retrieves policy analysis results from an online privacy policy repository or, if no such results are available, performs automatic classifications. While our classifiers achieve an overall F-1 score of 90%, our experimental results suggest that classifier performance is inherently limited as it correlates to the same variable to which human interpretations correlate—the ambiguity of natural language. This finding might be interpreted to call the notice-and-choice principle into question altogether. However, as our results further suggest that policy ambiguity decreases over time, we believe that the principle is workable. Consequently, we see Privee as a promising avenue for facilitating the notice-and-choice principle by accurately notifying Web users of privacy practices and increasing privacy transparency on the Web.

1 Introduction

Information privacy law in the U.S. and many other countries is based on the free market notice-and-choice principle [28]. Instead of statutory laws and regulations, the privacy regime is of a contractual nature—the provider of a Web service posts a privacy policy, which a user accepts by using the site. In this sense, privacy policies are fundamental building blocks of Web privacy. The Federal Trade Commission (FTC) strictly enforces companies' violations of their promises in privacy policies. However, only few users read privacy policies and those who do find them oftentimes hard to understand [58]. The resulting information asymmetry leaves users uninformed about their privacy choices [58], can lead to market failure [57], and ultimately casts doubt on the notice-and-choice principle.

Various solutions were proposed to address the problem. However, none of them gained widespread acceptance—neither in the industry, nor among users. Most prominently, The Platform for Privacy Preferences (P3P) project [29, 32] was not widely adopted, mainly, because of a lack of incentive on part of the industry to express their policies in P3P format. In addition, P3P was also criticized for not having enough expressive power to describe privacy practices accurately and completely [28, 11]. Further, existing crowdsourcing solutions, such as Terms of Service; Didn't Read (ToS;DR) [5], may not scale well and still need to gain more popularity. Informed by these experiences, which we address in more detail in Section 2, we present Privee—a novel software architecture for analyzing Web privacy policies. In particular, our contributions are:

- the Privee concept that combines rule and machine learning (ML) classification with privacy policy crowdsourcing for seamless integration into the existing privacy regime on the Web (Section 3);
- an implementation of Privee in a Google Chrome browser extension that interacts with privacy policy websites and the ToS;DR repository of crowdsourced privacy policy results (Section 4);
- a statistical analysis of our experimental results showing that the ambiguity of privacy policies makes them inherently difficult to understand for both humans and automatic classifiers (Section 5);
- pointers for further research on notice-and-choice and adaptations that extend Privee as the landscape of privacy policy analysis changes and develops (Section 6).

2 Related Work

While only few previous works are directly applicable, our study is informed by four areas of previous research: privacy policy languages (Section 2.1), legal information extraction (Section 2.2), privacy policy crowdsourcing (Section 2.3), and usable privacy (Section 2.4).

2.1 Privacy Policy Languages

Initial work on automatic privacy policy analysis focused on making privacy policies machine-readable. That way a browser or other user agent could read the policies and alert the user of good and bad privacy practices. Reidenberg [67] suggested early on that Web services should represent their policies in the Platform for Internet Content Selection (PICS) format [10]. This and similar suggestions lead to the development of P3P [29, 32], which provided a machine-readable language for specifying privacy policies and displaying their content to users [33]. To that end, the designers of P3P implemented various end users tools, such as Privacy Bird [30], a browser extension for Microsoft's Internet Explorer that notifies users of the privacy practices of a Web service whose site they visit, and Privacy Bird Search [24], a P3P-enabled search engine that returns privacy policy information alongside search results.

The development of P3P was complemented by various other languages and tools. Of particular relevance was A P3P Preference Privacy Exchange Language (APPEL) [31], which enabled users to express their privacy preferences vis-à-vis Web services. APPEL was further extended in the XPath project [14] and inspired the User Privacy Policy (UPP) language [15] for use in social networks. For industry use, the Platform for Enterprise Privacy Practices (E-P3P) [47] was developed allowing service providers to formulate, supervise, and enforce privacy policies. Similar languages and frameworks are the Enterprise Privacy Authorization Language (EPAL) [18], the SPARCLE Policy Workbench [22, 23], Jeeves [78], and XACML [12]. However, despite all efforts the adoption rate of P3P policies among Web services remained low [11], and the P3P working group was closed in 2006 due to lack of industry participation [28].

Instead of creating new machine-readable privacy policy formats we believe that it is more effective to use what is already there—privacy policies in natural language. The reasons are threefold: First, natural language is the de-facto standard for privacy policies on the Web, and the P3P experience shows that there is currently no industry-incentive to move to a different standard. Second, U.S. governmental agencies are in strong support of the natural language format. In particular, the FTC, the main privacy regulator, called for more industry-efforts to increase policy standardization and comprehensibility [38]. Another agency, the National Science Foundation, awarded $3.75 million to the Usable Privacy Policy Project [9] to explore possibilities of automatic policy analysis. Third, natural language has stronger expressive power compared to a privacy policy language. It allows for industry-specific formulation of privacy practices and accounts for the changing legal landscape over time.

2.2 Legal Information Extraction

Given our decision to make use of natural language policies, the question becomes how salient information can be extracted from unordered policy texts. While most works in legal information extraction relate to domains other than privacy, they still provide some guidance. For example, Westerhout et al. [75, 76] had success in combining a rule-based classifier with an ML classifier to identify legal definitions. In another line of work de Maat et al. [35, 36] aimed at distinguishing statutory provisions according to types (such as procedural rules or appendices) and patterns (such as definitions, rights, or penal provisions). They concluded that it was unnecessary to employ something more complex than a simple pattern recognizer [35, 36]. Other tasks focused on the extraction of information from statutory and regulatory laws [21, 20], the detection of legal arguments [59], or the identification of case law sections [54, 71].

To our knowledge, the only works in the privacy policy domain are those by Ammar et al. [16], Costante et al. [26, 27], and Stamey and Rossi [70]. As part of the Usable Privacy Policy Project [9] Ammar et al. presented a pilot study [16] with a narrow focus on classifying provisions for the disclosure of information to law enforcement officials and users' rights to terminate their accounts. They concluded the feasibility of natural language analysis in the privacy policy domain in general. In their first work [26] Costante et al. used general natural language processing libraries to evaluate the suitability of rule-based identification of different types of user information that Web services collect. Their results are promising and indicate the feasibility of rule-based classifiers. In a second work [27] Costante et al. selected an ML approach for assessing whether privacy policies cover certain subject matters. Finally, Stamey and Rossi [70] provided a program for identifying ambiguous words in privacy policies.

The discussed works [16, 26, 27, 70] confirm the suitability of rule and ML classifiers in the privacy policy domain. However, neither provides a comprehensive concept, nor addresses, for example, how to process the policies or how to make use of crowdsourcing results. The latter point is especially important because, as shown in Section 5, automatic policy classification on its own is in-

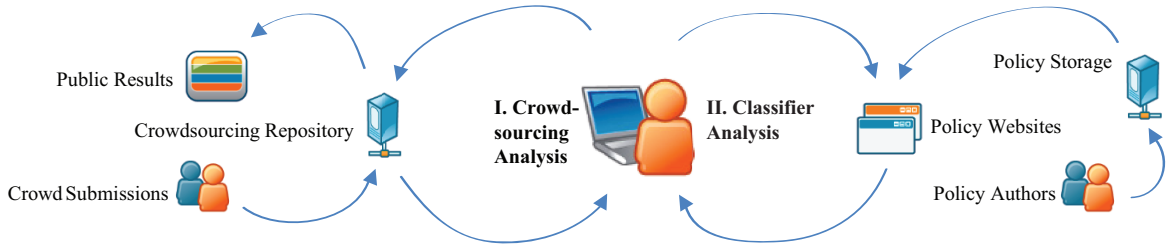

Figure 1: Privee overview. When a user requests a privacy policy analysis, the program checks whether the analysis results are available at a crowdsourcing repository (to which crowd contributors can submit analysis results of policies). If results are available, they are returned and displayed to the user (I. Crowdsourcing Analysis). If no results are available, the policy text is fetched from the policy website, analyzed by automatic classifiers on the client machine, and then the analysis results are displayed to the user (II. Classifier Analysis).

herently limited. In addition, as the previous works' purpose is to generally show the viability of natural language privacy policy analysis, they are constrained to classifying one or two individual policy terms or features. As they process each classification task separately, there was also no need to address questions of handling multiple classifiers or discriminating which extracted features belong to which classification task. Because of their limited scope none of the previous works relieves the user from actually reading the analyzed policy. In contrast, it is our goal to provide users with a privacy policy summary in lieu of the full policy. We want to condense a policy into essential terms, make it more comprehensible, provide guidance on the analyzed practices, and give an overall evaluation of its privacy level.

2.3 Privacy Policy Crowdsourcing

There are various crowdsourcing repositories where crowd contributors evaluate the content of privacy policies and submit their results into a centralized collection for publication on the Web. Sometimes policies are also graded. Among those repositories are ToS;DR [5], privacychoice [4], TOSBack [7], and TOSBack2 [8]. Crowdsourcing has the advantage that it combines the knowledge of a large number of contributors, which, in principle, can lead to much more nuanced interpretations of ambiguous policy provisions than current automatic classifiers could provide. However, all crowdsourcing approaches suffer from a lack of participation and, consequently, do not scale well. While the analysis results of the most popular websites may be available, those for many lesser known sites are not. In addition, some repositories only provide the possibility to look up the results on the Web without offering convenient user access, for example, by means of a browser extension or other software.

2.4 Usable Privacy

Whether the analysis of a privacy policy is based on crowdsourcing or automatic classifications, in order to notify users of the applicable privacy practices it is not enough to analyze policy content, but rather the results must also be presented in a comprehensible, preferably, standardized format [60]. In this sense, usable privacy is orthogonal to the other related areas: no matter how the policies are analyzed, a concise, user-friendly notification is always desirable. In particular, privacy labels may help to succinctly display privacy practices [48, 49, 51, 65, 66]. Also, privacy icons, such as those proposed by PrimeLife [39, 45], KnowPrivacy [11], and the Privacy Icons project [3], can provide visual clues to users. However, care must be taken that the meaning of the icons is clear to the users [45]. In any case, it should be noted that while usability is an important element of the Privee concept, we have not done a usability study for our Privee extension as it is just a proof of concept.

3 The Privee Concept

Figure 1 shows a conceptual overview of Privee. Privee makes use of automatic classifiers and complements them with privacy policy crowdsourcing. It integrates all components of the current Web privacy ecosystem. Policy authors write their policies in natural language and do not need to adopt any special machine-readable policy format. While authors certainly can express the same semantics as with P3P, which we demonstrate in Section 4.6.2, they can also go beyond and use their language much more freely and naturally.

When a user wants to analyze a privacy policy, Privee leverages the discriminative power of crowdsourcing. As we will see in Section 5 that classifiers and human interpretations are inherently limited by ambiguous language,

it is especially important to resolve those ambiguities by providing a forum for discussion and developing consensus among many crowd contributors. Further, Privee complements the crowdsourcing analysis with the ubiquitous applicability of rule and ML classifiers for policies that are not yet analyzed by the crowd. Because the computational requirements are low, as shown in Section 5.3, a real time analysis is possible.

As the P3P experience showed [28] that a large fraction of Web services with P3P policies misrepresented their privacy practices, presumably in order to prevent user agents from blocking their cookies, any privacy policy analysis software must be guarded against manipulation. However, natural language approaches, such as Privee, have an advantage over P3P and other machine-readable languages. Because it is not clear whether P3P policies are legally binding [69] and the FTC never took action to enforce them [55], the misrepresentation of privacy practices in those policies is a minor risk that many Web services are willing to take. This is true for other machine-readable policy solutions as well. In contrast, natural language policies can be valid contracts [1] and are subject to the FTC's enforcement actions against unfair or deceptive acts or practices (15 U.S.C. §45(a)(1)). Thus, we believe that Web services are more likely to ensure that their natural language policies represent their practices accurately.

Given that natural language policies attempt to truly reflect privacy practices, it is important that the policy text is captured completely and without additional text, in particular, free from advertisements on the policy website. Further, while it is true that an ill-intentioned privacy policy author might try to deliberately use ambiguous language to trick the classifier analysis, this strategy can only go so far as ambiguous contract terms are interpreted against the author (Restatement (Second) of Contracts, §206) and might also cause the FTC to challenge them as unfair or deceptive. Beyond safeguarding the classifier analysis, it is also important to prevent the manipulation of the crowdsourcing analysis. In this regard, the literature on identifying fake reviews should be brought to bear. For example, Wu et al. [77] showed that fake reviews can be identified by a suspicious grade distribution and their posting time following negative reviews. In order to ensure that the crowdsourcing analysis returns the latest results the crowdsourcing repository should also keep track of privacy policy updates.

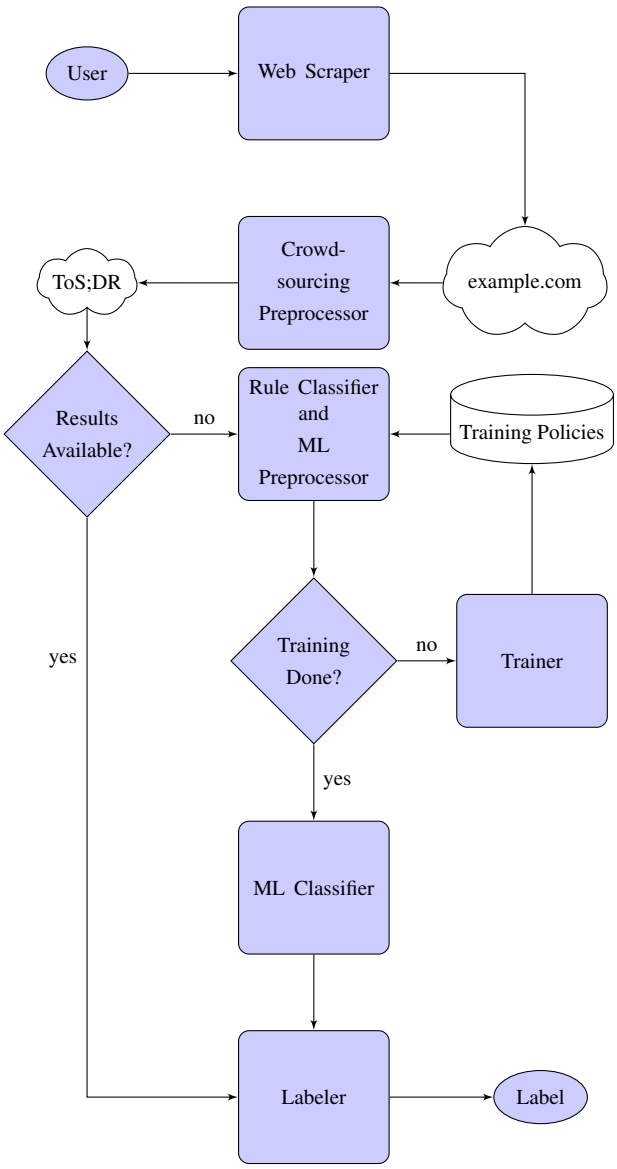

Figure 2: Simplified program flow. After the user has started the extension, the Web scraper obtains the text of the privacy policy to be analyzed (example.com) as well as the current URL (http://example.com/). The crowdsourcing preprocessor then extracts from the URL the ToS;DR identifier and checks the ToS;DR repository for results. If results are available, they are retrieved and forwarded to the labeler, which converts them to a label for display to the user. However, if no results are available on ToS;DR the policy text is analyzed. First, the rule classifier attempts a rule-based classification. However, if that is not possible the ML preprocessor prepares the ML classification. It checks if the ML classifier is already trained. If that is the case, the policy is classified by the ML classifier, assigned a label according to the classifications, and the results are displayed to the user. Otherwise, a set of training policies is analyzed by the trainer first and the program proceeds to the ML classifier and labeler afterwards. The set of training policies is included in the extension package and only needs to be analyzed for the first run of the ML classifier. Thereafter, the training results are kept in persistent storage until deletion by the user.

4 The Privee Browser Extension

We implemented Privee as a proof of concept browser extension for Google Chrome (version 35.0.1916.153). Figure 2 shows a simplified overview of the program flow. We wrote our Privee extension in JavaScript using

the jQuery library and Ajax functions for client-server communication. While we designed our extension as an end user tool, it can also be used for scientific or industrial research, for example, in order to easily compare different privacy policies to each other. In this Section we describe the various stages of program execution.

4.1 Web Scraper

The user starts the Privee extension by clicking on its icon in the Chrome toolbar. Then, the Web scraper obtains the text of the privacy policy that the user wants to analyze and retrieves the URL of the user's current website. While the rule and ML classifier analysis only works from the site that contains the policy to be analyzed, the crowdsourcing analysis works on any website whose URL contains the policy's ToS;DR identifier.

4.2 Crowdsourcing Preprocessor

The crowdsourcing preprocessor is responsible for managing the interaction with the ToS;DR repository. It receives the current URL from the Web scraper from which it extracts the ToS;Dr identifier. It then connects to the API of ToS;DR and checks for the availability of analysis results, that is, short descriptions of privacy practices and sometimes an overall letter grade. The results, if any, are forwarded to the labeler and displayed to the user. Then the extension terminates. Otherwise, the policy text, which the crowdsourcing preprocessor also received from the Web scraper, is forwarded to the rule classifier and ML preprocessor.

4.3 Rule Classifier and ML Preprocessor

Generally, classifiers can be based on rule or ML algorithms. In our preliminary experiments we found that for some classification categories a rule classifier worked better, in others an ML classifier, and in others again a combination of both [71, 76]. We will discuss our classifier selection in Section 5.1 in more detail. In this Section we will focus on the feature selection process for our rule classifier and ML preprocessor. Both rule classification and ML preprocessing are based on feature selection by means of regular expressions.

Our preliminary experiments revealed that classification performance depends strongly on feature selection. Ammar et al. [16] discuss a similar finding. Comparable to other domains [76], feature selection is particularly useful in our case for avoiding misclassifications due to the heavily imbalanced structure of privacy policies. For example, in many multi-page privacy policies there is often only one phrase that determines whether the Web service is allowed to combine the collected information with information from third parties to create personal profiles of users. Especially, supervised ML classifiers do not work well in such cases, even with undersampling (removal of uninteresting examples) or oversampling (duplication of interesting examples) [52]. Possible solutions to the problem are the separation of policies into different content zones and applying a classifier only to relevant content zones [54] or—the approach we adopted—running a classifier only on carefully selected features.

Our extension's feature selection process begins with the removal of all characters from the policy text that are not letters or whitespace and conversion of all remaining characters to lower case. However, the positions of removed punctuations are preserved because, as noted by Biagoli et al. [19], a correct analysis of the meaning of legal documents often depends on the position of punctuation. In order to identify the features that are most characteristic for a certain class we used the term frequency-inverse document frequency (tf-idf) statistic as a proxy. The tf-idf statistic measures how concentrated into relatively few documents the occurrences of a given word are in a document corpus [64]. Thus, words with high tf-idf values correlate strongly with the documents in which they appear and can be used to identify topics in that document that are not discussed in other documents. However, instead of using individual words as features we observed that the use of bigrams lead to better classification performance, which was also discussed in previous works [16, 59].

```
(ad|advertis.*) (compan.*|network.*|provider.*|
servin.*|serve.*|vendor.*)|(behav.*|context.*|
network.*|parti.*|serv.*) (ad|advertis.*)
```

Listing 1: Simplified pseudocode of the regular expression to identify whether a policy allows advertising tracking. For example, the regular expression would match "contextual advertising."

The method by which our Privee extension selects characteristic bigrams, which usually consist of two words, but can also consist of a word and a punctuation mark, is based on regular expressions. It applies a three-step process that encompasses both rule classification and ML preprocessing. To give an example, for the question whether the policy allows advertising tracking (e.g., by ad cookies) the first step consists of trying to match the regular expression in Listing 1, which identifies bigrams that nearly always indicate that advertising tracking is allowed. If any bigram in the policy matches, no further analysis happens, and the policy is classified by the rule classifier as allowing advertising tracking. If the regular expression does not match, the second step attempts to extract further features that can be associated with advertising tracking (which are, however, more gen-

eral than the previous ones). Listing 2 shows the regular expression used for the second step.

```
(ad|advertis|market) (.+)|(.+) (ad|advertis|
market)
```

Listing 2: Simplified pseudocode of the regular expression to extract relevant phrases for advertising tracking. For example, the regular expression would match "no advertising."

The second step—the ML preprocessing—is of particular importance for our analysis because it prepares classification of the most difficult cases. It extracts the features on which the ML classifier will run later. To that end, it first uses the Porter stemmer [63] to reduce words to their morphological root [19]. Such stemming has the effect that words with common semantics are clustered together [41]. For example, "collection," "collected," and "collect" are all stemmed into "collect." As a side note, while stemming had some impact, we did not find a substantial performance increase for running the ML classifier on stemmed features compared to unstemmed features. In the third step, if no features were extracted in the two previous steps, the policy is classified as not allowing advertising tracking.

4.4 Trainer

In the training stage our Privee extension checks whether the ML classifier is already trained. If that is not the case, a corpus of training policies is preprocessed and analyzed. The analysis of a training policy is similar to the analysis of a user-selected policy, except that the extension does not check for crowdsourcing results and only applies the second and third step of the rule classifier and ML preprocessor phase. The trainer's purpose is to gather statistical information about the features in the training corpus in order to prepare the classification of the user-selected policy. It stores the training results locally in the user's browser memory using persistent Web storage, which is, in principle, similar to cookie storage.

4.5 Training Data

The training policies are held in a database that is included in the extension package. The database holds a total of 100 training policies. In order to obtain a representative cross section of training policies, we selected the majority of our policies randomly from the Alexa top 500 websites for the U.S. [6] across various domains (banking, car rental, social networking, etc.). However, we also included a few random policies from lesser frequented U.S. sites and sites from other countries that published privacy policies in English. The trainer accesses these training policies one after another and adds the training results successively to the client's Web storage. After all results are added the ML classifier is ready for classification.

4.6 ML Classifier

We now describe the ML classifier design (Section 4.6.1) and the classification categories (Section 4.6.2).

4.6.1 ML Classifier Design

In order to test the suitability of different ML algorithms for analyzing privacy policies we performed preliminary experiments using the Weka library [43]. Performance for the different algorithms varied. We tested all algorithms available on Weka, among others the Sequential Minimal Optimization (SMO) algorithm with different kernels (linear, polynomial, radial basis function), random forest, J48 (C4.5), IBk nearest neighbor, and various Bayesian algorithms (Bernoulli naive Bayes, multinomial naive Bayes, Bayes Net). Surprisingly, the Bayesian algorithms were among the best performers. Therefore, we implemented naive Bayes in its Bernoulli and multinomial version. Because the multinomial version ultimately proved to have better performance, we settled on this algorithm.

As Manning et al. [56] observed, naive Bayes classifiers have good accuracy for many tasks and are very efficient, especially, for high-dimensional vectors, and they have the advantage that training and classification can be accomplished with one pass over the data. Our naive Bayes implementation is based on their specification [56]. In general, naive Bayes classifiers make use of Bayes' theorem. The probability, P, of a document, d, being in a category, c, is

$$P(c|d) \propto P(c) \prod_{1 \le k \le n_d} P(t_k|c), \tag{1}$$

where $P(c)$ is the prior probability of a document occurring in category c, n_d is the number of terms in d that are used for the classification decision, and $P(t_k|c)$ is the conditional probability of term t_k occurring in a document of category c [56]. In other words, $P(t_k|c)$ is interpreted as a measure of how much evidence t_k contributes for c being the correct category [56]. The best category to select for a document in a naive Bayes classification is the category for which it holds that

$$\arg\max_{c \in \mathbb{C}} \hat{P}(c|d) = \arg\max_{c \in \mathbb{C}} \hat{P}(c) \prod_{1 \le k \le n_d} \hat{P}(t_k|c), \tag{2}$$

where $\mathbb{C}$ is a set of categories, which, in our case, is always of size two (e.g., {ad tracking, no ad tracking}).

The naive assumption is that the probabilities of individual terms within a document are independent of each other given the category [41]. However, our implementation differs from the standard implementation and tries to alleviate the independence assumption. Instead of processing individual words of the policies we try to capture some context by processing bigrams.

Analyzing the content of a privacy policy requires multiple classification decisions. For example, the classifier has to decide whether personal information can be collected, disclosed to advertisers, retained indefinitely, and so on. This type of classification is known as multi-label classification because each analyzed document can receive more than one label. One commonly used approach for multi-label classification with L labels consists of dividing the task into $|L|$ binary classification tasks [74]. However, other solutions handle multi-label data directly by extending specific learning algorithms [74]. We found it simpler to implement the first approach. Specifically, at execution time we create multiple classifier instances—one for each classification category—by running the classifier on category-specific features extracted by the ML preprocessor.

4.6.2 Classification Categories

For which types of information should privacy policies actually be analyzed? In answering this question, one starting point are fair information practices [25]. Another one are the policies themselves. After all, while it is true that privacy law in the U.S. generally does not require policies to have a particular content, it can be observed that all policies conventionally touch upon four different themes: information collection, disclosure, use, and management (management refers to the handling of information, for example, whether information is encrypted). The four themes can be analyzed on different levels of abstraction. For example, for disclosure of information, it could simply be analyzed whether information is disclosed to outside parties in general, or it could be investigated more specifically whether information is disclosed to service providers, advertisers, governmental agencies, credit bureaus, and so on.

At this point it should be noted that not all information needs to be analyzed. In some instances privacy policies simply repeat mandatory law without creating any new rights or obligations. For example, a federal statute in the U.S.—18 U.S.C. §2703(c)(1)(A) and (B)—provides that the government can demand the disclosure of customer information from a Web service provider after obtaining a warrant or suitable court order. As this law applies independently of a privacy policy containing an explicit statement to that end, the provision that the provider will disclose information to a governmental entity under the requirements of the law can be inferred from the law itself. In fact, even if a privacy policy states to the contrary, it should be assumed that such information disclosure will occur. Furthermore, if privacy policies stay silent on certain subject matters, default rules might apply and fill the gaps.

Another good indicator of what information should be classified is provided by user studies. According to one study [30], knowing about sharing, use, and purpose of information collection is very important to 79%, 75%, and 74% of users, respectively. Similarly, in another study [11] users showed concern for the types of personal information collected, how personal information is collected, behavioral profiling, and the purposes for which the information may be used. While it was only an issue of minor interest earlier [30], the question how long a company keeps personal information about its users is a topic of increasing importance [11]. Based on these findings, we decided to perform six different binary classifications, that is, whether or not a policy

- allows collection of personal information from users (Collection);
- provides encryption for information storage or transmission (Encryption);
- allows ad tracking by means of ad cookies or other trackers (Ad Tracking);
- restricts archiving of personal information to a limited time period (Limited Retention);
- allows the aggregation of information collected from users with information from third parties (Profiling);
- allows disclosure of personal information to advertisers (Ad Disclosure).

For purposes of our analysis, where applicable, it is assumed that the user has an account with the Web service whose policy is analyzed and is participating in any offered sweepstakes or the like. Thus, for example, if a policy states that the service provider only collects personal information from registered users, the policy is analyzed from the perspective of a registered user. Also, if certain actions are dependent on the user's consent, opt-in, or opt-out, it is assumed that the user consented, opted in, or did not opt out, respectively. As it was our goal to make the analysis results intuitively comprehensible to casual users, which needs to be confirmed by user studies, we tried to avoid technical terms. In particular, the term "personal information" is identical to what is known in the privacy community as personally identifiable information (PII) (while "information" on its own also encompasses non-PII, e.g., user agent information).

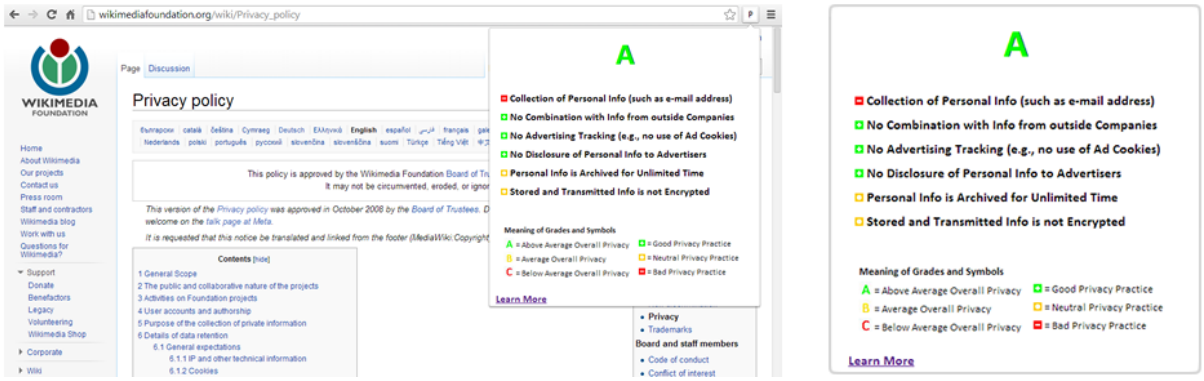

Figure 3: Privee extension screenshot and detailed label view. The result of the privacy policy analysis is shown to the user in a pop-up.

It is noteworthy that some of the analyzed criteria correspond to the semantics of the P3P Compact Specification [2]. For example, the P3P token NOI indicates that a Web service does not collect identified data while ALL means that it has access to all identified data. Thus, NOI and ALL correspond to our collection category. Also, in P3P the token IND means that information is retained for an indeterminate period of time, and, consequently, is equivalently expressed when our classifier comes to the conclusion that no limited retention exists. Further, PSA, PSD, IVA, and IVD are tokens similar to our profiling category. Generally, the correspondence between the semantics of the P3P tokens and our categories suggests that it is possible to automatically classify natural language privacy policies to obtain the same information that Web services would include in P3P policies without actually requiring them to have such.

4.7 Labeler

Our extension's labeler is responsible for creating an output label. As it was shown that users casually familiar with privacy questions were able to understand privacy policies faster and more accurately when those policies were presented in a standardized format [49] and that most users had a preference for standardized labels over full policy texts [49, 50], we created a short standardized label format. Generally, a label can be structured in one or multiple dimensions. The multidimensional approach has the advantage that it can succinctly display different privacy practices for different types of information. However, we chose a one-dimensional format as such were shown to be substantially more comprehensible [51, 66].

In addition to the descriptions for the classifications, the labeler also labels each policy with an overall letter grade, which depends on the classifications. More specifically, the grade is determined by the number of points, p, a policy is assigned. For collection, profiling, ad tracking, and ad disclosure a policy receives one minus point, respectively. However, for not allowing one of these practices a policy receives one plus point. However, a policy receives a plus point for featuring limited retention or encryption, respectively. As most policies in the training set had zero points, we took zero points as a mean and assigned grades as follows:

- A (above average overall privacy) if $p > 1$;
- B (average overall privacy) if $1 \leq p \geq -1$;
- C (below average overall privacy) if $p < -1$.

After the points are assigned to a policy, the corresponding label is displayed to the user as shown in Figure 3. As we intended to avoid confusion about the meaning of icons [45], we used short descriptions instead. The text in the pop-up is animated. If the user moves the mouse over it, further information is provided. The user can also find more detailed explanations about the categories and the grading by clicking on the blue "Learn More" link at the bottom of the label. It should be noted that analysis results retrieved from ToS;DR usually differ in content from our classification results, and are, consequently, displayed in a different label format.

5 Experimental Results

For our experiments we ran our Privee extension on a test set of 50 policies. Before this test phase we trained the ML classifier (with the 100 training policies that are included in the extension package) and tuned it (with a validation set of 50 policies). During the training, validation, and test phases we disabled the retrieval of crowdsourcing results. Consequently, our experimental results only refer to rule and ML classification. The policies of the test and validation sets were selected according to the same criteria as described for the training set in Section

	Base.	Acc.	Prec.	Rec.	F-1
Overall	**68%**	**84%**	**94%**	**89%**	**90%**
Collection	100%	100%	100%	100%	100%
Encryption	52%	98%	96%	100%	98%
Ad Tracking	64%	96%	94%	100%	97%
L. Retention	74%	90%	83%	77%	80%
Profiling	52%	86%	100%	71%	83%
Ad Disclosure	66%	76%	69%	53%	60%

Table 1: Privee extension performance overall and per category. For the 300 test classifications (six classifications for each of the 50 test policies) we observed 27 misclassifications. 154 classifications were made by the rule classifier and 146 by the ML classifier. The rule classifier had 11 misclassifications (2 false positives and 9 false negatives) and the ML classifier had 16 misclassifications (7 false positives and 9 false negatives). It may be possible to decrease the number of false negatives by adding more rules and training examples. For the ad tracking category the rule classifier had an F-1 score of 98% and the ML classifier had an F-1 score of 94%. For the profiling category the rule classifier had an F-1 score of 100% and the ML classifier had an F-1 score of 53%. 28% of the policies received a grade of A, 50% a B, and 22% a C.

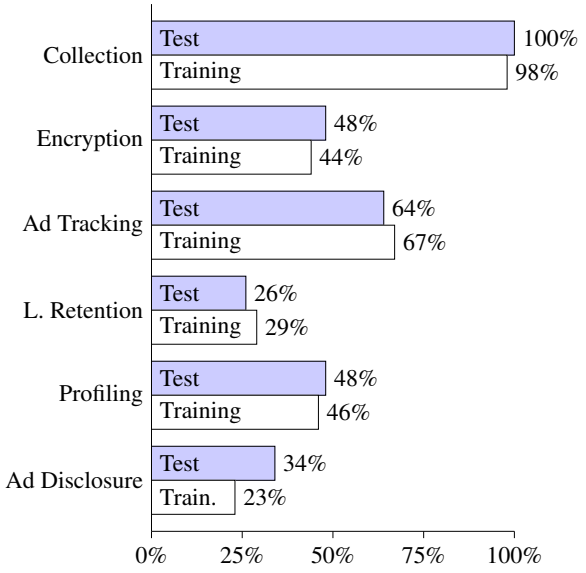

Figure 4: Annotation of positive cases in percent for the 50 test policies (blue) and the 100 training policies (white).

4.5. In this Section we first discuss the classification performance (Section 5.1), then the gold standard that we used to measure the performance (Section 5.2), and finally the computational performance (Section 5.3).

5.1 Classification Performance

In the validation phase we experimented with different classifier configurations for each of our six classification tasks. For the ad tracking and profiling categories the combination of the rule and ML classifier lead to the best results. However, for collection, limited retention, and ad disclosure the ML classifier on its own was preferable. Conversely, for the encryption category the rule classifier on its own was the best. It seems that the language used for describing encryption practices is often very specific making the rule classifier the first choice. Words such as "ssl" are very distinctive identifiers for encryption provisions. Other categories use more general language that could be used in many contexts. For example, phrases related to time periods must not necessarily refer to limited retention. For those instances the ML classifier seems to perform better. However, if categories exhibit both specific and general language the combination of the rule and ML classifier is preferable.

The results of our extension's privacy policy analysis are based on the processing of natural language. However, as natural language is often subject to different interpretations, the question becomes how the results can be verified in a meaningful way. Commonly applied metrics for verifying natural language classification tasks are accuracy (Acc.), precision (Prec.), recall (Rec.), and F-1 score (F-1). Accuracy is the fraction of classifications that are correct [56]. Precision is the fraction of retrieved documents that are relevant, and recall is the fraction of relevant documents that are retrieved [56]. Precision and recall are often combined in their harmonic mean, known as the F-1 score [46].

In order to analyze our extension's performance we calculated the accuracy, precision, recall, and F-1 score for the test policy set classifications. Table 1 shows the overall performance and the performance for each classification category. We also calculated the baseline accuracy (Base.) for comparison against the actual accuracy. The baseline accuracy for each category was determined by always selecting the classification corresponding to the annotation that occurred the most in the training set annotations, which we report in Figure 4. The baseline accuracy for the overall performance is the mean of the category baseline accuracies. Because the classification of privacy policies is a multi-label classification task, as described in Section 4.6.1, we calculated the overall results based on the method for measuring multi-label classifications given by Godbole and Sarawagi [42]. According to their method, for each document, d_j in set D, let t_j be the true set of labels and s_j be the predicted set of labels. Then we obtain the means by

$$Acc(D) = \frac{1}{|D|}\sum_{i=1}^{|D|}\frac{|t_j \cap s_j|}{|t_j \cup s_j|}, \tag{3}$$

$$Prec(D) = \frac{1}{|D|}\sum_{i=1}^{|D|}\frac{|t_j \cap s_j|}{|s_j|}, \tag{4}$$

$$Rec(D) = \frac{1}{|D|}\sum_{i=1}^{|D|}\frac{|t_j \cap s_j|}{|t_j|}, \tag{5}$$

$$F\text{-}1(D) = \frac{1}{|D|}\sum_{i=1}^{|D|}\frac{2\,Prec(d_j)\,Rec(d_j)}{(Prec(d_j)+Rec(d_j))}. \quad (6)$$

From Table 1 it can be observed that the accuracies are at least as good as the corresponding baseline accuracies. For example, in the case of limited retention the baseline classifies all policies as not providing for limited retention because, as show in Figure 4, only 29% of the training policies were annotated as having a limited retention period, which would lead to a less accurate classification of 74% in the test set compared to the actual accuracy of 90%. For the collection category it should be noted that there is a strong bias because nearly every policy allows the collection of personal information. However, in our validation set we had two policies that did not allow this practice, but still were correctly classified by our extension. Generally, our F-1 performance results fall squarely within the range reported in the earlier works. For identifying law enforcement disclosures Ammar et Al. [16] achieved an F-1 score of 76% and Costante et al. reported a score of 83% for recognizing types of collected information [26] and 92% for identifying topics discussed in privacy policies [27].

In order to investigate the reasons behind our extension's performance we used two binary logistic regression models. Binary logistic regression is a statistical method for evaluating the dependence of a binary variable (the dependent variable) on one or more other variables (the independent variable(s)). In our first model each of the 50 test policies was represented by one data point with the dependent variable identifying whether it had any misclassification and the independent variables identifying (1) the policy's length in words, (2) its mean Semantic Diversity (SemD) value [44], and (3) whether there was any disagreement among the annotators in annotating the policy (Disag.). In our second model we represented each of 185 individual test classifications by one data point with the dependent variable identifying whether it was a misclassification and the independent variables identifying (1) the length (in words) of the text that the rule classifier or ML preprocessor extracted for the classification, (2) the text's mean SemD value, and (3) whether there was annotator disagreement on the annotation corresponding to the classification.

Hoffman et al.'s [44] SemD value is an ambiguity measure for words based on latent semantic analysis, that is, the similarity of contexts in which words are used. It can range from 0 (highly unambiguous) to 2.5 (highly ambiguous). We represented the semantic diversity of a document (i.e., a policy or extracted text) by the mean SemD value of its words. However, as Hoffman et al. only provide SemD values for words on which they had sufficient analytical data (31,739 different words in total), some words could not be taken into account for calculating a document's mean SemD value. Thus, in order to avoid skewing of mean SemD values in our models, we only considered documents that had SemD values for at least 80% of their words. In our first model all test policies were above this threshold. However, in our second model we excluded some of the 300 classifications. Particularly, all encryption classifications were excluded because words, such as "encryption" and "ssl" occurred often and had no SemD value. Also, in the second model the mean SemD value of an extracted text was calculated after stemming its words with the Porter stemmer and obtaining the SemD values for the resulting word stems (while the SemD value of each word stem was calculated from the mean SemD value of all words that have the respective word stem).

Per Policy	Length	SemD	Disag.
Mean	2873.4	2.08	0.6
Significance (P)	0.64	0.74	0.34
Odds Ratio (Z)	1.15	1.11	0.54
95% Confidence Interval (Z)	0.64-2.08	0.61-2.01	0.16-1.89

Table 2: Results of the first logistic regression model. The Nagelkerke pseudo R^2 is 0.03 and the Hosmer and Lemeshow value 0.13.

Per Extr. Text	Length	SemD	Disag.
Mean	37.38	1.87	0.17
Significance (P)	0.22	**0.02**	0.81
Odds Ratio (Z)	0.58	**2.07**	0.86
95% Confidence Interval (Z)	0.24-1.38	1.12-3.81	0.25-2.97

Table 3: Results of the second logistic regression model. The Nagelkerke pseudo R^2 is 0.11 and the Hosmer and Lemeshow value 0.051.

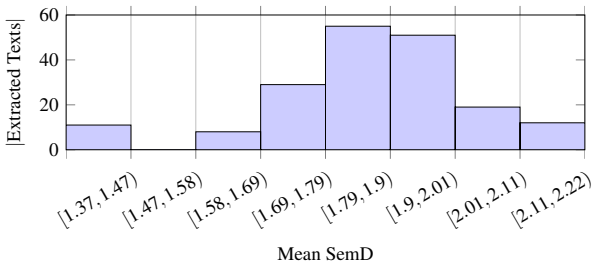

Figure 5: Mean SemD value distribution for the 185 extracted texts. The standard deviation is 0.17.

For our first model the results of our analysis are shown in Table 2 and for our second model in Table 3. Figure 5 shows the distribution of mean SemD values for the extracted texts in our second model. Using the

Wald test, we evaluated the relationship between an independent variable and the dependent variable through the P value relating to the coefficient of that independent variable. If the P value is less than 0.05, we reject the null hypothesis, i.e., that that coefficient is zero. Looking at our results, it is noteworthy that both models do not reveal a statistically relevant correlation between the annotator disagreements and misclassifications. Thus, a document with a disagreement did not have a higher likelihood of being misclassified than one without. However, it is striking that the second model has a P value of 0.02 for the SemD variable. Standardizing our data points into Z scores and calculating the odds ratios it becomes clear that an increase of the mean SemD value in an extracted text by 0.17 (one standard deviation) increased the likelihood of a misclassification by 2.07 times (odds ratio). Consequently, our second model shows that the ambiguity of text in privacy policies, as measured by semantic diversity, has statistical significance for whether a classification decision is more likely to succeed or fail.

Besides evaluating the statistical significance of individual variables, we also assessed the overall model fit. While the goodness of fit of linear regression models is usually evaluated based on the R^2 value, which measures the square of the sample correlation coefficient between the actual values of the dependent variable and the predicted values (in other words, the R^2 value can be understood as the proportion of the variance in a dependent variable attributable to the variance in the independent variable), there is no consensus for measuring the fit of binary logistic regression models. Various pseudo R^2 metrics are discussed. We used the Nagelkerke pseudo R^2 because it can range from 0 to 1 allowing an easy comparison to the regular R^2 (which, however, has to account for the fact that the Nagelkerke pseudo R^2 is often substantially lower than the regular R^2). While the Nagelkerke pseudo R^2 of 0.03 for our first model indicates a poor fit, the value of 0.11 for our second model can be interpreted as moderate. Further, the Hosmer and Lemeshow test, whose values were over 0.05 for both of our models, demonstrates the model fit as well.

In addition to the experiments just discussed, we also evaluated our models with further independent variables. Specifically, we evaluated our first model with the policy publication year, the second model with the extracted texts' mean tf-idf values, and both models with Flesch-Kincaid readability scores as independent variables. Also, using only ML classifications we evaluated our second model with the number of available training examples as independent variable. Only for the latter we found statistical significance at the 0.05 level. The number of training examples correlated to ML classification performance, which confirms Ammar et al.'s respective conjecture [16]. The more training examples the ML classifier had, the less likely a misclassification became.

5.2 Inter-annotator Agreement

Having discussed the classification performance, we now turn to the gold standard that we used to measure that performance. For our performance results to be reliable our gold standard must be reliable. One way of producing a gold standard for privacy policies is to ask the providers whose policies are analyzed to explain their meaning [11]. However, this approach should not be used, at least in the U.S., because the Restatement of Contracts provides that a contract term is generally given the meaning that *all* parties associate with it (Restatement (Second) of Contracts, §201). Consequently, policies should be interpreted from the perspective of both the provider and user. The interpretation would evaluate whether their perspectives lead to identical meanings or, if that is not the case, which one should prevail under applicable principles of legal interpretation. In addition, since technical terms are generally given technical meaning (Restatement (Second) of Contracts, §202(3)(b)), it would be advantageous if the interpretation is performed by annotators familiar with the terminology commonly used in privacy policies. The higher the number of annotations on which the annotators agree, that is, the higher the inter-annotator agreement, the more reliable the gold standard will be.

Because the annotation of a large number of documents can be very laborious, it is sufficient under current best practices for producing a gold standard to measure inter-annotator agreement only on a data sample [62], such that it can be inferred that the annotation of the remainder documents is reliable as well. Following this practice, we only measured the inter-annotator agreement for our test set, which would then provide an indicator for the reliability of our training and validation set annotation as well. To that end, one author annotated all policies and additional annotations were obtained for the test policies from two other annotators. All annotators worked independently from each other. As the author who annotated the policies studied law and has expertise in privacy law and the two other annotators were law students with training in privacy law, all annotators were considered equally qualified, and the annotations for the gold standard were selected according to majority vote (i.e., at least two annotators agreed). After the annotations of the test policies were made, we ran our extension on these policies and compared its classifications to the annotations, which gave us the results in Table 1.

The reliability of our gold standard depends on the degree to which the annotators agreed on the annotations. There are various measures for inter-annotator agreement. One basic measure is the count of disagreements.

	Disag.	% Ag.	K.'s α/F.'s κ
Overall	**8.12**	**84%**	**0.77**
Collection	0	100%	1
Encryption	6	88%	0.84
Ad Tracking	7	86%	0.8
L. Retention	9	82%	0.68
Profiling	11	78%	0.71
Ad Disclosure	16	68%	0.56

Table 4: Inter-annotator agreement for the 50 test policies. The values for Krippendorff's α and Fleiss' κ are identical.

Per Policy	Length	SemD	Flesch-K.
Mean	2873.4	2.08	14.53
Significance (P)	0.2	0.11	0.76
Odds Ratio (Z)	1.65	1.87	1.12
95% Confidence Interval (Z)	0.78-3.52	0.87-4	0.55-2.29

Table 5: Results of the third logistic regression model. The Nagelkerke pseudo R^2 is 0.19 and the Hosmer and Lemeshow value 0.52.

Per Section	Length	SemD	Flesch-K.
Mean	306.76	2.08	15.59
Significance (P)	0.29	**0.04**	0.49
Odds Ratio (Z)	1.18	**1.51**	0.86
95% Confidence Interval (Z)	0.87-1.6	1.02-2.22	0.56-1.32

Table 6: Results of the fourth logistic regression model. The Nagelkerke pseudo R^2 is 0.05 and the Hosmer and Lemeshow value 0.83.

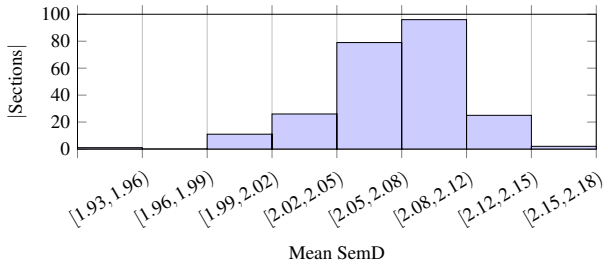

Figure 6: Mean SemD value distribution for the 240 policy sections. The standard deviation is 0.03.

Another one is the percentage of agreement (% Ag.), which is the fraction of documents on which the annotators agree [17]. However, disagreement count and percentage of agreement have the disadvantage that they do not account for chance agreement. In this regard, chance-corrected measures, such as Krippendorff's α (K.'s α) [53] and Fleiss' κ (F.'s κ) [40] are superior. For Krippendorff's α and Fleiss' κ the possible values are constrained to the interval $[-1;1]$, where 1 means perfect agreement, -1 means perfect disagreement, and 0 means that agreement is equal to chance [37]. Generally, values above 0.8 are considered as good agreement, values between 0.67 and 0.8 as fair agreement, and values below 0.67 as dubious [56]. However, those ranges are only guidelines [17]. Particularly, ML algorithms can tolerate data with lower reliability as long as the disagreement looks like random noise [68].

Based on the best practices and guidelines for interpreting inter-annotator agreement measurements, our results in Table 4 confirm the general reliability of our annotations and, consequently, of our gold standard. For every individual category, except for the ad disclosure category, we obtained Krippendorff's α values indicating fair or good agreement. In addition, the overall mean agreement across categories is 0.77, and, therefore, provides evidence for fair overall agreement as well. For the overall agreement it should be noted that, corresponding to the multi-label classification task, the annotation of privacy policies is a multi-label annotation task as well. However, there are only very few multi-label annotation metrics, such as Passonneau's Measuring Agreement on Set-valued Items (MASI) [61]. As none of the metrics were suitable for our purposes, we selected as overall metric the mean over the results of the individual classification categories.

We investigated our inter-annotator agreement results by applying a third and fourth binary logistic regression model. In our third model each of the 50 test policies was represented by one data point with the dependent variable identifying whether the annotators had any disagreement in annotating the policy and the independent variables identifying (1) the policy's length in words, (2) its mean SemD value, and (3) its Flesch-Kincaid score. In our fourth model we represented each of 240 individual annotations by one data point with the dependent variable identifying whether the annotators disagreed for that annotation and the independent variables identifying (1) the length (in words) of the policy text section that the annotation is referring to, (2) the section's mean SemD value, and (3) its Flesch-Kincaid score. For the fourth model we excluded some of the 300 annotations because not every policy had a section for each category. For example, some policies did not discuss advertisement or disclosure of information. The Flesch-Kincaid readability score measures the number of school years an average reader would need to understand a text.

For our third and fourth model the results of our analysis are shown in Table 5 and 6, respectively. Figure 6 shows the distribution of mean SemD values for the policy sections in our fourth model. Both models were

significant, as indicated by their Nagelkerke and Hosmer and Lemeshow values. Our results confirm that the readability of policies, as measured by the Flesch-Kincaid score, does not impact their comprehensibility [58]. In our third model we were unable to identify any statistically relevant variables (although, semantic diversity and length may be statistically significant in a larger data set). However, our fourth model proved to be more meaningful. Remarkably, corresponding to our finding in Section 5.1, according to which classifier performance correlates to semantic diversity, the statistically relevant P value of 0.04 for the mean SemD variable also indicates a correlation of inter-annotator agreement to semantic diversity. Standardizing our data points into Z scores and calculating the odds ratios it becomes clear that an increase of the mean SemD value of a section by 0.03 (one standard deviation) increased the likelihood of a disagreement by 1.51 times (odds ratio). It is astounding that even qualified annotators trained in privacy law had difficulties to avoid disagreements when semantic diversity increased to slightly above-mean levels.

While neither our first nor our second model in Section 5.1 showed a correlation between inter-annotator agreement and classifier performance, the results for our second and fourth model demonstrate that performance and agreement both correlate to one common variable—semantic diversity. More specifically, performance correlates to the semantic diversity of extracted text phrases and agreement correlates to the semantic diversity of policy sections. This result suggests, for example, that the relatively high number of misclassifications and disagreements in the ad disclosure category is inherent in the nature of the category. Indeed, in cases of fuzzy categories disagreements among annotators do not necessarily reflect a quality problem of the gold standard, but rather a structural property of the annotation task, which can serve as an important source of empirical information about the structural properties of the investigated category [13]. Thus, it is no surprise that for all six categories the values of Krippendorff's α correlate to the F-1 scores. The higher the value of Krippendorff's α, the higher the F-1 score. Figure 7 shows the correlation.

As both classifier performance and inter-annotator agreement decrease with an increase in semantic diversity, the practicability of the notice-and-choice principle becomes questionable. After all, privacy policies can only provide adequate notice (and choice) if they are not too ambiguous. In order to further examine policy ambiguity we calculated the mean SemD value for our test policies over time. Our test set analysis exhibited a statistically significant trend of decreasing semantic diversity with a P value of 0.049. Figure 8 illustrates our approach. We can think of two explanations for the decrease over time. First, it could be a consequence of the FTC's enforcement actions and its call for policies to "be clearer, shorter, and more standardized" [38]. Second, we might be in the midst of a consolidation process leading to more standardized policy language. As de Maat et al [34] observed, drafters of legal documents tend to use language that adheres to writing conventions of earlier texts and similar statements. Independent of the reason, our result suggests that the notice-and-choice principle can overcome the problem of ambiguity over time.

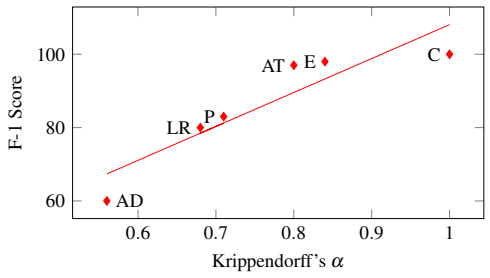

Figure 7: Linear regression plot with the F-1 score as dependent variable and Krippendorff's α as independent variable. The coordinate labels identify the categories: AD = Ad Disclosure, LR = Limited Retention, P = Profiling, AT = Ad Tracking, E = Encryption, and C = Collection. With an R^2 value of 0.83 the model has an excellent fit, which, however, should be interpreted in light of the small number of data points.

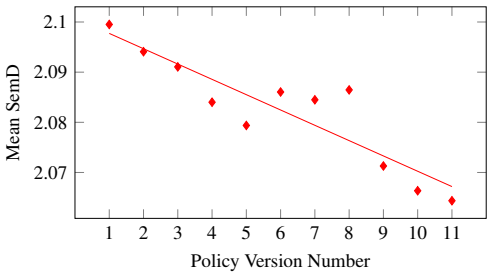

Figure 8: Linear regression plot for Symantec's privacy policy (which was part of our test set) with the mean SemD value of a policy version as dependent variable and the policy version number as independent variable. The first version of Symantec's policy [73] dates back to August 5, 1999, and the eleventh version [72] was adopted on August 12, 2013. The mean SemD value of Symantec's privacy policy decreased from 2.1 in the first version to 2.06 in the eleventh version as shown. We observed a similar decrease for 29 out of 44 test policies (6 of the test policies were only available in a single version and, therefore, could not be included in our analysis. However, for the 44 included policies we obtained on average 8 different versions over time.).

5.3 Computational Performance

We finish the discussion of our experimental results with our extension's computational performance. We report the mean duration in seconds for obtaining analysis results for each of 50 randomly selected policies from ToS;DR (Crowdsourcing), processing each of the 50 test policies (Classifier), and processing each of the 50 test

Per Policy	Crowdsourcing	Classifier	Training
Mean	0.39 sec	0.78 sec	20.29 sec

Table 7: Computational performance of the Privee extension. The performance was evaluated on a Windows laptop with Intel Core2 Duo CPU at 2.13 GHz with 4 GB RAM. The space requirements for the installation on the hard disk are 2.11 MB (including 1.7 MB of training data and 286 KB for the jQuery library) and additional 230 KB during the program execution for storing training results.

policies each with initial training (Training) in Table 7. Notably, retrieving policy results from ToS;DR is twice as fast as analyzing a policy with our classifiers.

6 Conclusion

We introduced Privee—a novel concept for analyzing natural language privacy policies based on crowdsourcing and automatic classification techniques. We implemented Privee in a proof of concept browser extension for Google Chrome, and our automatic classifiers achieved an overall F-1 score of 90%. Our experimental results revealed that the automatic classification of privacy policies encounters the same constraint as human interpretation—the ambiguity of natural language, as measured by semantic diversity. Such ambiguity seems to present an inherent limitation of what automatic privacy policy analysis can accomplish. Thus, on a more fundamental level, the viability of the notice-and-choice principle might be called into question altogether. However, based on the decrease of policy ambiguity over time we would caution to draw such conclusion. We remain optimistic that the current notice-and-choice ecosystem is workable and can be successfully supplemented by Privee.

The most important task for making the notice-and-choice principle work is to decrease policy ambiguity. However, other areas require work as well: What are the types of information that policies should be analyzed for? What is the most usable design? What are the best features and algorithms? Are more intricate ML or natural language processing algorithms better at resolving ambiguities? What is the ideal size and composition of the training set? How can the interaction between the classifier and crowdsourcing analysis be improved? In particular, how can a program connect to many crowdsourcing repositories, and, possibly, decide which analysis is the best? Can crowdsourced policy results be used by the classifiers as training data? How can it be assured that the crowdsourcing results are always up to date? How can the quality and consistency of crowdsourcing and ML analyses be guaranteed? And, finally, what solutions are viable for different legal systems and the mobile world?

7 Acknowledgments

For their advice and help we thank Kapil Thadani, Rebecca Passonneau, Florencia Marotta-Wurgler, Sydney Archibald, Shaina Hyder, Jie S. Privacy in Pharmacogenetics: An End-to-End Case Study of Personalized Warfarin Dosing

Matthew Fredrikson*, Eric Lantz*, Somesh Jha*, Simon Lin†, David Page*, Thomas Ristenpart*
University of Wisconsin, Marshfield Clinic Research Foundation*†

Abstract

We initiate the study of privacy in pharmacogenetics, wherein machine learning models are used to guide medical treatments based on a patient's genotype and background. Performing an in-depth case study on privacy in personalized warfarin dosing, we show that suggested models carry privacy risks, in particular because attackers can perform what we call *model inversion*: an attacker, given the model and some demographic information about a patient, can predict the patient's genetic markers.

As differential privacy (DP) is an oft-proposed solution for medical settings such as this, we evaluate its effectiveness for building private versions of pharmacogenetic models. We show that *DP mechanisms prevent our model inversion attacks when the privacy budget is carefully selected*. We go on to analyze the impact on utility by performing simulated clinical trials with DP dosing models. We find that for privacy budgets effective at preventing attacks, *patients would be exposed to increased risk of stroke, bleeding events, and mortality*. We conclude that *current* DP mechanisms do not simultaneously improve genomic privacy while retaining desirable clinical efficacy, highlighting the need for new mechanisms that should be evaluated *in situ* using the general methodology introduced by our work.

1 Introduction

In recent years, technical advances have enabled inexpensive, high-fidelity molecular analyses that characterize the genetic make-up of an individual. This has led to widespread interest in *personalized medicine*, which tailors treatments to each individual patient using genotype and other information to improve outcomes. Much of personalized medicine is based on *pharmacogenetic* (sometimes called *pharmacogenomic*) models [3, 14, 21, 40] that are constructed using supervised machine learning over large patient databases containing clinical and genomic data. Prior works [36, 37] in non-medical settings have shown that leaking datasets can enable de-anonymization of users and other privacy risks. In the pharmacogenetic setting, datasets themselves are often only disclosed to researchers, yet the models learned from them are made public (e.g., published in a paper). *Our focus is therefore on determining to what extent the models themselves leak private information, even in the absence of the original dataset.*

To do so, we perform a case study of warfarin dosing, a popular target for pharmacogenetic modeling. Warfarin is an anticoagulant widely used to help prevent strokes in patients suffering from atrial fibrillation (a type of irregular heart beat). However, it is known to exhibit a complex dose-response relationship affected by multiple genetic markers [43], with improper dosing leading to increased risk of stroke or uncontrolled bleeding [41]. As such, a long line of work [3, 14, 16, 21, 40] has sought pharmocogenetic models that can accurately predict proper dosage based on patient clinical history, demographics, and genotype. A review of this literature is given in [23].

Our study uses a dataset collected by the *International Warfarin Pharmocogenetics Consortium* (IWPC), to date the most expansive such database containing demographic information, genetic markers, and clinical histories for thousands of patients from around the world. While this particular dataset is publicly-available in a deidentified form, it is equivalent to data used in other studies that must be kept private (e.g., due to lack of consent to release). We therefore use it as a proxy for a private dataset. The paper authored by IWPC members [21] details methods to learn linear regression models from this dataset, and shows that using the resulting models to predict initial dose outperforms the standard clinical regimen in terms of absolute distance from stable dose. Randomized trials have been done to evaluate clinical effectiveness, but have not yet validated the utility of genetic information [27].

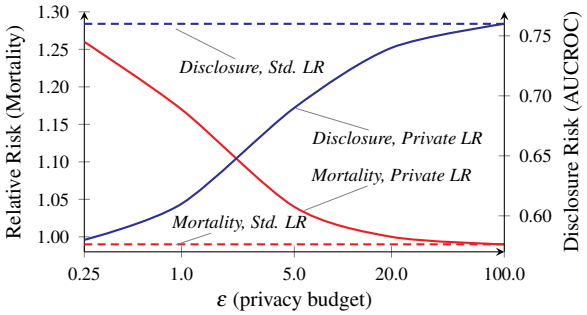

Figure 1: Mortality risk (relative to current clinical practice) for, and VKORC1 genotype disclosure risk of, ε-differentially private linear regression (LR) used for warfarin dosing (over five values of ε, curves are interpolated). Dashed lines correspond to non-private linear regression.

Model inversion. We study the degree to which these models leak sensitive information about patient genotype, which would pose a danger to genomic privacy. To do so, we investigate *model inversion attacks* in which an adversary, given a model trained to predict a specific variable, uses it to make predictions of unintended (sensitive) attributes used as input to the model (i.e., an attack on the privacy of attributes). Such attacks seek to take advantage of correlation between the target, unknown attributes (in our case, demographic information) and the model output (warfarin dosage). A priori it is unclear whether a model contains enough exploitable information about these correlations to mount an inversion attack, and it is easy to come up with examples of models for which attackers will not succeed.

We show, however, that warfarin models do pose a privacy risk (Section 3). To do so, we provide a general model inversion algorithm that is optimal in the sense that it minimizes the attacker's *expected misprediction rate* given the available information. We find that when one knows a target patient's background and stable dosage, their genetic markers are predicted with significantly better accuracy (up to 22% better) than guessing based on marginal distributions. In fact, *it does almost as well as regression models specifically trained to predict these markers (only ˜5% worse)*, suggesting that model inversion can be nearly as effective as learning in an "ideal" setting. Lastly, the inverted model performs measurably better for members of the training cohort than others (yielding an increased 4% accuracy) indicating a leak of information specifically about those patients.

Role of differential privacy. Differential privacy (DP) is a popular framework for designing statistical release mechanisms, and is often proposed as a solution to privacy concerns in medical settings [10, 12, 45, 47]. DP is parameterized by a value ε (sometimes referred to as the *privacy budget*), and a DP mechanism guarantees that the likelihood of producing any particular output from an input cannot vary by more than a factor of e^{ε} for "similar" inputs differing in only one subject.

Following this definition in our setting, DP guarantees protection against attempts to infer whether a subject was included in the training set used to derive a machine learning model. It does *not* explicitly aim to protect attribute privacy, which is the target of our model inversion attacks. However, others have motivated or designed DP mechanisms with the goal of ensuring the privacy of patients' diseases [15], features on users' social network profiles [33], and website visits in network traces [38]—all of which relate to attribute privacy. Furthermore, recent theoretical work [24] has shown that in some settings, including certain applications of linear regression, incorporating noise into query results preserves attribute privacy. This led us to ask: can *genomic* privacy benefit from the application of DP mechanisms in our setting?

To answer this question, we performed the first end-to-end evaluation of DP in a medical application (Section 5). We employ two recent algorithms on the IWPC dataset: the *functional mechanism* of Zhang *et al.* [47] for producing private linear regression models, and Vinterbo's *privacy-preserving projected histograms* [44] for producing differentially-private synthetic datasets, over which regression models can be trained. These algorithms represent the current state-of-the-art in DP mechanisms for their respective models, with performance reported by the authors that exceeds previous DP mechanisms designed for similar tasks.

On one end of our evaluation, we apply a model inverter to quantify the amount of information leaked about patient genetic markers by ε-DP versions of the IWPC model. On the other end, we quantify the impact of ε on patient outcomes, performing *simulated clinical trials* via techniques widely used in the medical literature [4, 14, 18, 19]. Our main results, a subset of which are shown in Figure 1, show a clear trade-off between patient outcomes and privacy:

- ***"Small ε"-DP protects genomic privacy***: Even though DP was not specifically designed to protect attribute privacy, we found that for sufficiently small ε (≤ 1), genetic markers cannot be accurately predicted (see the line labeled "Disclosure, private LR" in Figure 1), and there is no discernible difference between the model inverter's performance on the training and validation sets. However, this effect quickly vanishes as ε increases, where genotype is predicted with up to 58% accuracy (0.76 AUCROC). This is significantly (22%) better than the 36% accuracy one achieves without the models, and not far below (5%) the "best possible" performance of a non-private regression model trained to predict the same genotype using IWPC data.

- ***Current DP mechanisms harm clinical efficacy***: Our simulated clinical trials reveal that for $\varepsilon \leq 5$ the risk of fatalities or other negative outcomes increases significantly (up to $1.26\times$) compared to the current clinical practice, which uses non-personalized, fixed dosing and so leaks no information at all. Note that the range of ε (> 5) that provides clinical utility not only fails to protect genomic privacy, but are commonly assumed to provide insufficient DP guarantees as well. (See the line labeled "Mortality, private LR" in Figure 1.)

Put simply: our analysis indicates that in this setting where utility is paramount, the best known mechanisms for our application do not give an ε for which state-of-the-art DP mechanisms can be reasonably employed.

Implications of our results. Our results suggest that there is still much to learn about pharmacogenetic privacy. Differential privacy is suited to settings in which *privacy and utility requirements are not fundamentally at odds*, and can be balanced with an appropriate privacy budget. Although the mechanisms we studied do not properly strike this balance, future mechanisms may be able to do so—the *in situ* methodology given in this paper may help to guide such efforts. In settings where privacy and utility *are* fundamentally at odds, release mechanisms of any kind will fail, and restrictive access control policies may be the best answer. The model inversion techniques outlined here can help to identify these situations, and quantify the risks.

2 Background

Warfarin and Pharmacogenetics Warfarin, also known in the United States by the brand name Coumadin, is a widely prescribed anticoagulant medication. It is used to treat patients suffering from cardiovasvular problems, including atrial fibrillation (a type of irregular heart beat) and heart valve replacement. By reducing the tendency of blood to clot, at appropriate dosages it can reduce risk of clotting events, particularly stroke. Unfortunately, warfarin is also very difficult to dose: proper dosages can differ by an order of magnitude between patients, and this has led to warfarin's status as one of the leading causes of drug-related adverse events in the United States [26]. Underestimating the dose can result in failure to prevent the condition the drug was prescribed to treat. Overestimating the dose can, just as seriously, lead to uncontrolled bleeding events because the drug interferes with clotting. Because of these risks, in existing clinical practice patients starting on warfarin are given a fixed initial dose but then must visit a clinic many times over the first few weeks or months of treatment in order to determine the correct dosage which gives the desired therapeutic effect.

Stable dose is assessed clinically by measuring the time it takes for blood to clot, called prothrombin time. This measure is standardized between different manufacturers as an international normalized ratio (INR). Based on the patient's indication for (i.e., the reason to prescribe) warfarin, a clinician determines a target INR range. After the fixed initial dose, later doses are modified until the patient's INR is within the desired range and maintained at that level. INR in the absence of anticoagulation therapy is approximately 1, while the desired INR for most patients in anticoagulation therapy is in the range 2–3 [5]. INR is the response measured by the physiological model used in our simulations in Section 5.

Genetic variability among patients is known to play an important role in determining the proper dose of warfarin [23]. Polymorphisms in two genes, VKORC1 and CYP2C9, are associated with the mechanism with which the body metabolizes the drug, which in turn affects the dose required to reach a given concentration in the blood. Warfarin works by interfering with the body's ability to recycle vitamin K, which is used to regulate blood coagulation. VKORC1, part of the vitamin K epoxide reductase complex, is a component of the vitamin K cycle. CYP2C9 encodes for a variant of cytochrome P450, a family of proteins which oxidize a variety of medications. Since each person has two copies of each gene, there are several combinations of variants possible. Following the IWPC paper [21], we represent VKORC1 polymorphisms by single nucleotide polymorphism (SNP) rs9923231, which is either G (common variant) or A (uncommon variant), resulting in three combinations G/G, A/G, or A/A. Similarly, CYP2C9 variants are *1 (most common), *2, or *3, resulting in 6 combinations.

Taken together with age and height, Sconce *et al.* [40] demonstrated that CYP2C9 and VKORC1 account for 54% of the total warfarin dose requirement variability. In turn, a large literature (over 50 papers as of early 2013) has sought pharmacogenetic algorithms that predict proper dose by taking advantage of patient genetic markers for CYP2C9 and VKORC1, together with demographic information and clinical history (e.g., current medications). These typically involve learning a simple predictive model of stable dose from previously obtained outcomes. We focus on the IWPC algorithm [21], a study resulting in production of a linear regression model that, when used to predict the initial dosage, has been shown to provide improved outcomes in simulated clinical trials using the IWPC dataset discussed below. Interestingly, linear regression performed as well or better than a wide variety of other, more complex machine learning techniques. Some pharmacogenetic algorithms for warfarin are currently also undergoing (real) clinical trials [1].

Dataset The IWPC [21] collected data on patients who were prescribed warfarin from 21 sites in 9 countries on 4 continents. The data was curated by staff at the Pharmacogenomics Knowledge Base [2], and each site obtained informed consent to use de-identified data from patients prior to the study. Because the dataset contains no protected health information, and the Pharmacogenomics Knowledge Base has since made the dataset publicly available for research purposes, it is exempt from institutional review board review. However, the type of data contained in the IWPC dataset is equivalent to many other medical datasets that have not been released publicly [3, 7, 16, 40], and are considered private.

Each patient was genotyped for at least one SNP in VKORC1, and for variants of CYP2C9. In addition, other information such as age, height, weight, race, and other medications was collected. The outcome variable is the stable therapeutic dose of warfarin, defined as the steady-state dose that led to stable anticoagulation levels. The patients in our dataset were restricted to those with target INR in the range 2–3 (the vast majority of patients), as is standard practice with most studies of warfarin dosing efficacy [3, 14]. We divided the data into two cohorts based on those used in IWPC [21]. The first (training) cohort was used to build a set of pharmacogenetic dosing algorithms. The second (validation) cohort was used to test privacy attacks as well as draw samples for the clinical simulations. To make the data suitable for regression we removed all patients missing CYP2C9 or VKORC1 genotype, normalized the data to the range [-1,1], converted all nominal attributes into binary-valued numeric attributes, and scaled each row into the unit sphere. Our eventual training cohort consisted of 2644 patients, and our validation cohort of 853 patients, and corresponds to the same training-validation split used by IWPC (but without the missing values used in the IWPC split).

3 Privacy of Pharmacogenetic Models

In this section we investigate the risks involved in releasing regression models trained over private data, using models that predict warfarin dose as our case study. We consider a setting where an adversary is given access to such a model, the warfarin dosage of an individual, some rudimentary information about the data set, and possibly some additional attributes about that individual. The adversary's goal is to predict one of the *genotype* attributes for that individual. In order for this setting to make sense, the genotype attributes, warfarin dose, and other attributes known to the adversary must all have been in the private data set. We emphasize that the techniques introduced can be applied more generally, and save as future work investigating other pharmacogenetic settings.

3.1 Attack Model

We assume an adversary who employs an inference algorithm $\mathcal{A}$ to discover the genotype (in our experiments, either CYP2C9 or VKORC1) of a target individual α. The adversary has access to a linear model f trained over a dataset D drawn i.i.d. from an unknown prior distribution p. D has domain $\mathbf{X} \times Y$, where $\mathbf{X} = X_1, \ldots, X_d$ is the domain of possible *attributes* and Y is the domain of the *response*. α is represented by a single row in D, $(\mathbf{x}^\alpha, y^\alpha)$, and the attribute learned by the adversary is referred to as the *target attribute* $\mathbf{x}_t^\alpha$.

In addition to f, the adversary has access to marginals[1] $p_{1,\ldots,d,y}$ of the joint prior p, the dataset domain $\mathbf{X} \times Y$, α's stable dosage y^α of warfrain, some information π about f's performance (details in the following section), and either of the following subsets $\mathbf{x}_K^\alpha$ of α's attributes:

- *Basic demographics*: a subset of α's demographic data, including age (binned into eight groups by the IWPC), race, height, and weight (denoted $x_{\text{age}}^\alpha, x_{\text{race}}^\alpha, \ldots$). Note that this corresponds to a subset of the non-genetic attributes in D.
- *All background*: all of p's attributes except CYP2C9 or VKORC1 genotype.

The adversary has black-box access to f. Unless it is clear from the context, we will specify whether f is the output of a DP mechanism, and which type of background information is available.

3.2 Model Inversion

In this section, we discuss a technique for inferring CYP2C9 and VKORC1 genotype from a model designed to predict warfarin dosing. Given a model f that takes inputs $\mathbf{x}$ and outputs a predicted stable dose y, the attacker seeks to build an algorithm $\mathcal{A}$ that takes as input some subset $\mathbf{x}_K^\alpha$ of attributes (corresponding to demographic or additional background attributes from $\mathbf{X}$), a known stable dose y^α, and outputs a prediction of $\mathbf{x}_t$ (corresponding either to CYP2C9 or VKORC1). We begin by presenting a general-purpose algorithm, and show how it can be applied to linear regression models.

A general algorithm. We present an algorithm for model inversion that is independent of the underlying model structure (Figure 2). The algorithm works by estimating the probability of a potential target attribute given the available information and the model. Its operation is straightforward: *candidate* database rows that are similar to what is known about α are run *forward* through

[1] These are commonly published in studies, and when it is clear from the context, we will drop the subscript.

1. Input: $\mathbf{z}_K = (x_1, \ldots, x_k, y), f, p_{1,\ldots,d,y}$
2. Find the *feasible set* $\hat{\mathbf{X}} \subseteq \mathbf{X}$, i.e., such that $\forall \mathbf{x} \in \hat{\mathbf{X}}$
   (a) $\mathbf{x}$ matches $\mathbf{z}_K$ on known attributes: for $1 \le i \le k, \mathbf{x}_i = x_i$.
   (b) f evaluates to y as given in $\mathbf{z}_K$: $f(\mathbf{x}) = y$.
3. If $|\hat{\mathbf{X}}| = 0$, return $\perp$.
4. Return x_t that maximizes $\sum_{\mathbf{x} \in \hat{\mathbf{X}}: \mathbf{x}_t = x_t} \prod_{1 \le i \le d} p_i(\mathbf{x}_i)$

(a) $\mathcal{A}_0$: Model inversion without performance statistics.

1. Input: $\mathbf{z}_K = (x_1, \ldots, x_k, y)$, f, π, $p_{1,\ldots,d,y}$
2. Find the *feasible set* $\hat{\mathbf{X}} \subseteq \mathbf{X}$, i.e., such that $\forall \mathbf{x} \in \hat{\mathbf{X}}$
   (a) $\mathbf{x}$ matches $\mathbf{z}_K$ on known attributes: for $1 \le i \le k$, $\mathbf{x}_i = x_i$.
3. If $|\hat{\mathbf{X}}| = 0$, return $\perp$.
4. Return x_t that maximizes $\sum_{\mathbf{x} \in \hat{\mathbf{X}}: \mathbf{x}_t = x_t} \pi_{y, f(\mathbf{x})} \prod_{1 \le i \le d} p_i(\mathbf{x}_i)$

(b) $\mathcal{A}_\pi$: Model inversion with performance statistics π.

Figure 2: Model inversion algorithm.

the model. Based on the known priors, and how well the model's output on that row coincides with α's known response value, the candidate rows are weighted. The target attribute with the greatest weight, computed by marginalizing the other attributes, is returned.

Below, we describe this algorithm in more detail. We derive each step by showing how to compute the *least biased* estimate of the target attribute's likelihood, which the model inversion algorithm maximizes to form a prediction. As we reason below, this approach is *optimal* in the sense that it minimizes the expected misclassification rate when the adversary has no other information (i.e., makes no further assumptions) beyond what is given in Section 3.1.

Derivation. We begin the description with a simpler restricted case in which the model always produces the correct response. Assume for now that f is *perfect*, i.e., it never makes a misprediction, and we can assume that $f(\mathbf{x}) = y$ almost surely for any sample $(\mathbf{x}, y)$; this case is covered by $\mathcal{A}_0$ in Figure 2. In the following, we assume the sample corresponds to the individual α, and drop the superscript for clarity. Suppose the adversary wishes to learn the probability that $\mathbf{x}_t$ takes a certain value x_t, i.e., $\mathbf{Pr}[\mathbf{x}_t = x_t | \mathbf{x}_K, y]$, given some known attributes $\mathbf{x}_K$, response variable y, and the model f. Here, and in the following discussion, the probabilities in $\mathbf{Pr}[\cdot]$ expressions are always over draws from the unknown joint prior p unless stated otherwise. Let $\hat{\mathbf{X}} = \{\mathbf{x}' : \mathbf{x}'_K = \mathbf{x}_K \text{ and } f(\mathbf{x}') = y\}$ be the subset of $\mathbf{X}$ matching the given information $\mathbf{x}_K$ and y. Then by straightforward computation,

$$\mathbf{Pr}[x_t | \mathbf{x}_K, y] = \frac{\mathbf{Pr}[x_t, \mathbf{x}_K, y]}{\mathbf{Pr}[\mathbf{x}_K, y]} = \frac{\sum_{\mathbf{x}' \in \hat{\mathbf{X}}: \mathbf{x}'_t = x_t} p(\mathbf{x}', y)}{\sum_{\mathbf{x}' \in \hat{\mathbf{X}}} p(\mathbf{x}', y)} \quad (1)$$

Now, the adversary does not know the true underlying joint prior p. He only knows the marginals $p_{1,\ldots,d,y}$, so any distribution with these marginals is a possible prior. To characterize the unbiased prior that satisfies these constraints, we apply the *prinicipal of maximum entropy*[2] [22], which in our setting gives the prior:

$$p(\mathbf{x}, y) = p(y) \cdot \prod_{1 \le i \le d} p(\mathbf{x}_i) \quad (2)$$

Continuing with the previous expression, we now have,

$$\mathbf{Pr}[x_t | \mathbf{x}_K, y] = \frac{\sum_{\mathbf{x}' \in \hat{\mathbf{X}}: \mathbf{x}'_t = x_t} p(y) \prod_i p(\mathbf{x}'_i)}{\sum_{\mathbf{x}' \in \hat{\mathbf{X}}} p(y) \prod_i p(\mathbf{x}'_i)} \quad (3)$$

$$\propto \sum_{\mathbf{x}' \in \hat{\mathbf{X}}: \mathbf{x}'_t = x_t} \prod_i p(\mathbf{x}'_i) \quad (4)$$

This last step follows because the denominator is independent of the choice of x_t. Notice that this is exactly the quantity that is maximized by the value returned by $\mathcal{A}_0$ (Figure 2 (a)). This is the *maximum a posteriori probability* (MAP) estimate, which minimizes the adversary's expected misclassification rate. Under these assumptions, $\mathcal{A}_0$ is an optimal algorithm for model inversion.

$\mathcal{A}_\pi$ in Figure 2 (b) generalizes this reasoning to the case where f is not assumed to be perfect, and the adversary has information about the performance of f over samples drawn from p. We model this information with a function π, defined in terms of a random sample $\mathbf{z}$ from p,

$$\pi(y, y') = \mathbf{Pr}\left[\mathbf{z}_y = y | f(\mathbf{z}_\mathbf{x}) = y'\right] \quad (5)$$

In other words, $\pi(y, y')$ gives the probability that the true response drawn with attributes $\mathbf{z}_\mathbf{x}$ is y given that the model outputs y'. We write $\pi_{y,y'}$ to simplify notation. In practice, π can be estimated using statistics commonly released with models, such as confusion matrices or standardized regression error.

Because f is not assumed to be perfect in the general setting, $\hat{\mathbf{X}}$ is defined slightly differently than in $\mathcal{A}_0$; the second restriction, that $f(\mathbf{x}^\alpha) = y^\alpha$, is removed. After constructing $\hat{\mathbf{X}}$, $\mathcal{A}_\pi$ uses the marginals and π to weight each candidate $\mathbf{x} \in \hat{\mathbf{X}}$ by the probability that f behaves as observed (i.e., outputs $f(\mathbf{x})$) when the response variable matches what the adversary knows to be true (i.e.,

[2] *cf.* Jaynes [22], "[The maximum entropy prior] is least biased estimate possible on the given information; i.e., it is maximally noncommittal with regard to missing information."

y). Again, using the maximum entropy prior from before gives the MAP estimate in the more general setting,

$$\mathbf{Pr}[x_t|\mathbf{x}_K, y^\alpha, f] = \frac{\sum_{\mathbf{x}'\in\hat{\mathbf{X}}:\mathbf{x}'_t=x_t} \mathbf{Pr}[\mathbf{x}', y, f(\mathbf{x}')]}{\sum_{\mathbf{x}'\in\hat{\mathbf{X}}} \mathbf{Pr}[\mathbf{x}', y, f(\mathbf{x}')]} \quad (6)$$

$$= \frac{\sum_{\mathbf{x}'\in\hat{\mathbf{X}}:\mathbf{x}'_t=x_t} \mathbf{Pr}[y|\mathbf{x}', f(\mathbf{x}')]\, p(\mathbf{x}')}{\sum_{\mathbf{x}'\in\hat{\mathbf{X}}} \mathbf{Pr}[\mathbf{x}', y, f(\mathbf{x}')]} \quad (7)$$

$$\propto \sum_{\mathbf{x}'\in\hat{\mathbf{X}}:\mathbf{x}'_t=x_t} \pi_{y,f(\mathbf{x}')} \left(\prod_i p(\mathbf{x}'_i)\right) \quad (8)$$

The second step follows from the independence of the maximum entropy prior in our setting, and the fact that $\mathbf{x}$ determines $f(\mathbf{x})$ so $\mathbf{Pr}[f(\mathbf{x}'), \mathbf{x}'] = \mathbf{Pr}[\mathbf{x}']$.

Application to linear regression. Recall that a linear regression model assumes that the response is a linear function of the attributes, i.e., there exists a coefficient vector $\mathbf{w} \in \mathbb{R}^d$ and random *residual error* δ such that $y = \mathbf{w}^T\mathbf{x} + b + \delta$ for some bias term b. A linear regression model f_L is then an estimate $(\hat{\mathbf{w}}, \hat{b})$ of $\mathbf{w}$ and the bias term, which operates as: $f_L(\mathbf{x}) = \hat{b} + \hat{\mathbf{w}}^T\mathbf{x}$. It is typical to assume that δ has a fixed Gaussian distribution $\mathcal{N}(0, \sigma^2)$ for some variance σ. Most regression software estimates σ^2 empirically from training data, so it is often published alongside a linear regression model. Using this the adversary can derive an estimate of π,

$$\hat{\pi}(y, y') = \mathbf{Pr}_{\mathcal{N}(0,\sigma^2)}[y - y']$$

Steps 2 and 4 of $\mathcal{A}_\pi$ may be expensive to compute if $|\hat{\mathbf{X}}|$ is large. In this case, one can approximate using Monte Carlo techniques to sample members of $\hat{\mathbf{X}}$. Fortunately, in our setting, the nominal-valued variables all come from sets with small cardinality. The continuous variables have natural discretizations, as they correspond to attributes such as age and weight. Thus, step 4 can be computed directly by taking a discrete convolution over the unknown attributes without resorting to approximation.

Discussion. We have argued that $\mathcal{A}_\pi$ is optimal in one particular sense, i.e., it minimizes the expected misclassification rate on the maximum-entropy prior given the available information (the model and marginals). However, it is not hard to specify joint priors p for which the marginals $p_{1,\ldots,d,y}$ convey little useful information, so the expected misclassification rate minimized here diverges substantially from the true rate. In these cases, $\mathcal{A}_\pi$ may perform poorly, and more background information is needed to accurately predict model inputs.

There is also the possibility that the model itself does not contain enough useful information about the correlation between certain input attributes and the output. For illustrative purposes, consider a model taking one input attribute, that discards all information about that attribute except a single bit, e.g., it performs a comparison with a fixed constant. If the attribute is distributed uniformly across a large domain, then $\mathcal{A}_\pi$ will only perform negligibly better than guessing from the marginal. Thus, determining how well a model allows one to predict sensitive inputs generally requires further analysis, which is the purpose of the evaluation that we discuss next (see also Section 4).

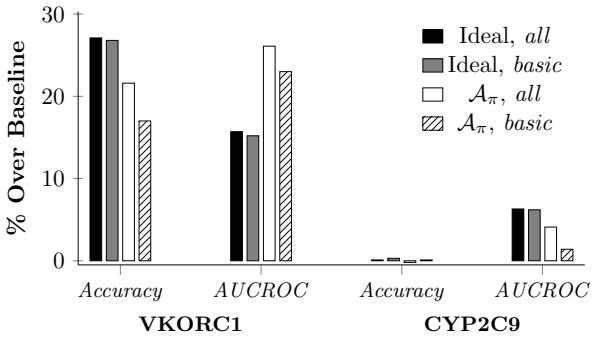

Figure 3: Model inversion performance, as improvement over baseline guessing from marginals, given a linear model derived from the training data. Available background information specified by *all* and *basic* as discussed in Section 3.1.

Results on non-private regression. To evaluate $\mathcal{A}_\pi$, we split the IWPC dataset into a training and validation set (see Section 2), D_T and D_V respectively, use D_T to derive a least-squares linear model f, and then run $\mathcal{A}_\pi$ on every α in D_T with either of the two background information types (*all* or *basic*, see Section 3.1) to predict both genotypes. In order to determine how how well one can predict these genotypes in an *ideal* setting, we built and evaluated a multinomial logistic regression model (using R's `nnet` package) for each genotype from the IWPC data. This allows us to compare the performance of $\mathcal{A}_\pi$ against "best-possible" results achieved using standard machine learning techniques with linear models.

We measure performance both in terms of *accuracy*, which is the percentage of samples for which the algorithm correctly predicted genotype, and *AUCROC*, which is the multi-class area under the ROC curve defined by Hand and Till [17]. While accuracy is generally easier to interpret, it can give a misleading characterization of predictive ability for *skewed* distributions—if the predicted attribute takes a particular value in 75% of the samples, then a trivial algorithm can easily obtain 75% accuracy by always guessing this value. AUCROC does not suffer this limitation, and so gives a more balanced characterization of how well an algorithm predicts both common and rare values.

The results are given in Figure 3, which shows the performance of $\mathcal{A}_\pi$ and "ideal" multinomial regression predicting VKORC1 and CYP2C9 on the training set. The numbers are given relative to the baseline performance obtained by always guessing the most probable genotype based on the given marginal prior–36% accuracy on VKORC1, 75% accuracy on CYP2C9, and 0.5 AUCROC for both genotypes. We see that $\mathcal{A}_\pi$ comes close to ideal accuracy on VKORC1 (5% less accurate with all background information), and actually exceeds the ideal predictor in terms of AUCROC. This means that $\mathcal{A}_\pi$ does a better job predicting *rare* genotypes than the ideal model, but does slightly worse overall, and may be a result of the ideal model avoiding overfitting to uncommon data points.

The results for CYP2C9 are quite different. Neither $\mathcal{A}_\pi$ or the ideal model were able to predict this genotype more accurately than baseline. This indicates that CYP2C9 is difficult to predict using linear models, and because we use a linear model to run $\mathcal{A}_\pi$ in this case, it is no surprise that it inherits this limitation. Both the ideal model and $\mathcal{A}_\pi$ slightly outperform baseline prediction in terms of AUCROC, and $\mathcal{A}_\pi$ comes very close to ideal performance (within 2%). In one case $\mathcal{A}_\pi$ does slightly worse (0.2%) than baseline accuracy; this may be due to the fact that the marginals and $\hat{\pi}$ used by $\mathcal{A}_\pi$ are approximations to the true marginals and error distribution π.

We also evaluated $\mathcal{A}_\pi$ on the validation set (using a model f derived from the training set). We found that both genotypes are predicted more accurately on the training set than validation. For VKORC1, $\mathcal{A}_\pi$ was 3% more accurate and yielded an additional 4% AUCROC. The difference was less pronounced with CYP2C9, which was 1.5% more accurate with an additional 2% AUCROC. Although these differences are not as large as the aboslute gain over baseline prediction, they persist across other training/validation splits. We ran 100 instances of cross-validation, and measured the difference between training and validation performance. We found that we were on average able to better predict the training cohort ($p < 0.01$).

4 Differentially-Private Mechanisms and Pharmacogenetics

In the last section, we saw that linear models trained on private datasets leak information about patients in the training cohort. In this section, we explore the issue on models and datasets for which differential privacy has been applied.

As in the previous section, we take the perspective of the adversary, and attempt to infer patients' genotype given differentially-private models and different types of background information on the targeted individual. As such, we use the same attack model, but rather than assuming the adversary has access to f, we assume access to a *differentially private version of* the original dataset D or f. We use two published differentially-private mechanisms with publicly-available implementations: *private projected histograms* [44] and the *functional mechanism* [47] for learning private linear regression models. Although full histograms are typically not published in pharmacogenetic studies, we analyze their privacy properties here to better understand the behavior of differential privacy across algorithms that implement it differently.

Our key findings are summarized as follows:

- Some ε values effectively protect genomic privacy for DP linear regression. For $\varepsilon \leq 1$, $\mathcal{A}_\pi$ could not predict VKORC1 better on the training set than the validation set either in terms of accuracy or AUCROC. The same result holds on CYP2C9, but only when measured in terms of AUCROC. $\mathcal{A}_\pi$'s *absolute* performance for these ε is not much better than the baseline either: VKORC1 is predicted only 5% better at $\varepsilon = 1$, and CYP2C9 sees almost no improvement.

- "Large"-ε DP mechanisms offer little genomic privacy. When $\varepsilon \geq 5$, both DP mechanisms see a statistically-significant increase in training set performance over validation ($p < 0.02$), and as ε approaches 20 there is little difference from non-private mechanisms (between 3%-5%).

- Private histograms disclose significantly more information about genotype than private linear regression, even at identical ε values. At all tested ε, private histograms leaked more on the training than validation set. *This result holds even for non-private regression models*, where the AUCROC gap reached 3.7% area under the curve, versus the 3.9% - 5.9% gap for private histograms. This demonstrates that the relative nature of differential privacy's guarantee can lead to meaningful concerns.

Our results indicate that understanding the implications of differential privacy for pharmacogenomic dosing is a difficult matter—even small values of ε might lead to unwanted disclosure in many cases.

Differential Privacy Dwork introduced the notion of differential privacy [11] as a constructive response to an impossibility result concerning stronger notions of private data release. For our purposes, a dataset D is a number m of vector, value pairs $(\mathbf{x}^{\alpha_1}, y^{\alpha_1}), \ldots, (\mathbf{x}^{\alpha_m}, y^{\alpha_m})$

where $\alpha_1, \ldots, \alpha_m$ are (randomized) patient identifiers, each $\mathbf{x}^{\alpha_i} = [x_1^{\alpha_i}, \ldots, x_d^{\alpha_i}]$ is a patient's demographic information, age, genetic variants, etc., and y^{α_i} is the stable dose for patient α_i. A (differential) privacy mechanism K is a randomized algorithm that takes as input a dataset D and, in the cases we consider, either outputs a new dataset D_{priv} or a linear model M_{priv} (i.e., a real- valued linear function with n inputs. We denote the set of possible outputs of a mechanism as $\text{Range}(\mathsf{K})$.

A mechanism K achieves ε-differential privacy if for all databases D_1, D_2 differing in at most one row, and all $S \subseteq \text{Range}(\mathsf{K})$,

$$\Pr[\mathsf{K}(D_1) \in S] \leq \exp(\varepsilon) \times \Pr[\mathsf{K}(D_2) \in S]$$

Differential privacy is an information-theoretic guarantee, and holds regardless of the auxiliary information an adversary posesses about the database.

Differentially-private histograms. We first investigate a mechanism for creating a differentially-private version of a dataset via the private projected histogram method [44]. DP datasets are appealing because an (untrusted) analyst can operate with more freedom when building a model; he is free to select whichever algorithm or representation best suits his task, and need not worry about finding differentially-private versions of the best algorithms.

Because the numeric attributes in our dataset are too fine-grained for effective histogram computation, we first discretize each numeric attribute into equal-width bins. In order to select the number of bins, we use a heuristic given by Lei [32] and suggested by Vinterbo [44], which says that when numeric attributes are scaled to the interval $[0,1]$, the bin width is given by $(\log(n)/n)^{1/(d+1)}$, where $n = |D|$ and d is the dimension of D. In our case, this is implies two bins for each numeric attribute. We validated this parameter against our dataset by constructing 100 differentially-private datasets at $\varepsilon = 1$ with $2, 3, 4$, and 5 bins for each numeric attribute, and measured the accuracy of a dose-predicting linear regression model over each dataset. The best accuracy was given for $k = 2$, with the difference in means for $k = 2$ and $k = 3$ not attributable to noise. When the discretized attributes are translated into a private version of the original dataset, the median value from each bin is used to create numeric values.

To infer the private genomic attributes given a differentially-private version D_ε of a dataset, we can compute an empirical approximation $\hat{p}$ to the joint probability distribution p (see Section 3.1) by counting the frequency of tuples in D_ε. A minor complication arises due to the fact that numeric values in D_ε have been discretized and re-generated from the median of each bin. Therefore, the likelihood of finding a row in D_ε that matches any row in D_T or D_V is low. To account for this, we transform each numeric attribute in the background information to the nearest median from the corresponding attribute used in the discretization step when generating D_ε. We then use $\hat{p}$ to directly compute a prediction of the genotype x_t that maximizes $\Pr_{\hat{p}}[\mathbf{x}_t^\alpha = x_t | \mathbf{x}_K^\alpha, y^\alpha]$.

Differentially-private linear regression. We also investigate use of the functional mechanism [47] for producing differentially-private linear regression models. The functional mechanism works by adding Laplacian noise to the coefficients of the objective function used to drive linear regression. This technique stands in contrast to the more obvious approach of directly perturbing the output coefficients of the regression training algorithm, which would require an explicit sensitivity analysis of the training algorithm itself. Instead, deriving a bound on the amount of noise needed for the functional mechanism involves a fairly simple calculation on the objective function [47].

We produce private regression models on the IWPC dataset by first projecting the columns of the dataset into the interval $[-1, 1]$, and then scaling the non-response columns (i.e., all those except the patient's dose) of each row into the unit sphere. This is described in the paper [47] and performed in the publicly-available implementation of the technique, and is necessary to ensure that sufficient noise is added to the objective function (i.e., the amount of noise needed is not scale-invariant). In order to inter-operate with the other components of our evaluation apparatus, we re-implemented the algorithm in R by direct translation from the authors' Matlab implementation. We evaluated the accuracy of our implementation against theirs, and found no statistically-significant difference.

Applying model inversion to the functional mechanism is straightforward, as our technique from Section 3.2 makes no assumptions about the internal structure of the regression model or how it was derived. However, care must be taken with regards to data scaling, as the functional mechanism classifier is trained on scaled data. When calculating $\hat{X}$, all input variables must be transformed by the same scaling function used on the training data, and the predicted response must be transformed by the inverse of this function.

Results on private models. We evaluated our inference algorithms on both mechanisms discussed above at a range of ε values: 0.25, 1, 5, 20, and 100. For each algorithm and ε, we generated 100 private models on the training cohort, and attempted to infer VKORC1 and CYP2C9 for each individual in both the training and validation cohort. All computations were performed in R.

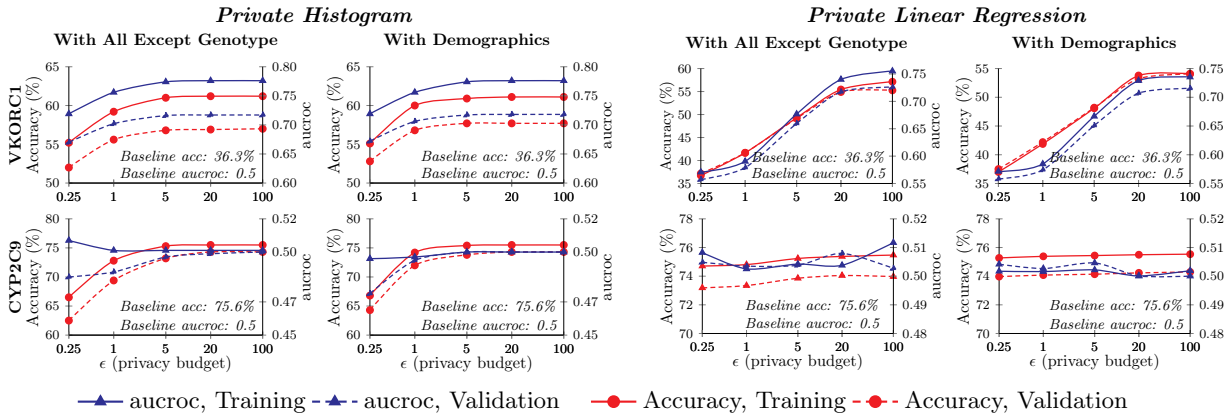

Figure 4: Inference performance for genomic attributes over IWPC training and validation set for private histograms (**left**) and private linear regression (**right**), assuming both configurations for background information. Dashed lines represent accuracy, solid lines area under the ROC curve (AUCROC).

Figure 4 shows our results in detail. In the following, we discuss the main takeaway points.

Private Histograms vs. Linear Regression. We found that private histograms leaked significantly more information about patient genotype than private linear regression models. The difference in AUCROC for histograms versus regression models is statistically significant for VKORC1 at all ε. As Figure 4 indicates, the magnitude of the difference from baseline is also higher for histograms when considering VKORC1, nearly reaching 0.8 AUCROC and 63% accuracy, while regression models achieved at most 0.75 AUCROC and 55–60% accuracy. The AUCROC performance for VKORC1 was greater than the baseline for all ε. However, for CYP2C9 this result only held when assuming all background information except genotype, and only for $\varepsilon \leq 5$; when we assumed only demographic information, there was no significant difference between baseline and private histogram performance.

Disclosure from Overfitting. In nearly all cases, we were able to better infer genotype for patients in the training set than those in the validation set. For private linear regression, this result holds for VKORC1 at $\varepsilon \geq 5.0$ for AUCROC. This is not an artifact of the training/validation split chosen by the IWPC; we ran 10-fold cross validation 100 times, measuring the AUCROC difference between training and test set validation, and found a similar difference between training and validation set performance ($p < 0.01$). The fact that the difference at certain ε values is not statistically significant is evidence that private linear regression is effective at preventing genotype disclosure at these ε. For private histograms, this result held for VKORC1 at all ε, and CYP2C9 at $\varepsilon < 5$ with all background information but genotype.

Differences in Genotype. For both private regression and histogram models, performance for CYP2C9 is strikingly lower than for VKORC1. Private regression models performed no differently from the baseline, achieving essentialy no gain in terms of accuracy and at most 1% gain in AUCROC. We observe that this also held in the non-private setting, and the ideal model achieved the same accuracy as baseline, and only 7% greater AUCROC. This indicates that CYP2C9 is not well-predicted using linear models, and $\mathcal{A}_\pi$ performed nearly as well as is possible.

5 The Cost of Privacy: Negative Outcomes

In addition to privacy, we are also concerned with the utility of a warfarin dosing model. The typical approach to measuring this is a simple accuracy comparison against known stable doses, but ultimately we're interested in how errors in the model will affect patient health. In this section, we evaluate the potential medical consequences of using a differentially-private regression algorithm to make dosing decisions in warfarin therapy. Specifically, we estimate the increased risk of stroke, bleeding, and fatality resulting from the use of differentially-private warfarin dosing at several privacy budget settings. This approach differs from the normal methodology used for evaluating the utility of differentially-private data mining techniques. Whereas evaluation typically ends with a comparison of simple predictive accuracy against non-private methods, we actually simulate the application of a privacy-preserving technique to its domain-specific task, and compare the

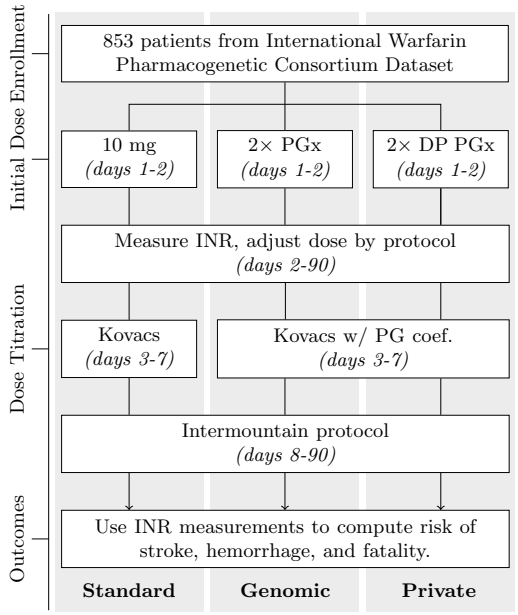

Figure 5: Overview of the Clinical Trial Simulation. *PGx* signifies the pharmacogenomic dosing algorithm, and *DP* differential privacy. The trial consists of three arms differing primarily on initial dosing strategy, and proceeds for 90 days. Details of Kovacs and Intermountain protocol are given in Section 5.3.

outcomes of that task to those achieved without the use of private mechanisms.

5.1 Overview

In order to evaluate the consequences of private genomic dosing algorithms, we simulate a clinical trial designed to measure the effectiveness of new medication regimens. The practice of simulating clinical trials is well-known in the medical research literature [4, 14, 18, 19], where it is used to estimate the impact of various decisions before initiating a costly real-world trial involving human subjects. Our clinical trial simulation follows the design of the CoumaGen clinical trials for evaluating the efficacy of pharmacogenomic warfarin dosing algorithms [3], which is the largest completed real-world clinical trial to date for evaluating these algorithms. At a high level, we train a pharmacogenomic warfarin dosing algorithm and a set of private pharmacogenomic dosing algorithms on the training set. The simulated trial draws random patient samples from the validation set, and for each patient, applies three dosing algorithms to determine the simulated patient's starting dose: the current standard clinical algorithm, the non-private pharmacogenomic algorithm, and one of the private pharmacogenomic algorithms. We then simulate the patient's physiological respose to the doses given by each algorithm using a dose *titration* (i.e., modification) protocol defined by the original CoumaGen trial.

In more detail, our trial simulation defines three parallel *arms* (see Figure 5), each corresponding to a distinct method for assigning the patient's initial dose of warfarin:

1. *Standard:* the current standard practice of initially prescribing a fixed 10mg/day dose.
2. *Genomic:* Use of a genomic algorithm to assign the initial dose.
3. *Private:* Use of a differentially-private genomic algorithm to assign initial dose.

Within each arm, the trial proceeds for 90 simulated days in several stages, as depicted in Figure 5:

1. *Enrollment:* A patient is sampled from the population distribution, and their genotype and demographic characteristics are used to construct an instance of a *Pharmacokinetic/Pharmacodynamic (PK/PD) Model* that characterizes relevant aspects of their physiological response to warfarin (i.e., INR). The PK/PD model contains random variables that are parameterized by genotype and demographic information, and are designed to capture the variance observed in previous population-wide studies of physiological response to warfarin [16].
2. *Initial Dosing:* Depending on which arm of the trial the current patient is in, an initial dose of warfarin is prescribed and administered for the first two days of the trial.
3. *Dose Titration:* For the remaining 88 days of the simulated trial, the patient administers a prescribed dose every 24 hours. At regular intervals specified by the titration protocol, the patient makes "clinic visits" where INR response to previous doses is measured, a new dose is prescribed based on the measured response, and the next clinic visit is scheduled based on the patient's INR and current dose. This is explained in more detail in Sections 5.3 and 5.4.
4. *Measure Outcomes:* The measured responses for each patient at each clinic visit are tabulated, and the risk of negative outcomes is computed.

5.2 Pharmacogenomic Warfarin Dosing

To build the non-private regression model, we use regularized least-squares regression in R, and obtained 15.9% average absolute error (see Figure 6). To build

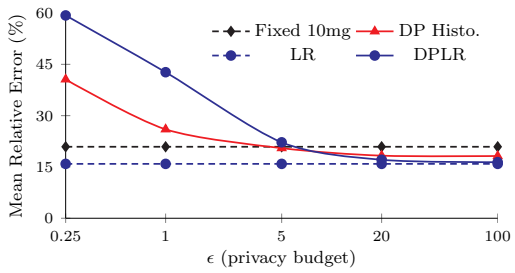

Figure 6: Pharmacogenomic warfarin dosing algorithm performance measured against clinically-deduced ground truth in IWPC dataset.

differentially-private models, we use two techniques: the functional mechanism of Zhang *et al.* [47] and regression models trained on Vinterbo's private projected histograms [44].

To obtain a baseline estimate of these algorithms' performance, we constructed a set of regression models for various privacy budget settings ($\varepsilon = 0.25, 1, 5, 20, 100$) using each of the above methods. The average absolute predictive error, over 100 distinct models at each parameter level, is shown in Figure 6. Although the average error of the private algorithms at low privacy budget settings is quite high, it is not clear how that will affect our simulated patients. In addition to the magnitude of the error, its *direction* (i.e., whether it under- or over-prescribes) matters for different types of risk. Futhermore, because the patient's initial dose is subsequently titrated to more appropriate values according to their INR response, it may be the case that a poor guess for initial dose, as long as the error is not too significant, will only pose a risk during the early portion of the patient's therapy, and a negligible risk overall. Lastly, the accuracy of the standard clinical and non-private pharmacogenomic algorithms are moderate (~15% and 21% error, respectively), and these are the best known methods for predicting initial dose. The difference in accuracy between these and the private algorithm is not extreme (e.g., greater than an order of magnitude), so lacking further information about the correlation between initial dose accuracy and patient outcomes, it is necessary to study their use in greater detail. Removing this uncertainty is the goal of our simulation-based evaluation.

5.3 Dose Assignment and Titration

To assign initial doses and control the titration process in our simulation, we follow the protocol used by the CoumaGen clinical trials on pharmacogenomic warfarin dosing algorithms [3]. In the standard arm, patients are given 10-mg doses on days 1 and 2, followed by dose adjustment according to the Kovacs protocol [29] for days 3 to 7, and final adjustment according to the Intermountain Healthcare protocol [3] for days 8 to 90. Both the Kovacs and Intermountain protocols assign a dose and next appointment time based on the patient's current INR, and possibly their previous dose.

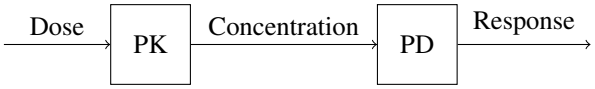

Figure 7: Basic functionality of PK/PD modelling.

The genomic arm differs from the standard arm for days 1-7. The initial dose for days 1-2 is predicted by the pharmacogenomic regression model, and multiplied by 2 [3]. On days 3-7, the Kovacs protocol is used, but the prescribed dose is multiplied by a coefficient C_{pg} that measures the ratio of the predicted pharmacogenomic dose to the standard 10mg initial dose: $C_{\text{pg}} = (\textit{Initial Pharmacogenomic Dose})/(5\text{ mg})$. On days 8-90, the genomic arm proceeds identically to the standard arm. The private arm is identical to the genomic arm, but the pharmacogenomic regression model is replaced with a differentially-private model.

To simulate realistic dosing increments, we assume any combination of three pills from those available at most pharmacies: 0.5, 1, 2, 2.5, 3, 4, 5, 6, 7, and 7.5 mg. The maximum dose was set to 15 mg/day, with possible dose combinations ranging from 0 to 15 mg in 0.5 mg increments.

5.4 PK/PD Model for INR response to Warfarin

A PK/PD model integrates two distinct pharmacologic models—pharmacokinetic (PK) and pharmacodynamic (PD)—into a single set of mathematical expressions that predict the intensity of a subject's response to drug administration over time. *Pharmacokinetics* is the course of drug absorption, distribution, metabolism, and excretion over time. Mechanistically, the pharmacokinetic component of a PK/PD model predicts the *concentration* of a drug in certain parts of the body over time. *Pharmacodynamics* refers to the effect that a drug has on the body, given its concentration at a particular site. This includes the intensity of its therapeutic and toxic effects, which is the role of the pharmacodynamic component of the PK/PD model. Conceptually, these pieces fit together as shown in Figure 7: the PK model takes a sequences of doses, produces a prediction of drug concentraation, which is given to the PD model. The final output is the predicted PD response to the given sequence of doses, both measures being taken over time. The input/output behavior of the model's components can be described as

the following related functions:

$$\begin{aligned} \mathsf{PKPDModel}(genotype, demographics) &\mapsto F_{\text{inr}} \\ F_{\text{inr}}(doses, time) &\mapsto INR \end{aligned}$$

The function PKPDModel transforms a set of patient characteristics, including the relevant genotype and demographic information, into an INR-response predictor F_{inr}. $F_{\text{inr}}(doses, t)$ transforms a sequence of doses, assumed to have been administered at 24-hour intervals starting at $time = 0$, as well as a time t, and produces a prediction of the patient's INR at time t. The function PKPDModel can be thought of as the routine that initializes the parameters in the PK and PD models, and F_{inr} as the function that composes the initialized models to translate dose schedules into INR measurements. For further details of the PK/PD model, consult Appendix A.

5.5 Calculating Patient Risk

INR levels correspond to the coagulation tendency of blood, and thus to the risk of adverse events. Sorensen *et al.* performed a pooled analysis of the correlation between stroke and bleeding events for patients undergoing warfarin treatment at varying INR levels [41]. We use the probabilities for various events as reported in their analysis. We calculate each simulated patient's risk for stroke, intra-cranial hemorrhage, extra-cranial hemorrhage, and fatality based on the predicted INR levels produced by the PK/PD model. At each 24-hour interval, we calculated INR and the corresponding risk for these events. The sum total risk for each event across the entire trial period is the endpoint we use to compare the arms. We also calculated the mean *time in therapeutic range* (TTR) of patients' INR response for each arm. We define TTR as any INR reading between 1.8–3.2, to maintain consistency with previous studies [3, 14].

The results are presented in Figure 8 in terms of relative risk (defined as the quotient of the patient's risk for a certain outcome when using a particular algorithm versus the fixed dose algorithm). The results are striking: for reasonable privacy budgets ($\varepsilon \leq 5$), private pharmacogenomic dosing results in greater risk for stroke, bleeding, and fatality events as compared to the fixed dose protocol. The increased risk is statistically significant for both private algorithms up to $\varepsilon = 5$ and all types of risk (including reduced TTR), except for private histograms, for which there was no significant increase in bleeding events with $\varepsilon > 1$.

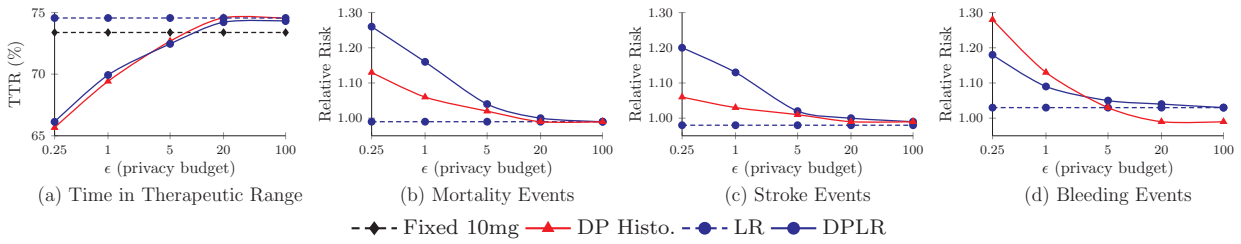
On the positive side, there is evidence that both algorithms may reduce all types of risk at certain privacy levels. Differentially-private histograms performed slightly better, improvements in all types of risk at $\varepsilon \geq 20$. Private linear regression seems to yield lower risk of stroke and fatality and increased TTR at $\varepsilon \geq 20$. However, the difference in bleeding risk for DPLR was not statistically significant at any $\varepsilon \geq 20$. *These results lead us to conclude that there is evidence that differentially-private statistical models may provide effective algorithms for predicting initial warfarin dose, but only at low settings of* $\varepsilon \geq 20$ *that yield little privacy (see Section 4).*

6 Related Work

The tension between privacy and data utility has been explored by several authors. Brickell and Shmatikov [6] found strong evidence for a tradeoff in attribute privacy and predictive performance in common data mining tasks when k-anonymity, ℓ-diversity, and t-closeness are applied before releasing a full dataset. Differential privacy arose partially as a response to Dalenius' desideratum: *anything that can be learned from the database about a specific individual should be learnable without access to the database* [9]. Dwork showed the impossibility of achieving this result in the presence of utility requirements [11], and proposed an alternative goal that proved feasible to achieve in many settings: *the risk to one's privacy should not substantially increase as a result of participating in a statistical database*. Differential privacy formalizes this goal, and constructive research on the topic has subsequently flourised.

Differential privacy is often misunderstood by those who wish to apply it, as pointed out by Dwork and others [13]. Kifer and Machanavajjhala [25] addressed several common misconceptions about the topic, and showed that under certain conditions, it fails to achieve a privacy goal related to Dwork's: *nearly all evidence of an individual's participation should be removed*. Using hypothetical examples from social networking and census data release, they demonstrate that when rows in a database are correlated, or when previous exact statistics for a dataset have been released, this notion of privacy may be violated even when differential privacy is used. Part of our work extends theirs by giving a concrete examples from a realistic application where common misconceptions about differential privacy lead to surprising privacy breaches, i.e., that it will protect genomic attributes from unwanted disclosure. We further extend their analysis by providing a quantitative study of the tradeoff between privacy and utility in the application.

Others have studied the degree to which differential privacy leaks various types of information. Cormode showed that if one is allowed to pose certain queries relating sensitive attributes to quasi-identifiers, it is possible to build a differentially-private Naive Bayes classifier that accurately predicts the sensitive attribute [8]. In contrast, we show that given a model for predicting a



(a) Time in Therapeutic Range (b) Mortality Events (c) Stroke Events (d) Bleeding Events

Figure 8: Trial outcomes for fixed dose, non-private linear regression (LR), differentially-private linear regression (DPLR), and private histograms. Horizontal axes represent ε.

certain outcome from a set of inputs (and no control over the queries used to construct the model), it is possible to make accurate predictions in the *reverse* direction: predict one of the inputs given a subset of the other values. Lee and Clifton [30] recognize the problem of setting ε and its relationship to the *relative* nature of differential privacy, and later [31] propose an alternative parametization of differential privacy in terms of the *probability that an individual contributes to the resulting model.* While this may make the privacy guarantee easier for non-specialists to understand, its close relationship to the standard definition suggests that it may not be effective at mitigating the types of disclosures documented in this paper; evaluating its efficacy remains future work, as we are not aware of any existing implementations that support their definition.

The risk of sensitive information disclosure in medical studies has been examined by many. Wang *et al.* [46], Homer *et al.* [20] and Sankararaman *et al.* [39] show that it is possible to recover parts of an individual's genotype given partial genetic information and detailed statistics from a GWAS. They do not evaluate the efficacy of their techniques against private versions of the statistics, and do not consider the problem of inference from a model derived from the statistics. Sweeny showed that a few pieces of identifying information are suitable to identify patients in medical records [42]. Loukides *et al.* [34] show that it is possible to identify a wide range of sensitive patient information from de-identified clinical data presented in a form standard among medical researchers, and later proposed a domain-specific utility-preserving scheme similar to *k*-anonymity for mitigating these breaches [35]. Dankar and Emam [10] discuss the use of differential privacy in medical applications, pointing out the various tradeoffs between interactive and non-interactive mechanisms and the limitation of utility guarantees in differential privacy, but do not study its use in any specific medical applications.

Komarova *et al.* [28] present an in-depth study of the problem of *partial disclosure*. There is some similarity between the model inversion attacks discussed here and this notion of partial disclosure. One key difference is that in the case of model inversion, an adversary is given the actual function corresponding to a statistical estimator (e.g., a linear model in our case study), whereas Komarova *et al.* consider static estimates from combined public and private sources. In the future we will investigate whether the techniques described by Komarova *et al.* can be used to refine, or provide additional information for, model inversion attacks.

7 Conclusion

We conducted the first end-to-end case study of the use of differential privacy in a medical application, exploring the tradeoff between privacy and utility that occurs when existing differentially-private algorithms are used to guide dosage levels in warfarin therapy. Using a new technique called *model inversion*, we repurpose pharmacogenetic models to infer patient genotype. We showed that models used in warfarin therapy introduce a threat to patients' genomic privacy. When models are produced using state-of-the-art differential privacy mechanisms, genomic privacy is protected for small $\varepsilon(\leq 1)$, but as ε increases towards larger values this protection vanishes.

We evaluated the *utility* of differential privacy mechanisms by simulating clinical trials that use private models in warfarin therapy. This type of evaluation goes beyond what is typical in the literature on differential privacy, where raw statistical accuracy is the most common metric for evaluating utility. We show that differential privacy substantially interferes with the main purpose of these models in personalized medicine: for ε values that protect genomic privacy, which is the central privacy concern in our application, the risk of negative patient outcomes increases beyond acceptable levels.

Our work provides a framework for assessing the tradeoff between privacy and utility for differential privacy mechanisms in a way that is directly meaningful for specific applications. For settings in which certain levels of utility performance *must* be achieved, and this tradeoff cannot be balanced, then alternative means of protecting individual privacy must be employed.

A PK/PD Model Details

We adopted a previously-developed PK/PD INR model to predict each patient's INR response to previous dosing choices [16]. The PK component of the model is a *two-compartment* model with *first-order absorption*. A two-compartment model assumes an abstract representation of the body as two discrete sections: the first being a *central* compartment into which a drug is administered and a *peripheral* compartment into which the drug eventually distributes. The central compartment (assumed to have volume V_1) represents tissues that equilibrate rapidly with blood (e.g., liver, kidney, *etc.*), and the peripheral (volume V_2) those that equilibrate slowly (e.g., muscle, fat, *etc.*). Three *rate constants* govern transfer between the compartments and elimination: k_{12}, k_{21}, for the central-peripheral and peripheral-central transfer, and k_{el} for elimination from the body, respectively. V_1, V_2, k_{12}, and k_{21} are related by the following equality: $V_1 k_{12} = V_2 k_{21}$. The *absorption rate* k_a governs the rate at which the drug enters the central compartment. In the model used in our simulation, each of these parameters is represented by a random variable whose distribution has been fit to observed population measurements of Warfarin absorption, distribution, metabolism, and elimination [16]. The elimination-rate constant k_{el} is parameterized by the patient's CYP2C9 genotype.

Given a set of PK parameters, the Warfarin concentration in the central compartment over time is calculated using standard two-compartment PK equations for oral dosing. Concentration in two-compartment pharmacokinetics diminishes in two distinct phases with differing rates: the α ("distribution") phase, and β ("elimination") phase. The expression for concentration C over time assuming doses $D_1, \ldots, D_n$ administered at times $t_{D_1}, \ldots, t_{D_n}$ has another term corresponding to the effect of oral absorption:

$$C(t) = \sum_{i=1}^{n} D_i (A e^{-\alpha t_i} + B e^{-\beta t_i} - (A+B) e^{-k_a t_i})$$

with $t_i = t - t_{D_i}$ and α, β satisfying $\alpha\beta = k_{21} k_{el}$, $\alpha + \beta = k_{el} + k_{12} + k_{21}$, and

$$A = \frac{k_a}{V_1} \frac{k_{21} - \alpha}{(k_a - \alpha)(\beta - \alpha)} \quad B = \frac{k_a}{V_1} \frac{k_{21} - \beta}{(k_a - \beta)(\alpha - \beta)}$$

Our model contains an error term with a zero-centered log-normal distribution whose variance depends on whether or not steady-state dosing has occurred; the term is given in the appendix of Hamberg *et al.* [16].

PD Model The PD model used in our simulations is an *inhibitory sigmiod-$E_{\max}$ model*. Recall that the purpose of the PD model is to describe the physiological response E, in this case INR, to Warfarin concentration at a particular time. $E_{\max}$ represents the maximal response, i.e., the maximal inhibition of coagulation, and E_{50} the concentration of Warfarin producing half-maximal inhibition. $E_{\max}$ is fixed to 1, and E_{50} is a patient-specific random variable that is a function of the patient's VKORC1 genotype. A sigmoidocity factor γ is used to model the fact that the concentration-effect response of Warfarin corresponds to a sigmoid curve at lower concentrations. The basic formula for calculating E at time t from concentration is: $1 - (E_{\max} C(t)^\gamma)/(E_{50}^\gamma + C(t)^\gamma)$. However, Warfarin exhibits a delay between exposure and anticoagulation response. To characterize this feature, Hamberg *et al.* showed that extending the basic $E_{\max}$ model with a *transit compartment model* with two parallel chains is adequate [16], as shown in Figure 9. The delay between exposure and concentration is modeled by assuming that the drug travels along two parallel *compartment chains* of differing lengths and turnover rates. The transit rate between compartments on the two chains is given by two constants k_{tr1} and k_{tr2}. The first chain consists of six compartments, and the second a single compartment. The first transit constant is a random zero-centered log-normal variable, whereas empirical data did not reilably support variance in the second [16]. The amount in a given compartment i, A_i, at time t is described by a system of coupled ordinary differential equations:

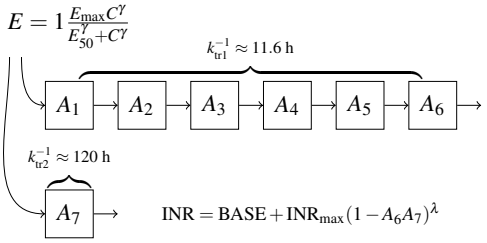

Figure 9: Overview of transit-compartment PD model [16].

$$\frac{dA_1}{dt} = k_{tr1} \left(1 - \frac{E_{\max} C(t)^\gamma}{E_{50}^\gamma + C(t)^\gamma}\right) - k_{tr1} A_1$$

$$\frac{dA_n}{dt} = k_{tr1}(A_{n-1} - A_n), n = 2,3,4,5,6$$

$$\frac{dA_7}{dt} = k_{tr2} \left(1 - \frac{E_{\max} C(t)^\gamma}{E_{50}^\gamma + C(t)^\gamma}\right) - k_{tr2} A_7$$

The final expression for INR at time t is given by solving for A_7 and A_7 starting from initial conditions $A_i = 1$, and calculating the expression: $\log(\text{INR}) = \log(\text{Base} + \text{INR}_{\max}(1 - A_6 A_7)^\lambda) + \varepsilon_{\text{INR}}$. In this expression, Base is the patient's baseline INR, $\text{INR}_{\max}$ is the maximal INR (assumed to be 20 [16]), λ is a scaling factor derived from empirical data [16], and ε_{INR} is a zero-centerd, symmetrically-distributed random variable with variance determined from empirical data [16].

Mimesis Aegis: A Mimicry Privacy Shield

A System's Approach to Data Privacy on Public Cloud

Abstract

Users are increasingly storing, accessing, and exchanging data through public cloud services such as those provided by Google, Facebook, Apple, and Microsoft. Although users may want to have faith in cloud providers to provide good security protection, the confidentiality of any data in public clouds can be violated, and consequently, while providers may not be "doing evil," we can not and should not trust them with data confidentiality.

To better protect the privacy of user data stored in the cloud, in this paper we propose a privacy-preserving system called *Mimesis Aegis (M-Aegis)* that is suitable for mobile platforms. M-Aegis is a new approach to user data privacy that not only provides isolation but also preserves the user experience through the creation of a conceptual layer called *Layer 7.5 (L-7.5)*, which is interposed between the application (OSI Layer 7) and the user (Layer 8). This approach allows M-Aegis to implement true end-to-end encryption of user data with three goals in mind: 1) complete data and logic isolation from untrusted entities; 2) the preservation of original user experience with target apps; and 3) applicable to a large number of apps and resilient to app updates.

In order to preserve the exact application workflow and look-and-feel, M-Aegis uses L-7.5 to put a transparent window on top of existing application GUIs to both intercept plaintext user input before transforming the input and feeding it to the underlying app, and to reverse-transform the output data from the app before displaying the plaintext data to the user. This technique allows M-Aegis to transparently integrate with most cloud services without hindering usability and without the need for reverse engineering. We implemented a prototype of M-Aegis on Android and show that it can support a number of popular cloud services, e.g. Gmail, Facebook Messenger, WhatsApp, etc.

Our performance evaluation and user study show that users incur minimal overhead when adopting M-Aegis on Android: imperceptible encryption/decryption latency and a low and adjustable false positive rate when searching over encrypted data.

1 Introduction

A continuously increasing number of users now utilize mobile devices [2] to interact with public cloud services (PCS) (e.g. Gmail, Outlook, and WhatsApp) as an essential part of their daily lives. While the user's connectivity to the Internet is improved with mobile platforms, the problem of preserving data privacy while interacting with PCS remains unsolved. In fact, news about the US government's alleged surveillance programs reminds everybody about a very unsatisfactory status quo: while PCS are essentially part of everyday life, the default method of utilizing them exposes users to privacy breaches, because it implicitly requires the users to trust the PCS providers with the confidentiality of their data; but such trust is unjustified, if not misplaced. Incidents that demonstrate breach of this trust are easy to come by: 1) PCS providers are bound by law to share their users' data with surveillance agencies [14], 2) it is the business model of the PCS providers to mine their users' data and share it with third parties [11, 22, 24, 40], 3) operator errors [34] can result in unintended data access, and 4) data servers can be compromised by attackers [47].

To alter this undesirable status quo, solutions should be built based on an updated trust model of everyday communication that better reflects the reality of the threats mentioned above. In particular, new solutions must first assume PCS providers to be untrusted. This implies that all other entities that are controlled by the PCS providers, including the apps that users installed to engage with the PCS, must also be assumed untrusted.

Although there are a plethora of apps available today that come in various combinations of look and feel and features, we observed that many of these apps provide text communication services (e.g. email or private/group

messaging categories). Users can still enjoy the same quality of service[1] without needing to reveal their plaintext data to PCS providers. PCS providers are essentially message routers that can function normally without needing to know the content of the messages being delivered, analogous to postmen delivering letters without needing to learn the actual content of the letters.

Therefore, applying end-to-end encryption (E2EE) without assuming trust in the PCS providers seems to solve the problem. However, in practice, the direct application of E2EE solutions onto the mobile device environment is more challenging than originally thought [65, 59]. A good solution must present clear advantages to the entire mobile security ecosystem. In particular it must account for these factors: 1) the users' ease-of-use, hence acceptability and adoptability; 2) the developers' efforts to maintain support; and 3) the feasibility and deployability of solution on a mobile system. From this analysis, we formulate three design goals that must be addressed coherently:

1. For a solution to be secure, it must be properly isolated from untrusted entities. It is obvious that E2EE cannot protect data confidentiality if plaintext data or an encryption key can be compromised by architectures that risk exposing these values. Traditional solutions like PGP [15] and newer solutions like Gibberbot [5], TextSecure [12], and SafeSlinger [41] provide good isolation, but force users to use custom apps, which can cause usability problems (refer to (2)). Solutions that repackage/rewrite existing apps to introduce additional security checks [68, 26] do not have this property (further discussed in Sect. 2.3). Solutions in the form of browser plugins/extensions also do not have this property (further discussed in Sect. 2.2), and they generally do not fit into the mobile security landscape because many mobile browsers do not support extensions [7], and mobile device users do not favor using mobile browsers [27] to access PCS. Therefore, we rule out conventional browser-plugin/extension-based solutions.
2. For a solution to be adoptable, it must preserve the user experience. We argue that users will not accept solutions that require them to switch between different apps to perform their daily tasks. Therefore, simply porting solutions like PGP to a mobile platform would not work, because it forces users to use a separate and custom app, and it is impossible to recreate the richness and unique user experience of all existing text routing apps offered by various PCS providers today. In the context of mobile devices, PCS are competing for market share not only by offering more reliable infrastructure to facilitate user communication, but also by offering a better user experience [16, 58]. Ultimately, users will choose apps that feel the most comfortable. To reduce interference with a user's interaction with the app of their choice, security solutions must be retrofittable to existing apps. Solutions that repackage/rewrite existing apps have this criterion.
3. For a solution to be sustainable, it must be easy to maintain and scalable: the solution must be sufficiently general-purpose, require minimal effort to support new apps, and withstand app updates. In the past, email was one of the very few means of communication. Protecting it is relatively straightforward because email protocols (e.g. POP and IMAP) are well defined. Custom privacy-preserving apps can therefore be built to serve this need. However, with the introduction of PCS that are becoming indispensable in a user's everyday life, a good solution should also be able to integrate security features into apps without requiring reverse engineering of the apps' logic and/or network protocols, which are largely undocumented and possibly proprietary (e.g. Skype, WhatsApp, etc.).

In this paper, we introduce *Mimesis Aegis (M-Aegis)*, a privacy-preserving system that mimics the look and feel of existing apps to preserve their user experience and workflow on mobile devices, without changing the underlying OS or modifying/repackaging existing apps. M-Aegis achieves the three design goals by operating at a conceptual layer we call *Layer 7.5 (L-7.5)* that is positioned above the existing application layer (OSI Layer 7 [8]), and interacts directly with the user (popularly labeled as Layer 8 [19, 4]).

From a system's perspective, L-7.5 is a transparent window in an isolated process that interposes itself between Layer 7 and 8. The interconnectivity between these layers is achieved using the accessibility framework, which is available as an essential feature on modern operating systems. Note that utilizing accessibility features for unorthodox purposes have been proposed by prior work [56, 48] that achieves different goals. L-7.5 extracts the GUI information of an app below it through the OS's user interface automation/accessibility (UIA) library. Using this information, M-Aegis is then able to proxy user input by rendering its own GUI (with a different color as visual cue) and subsequently handle those input (e.g. to process plaintext data or intercept user button click). Using the same UIA library, L-7.5 can also programmatically interact with various UI components of the app below on behalf of the user (refer to Sect. 3.3.2 for more details). Since major software vendors today have pledged their commitment towards continuous sup-

[1] the apps' functionalities and user experience are preserved

port and enhancement of accessibility interface for developers [9, 20, 6, 1], our UIA-based technique is applicable and sustainable on all major platforms.

From a security design perspective, M-Aegis provides two privacy guarantees during a user's interaction with a target app: 1) all input from the user first goes to L-7.5 (and is optionally processed) before being passed to an app. This means that confidential data and user intent can be fully captured; and 2) all output from the app must go through L-7.5 (and is optionally processed) before being displayed to the user.

From a developer's perspective, accessing and interacting with a target app's UI components at L-7.5 is similar to that of manipulating the DOM tree of a web app using JavaScript. While DOM tree manipulation only works for browsers, UIA works for all apps on a platform. To track the GUI of an app, M-Aegis relies on resource id names available through the UIA library. Therefore, M-Aegis is resilient to updates that change the look and feel of the app (e.g. GUI position or color). It only requires resource id names to remain the same, which, through empirical evidence, often holds true. Even if a resource id changes, minimal effort is required to rediscover resource id names and remap them to the logic in M-Aegis. From our experience, M-Aegis does not require developer attention across minor app updates.

From a user's perspective, M-Aegis is visible as an always-on-top button. When it is turned on, users will perceive that they are interacting with the original app in plaintext mode. The only difference is the GUI of the original app will appear in a different color to indicate that protection is activated. This means that subtle features that contribute towards the entire user experience such as spell checking and in-app navigation are also preserved. However, despite user perception, the original app *never* receives plaintext data. Figure 1 gives a high level idea of how M-Aegis creates an L-7.5 to protect user's data privacy when interacting with Gmail.

For users who would like to protect their email communications, they will also be concerned if encryption will affect their ability to search, as it is an important aspect of user productivity [64]. For this purpose, we designed and incorporated a new searchable encryption scheme named *easily-deployable efficiently-searchable symmetric encryption scheme* (EDESE) into M-Aegis that allows search over encrypted content without any server-side modification. We briefly discuss the design considerations and security concerns involved in supporting this functionality in Sect 3.3.4.

As a proof of concept, we implemented a prototype M-Aegis on Android that protects user data when interfacing with text-based PCS. M-Aegis supports email apps like Gmail and messenger apps like Google Hangout,

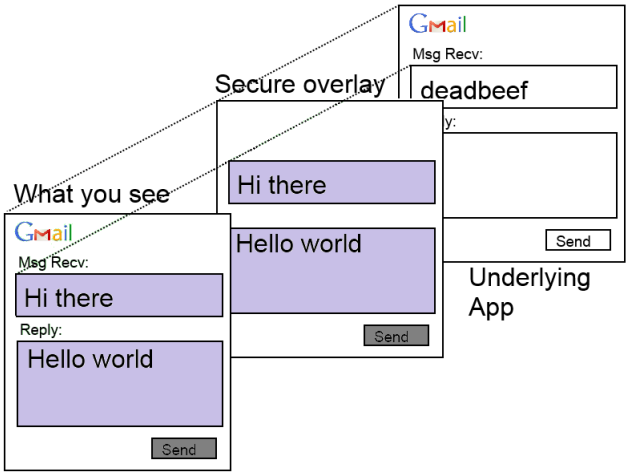

Figure 1: This diagram shows how M-Aegis uses L-7.5 to transparently reverse-transform the message "deadbeef" into "Hi there", and also allows a user to enter their plaintext message "Hello world" into M-Aegis's text box. To the user, the GUI looks exactly the same as the original app. When the user decides to send a message, the "Hello world" message will be transformed and relayed to the underlying app.

WhatsApp, and Facebook Chat. It protects data privacy by implementing E2EE that passes no plaintext to an app while also preserving the user experience and workflow. We also implemented a version of M-Aegis on the desktop to demonstrate the generality of our approach. Our initial performance evaluation and user study shows that users incur minimal overhead in adopting M-Aegis on Android. There is imperceptible encryption/decryption latency and a low and adjustable false positive rate when searching over encrypted data.

In summary, these are the major contributions of our work:

- We introduced Layer 7.5 (L-7.5), a conceptual layer that directly interacts with users on top of existing apps. This is a novel system approach that provides seemingly contrasting features: transparent interaction with a target app and strong isolation from the target app.
- We designed and built Mimesis Aegis based on the concept of L-7.5, a system that preserves user privacy when interacting with PCS by ensuring data confidentiality. Essential functionalities of existing apps, especially search (even over encrypted data), are also supported without any server-side modification.
- We implemented two prototypes of Mimesis Aegis, one on Android and the other on Windows, with

support for various popular public cloud services, including Gmail, Facebook Messenger, Google Hangout, WhatsApp, and Viber.

- We designed and conducted a user study that demonstrated the acceptability of our solution.

The rest of the paper is structured as follows. Section 2 compares our work to related work. Section 3 discusses the threat model and the design of M-Aegis. Section 4 presents the implementation of M-Aegis and the challenges we solved during the process. Section 5 presents performance evaluations and user study of the acceptability of M-Aegis on Android. Section 6 discusses limitations of our work and answers some common questions that readers may have about our system. Section 7 discusses future work and concludes our work.

2 Related Work

Since M-Aegis is designed to achieve the three design goals described in Sect. 1 while seamlessly integrating end-to-end encryption into user's communication, we discuss how well existing works achieve some of these goals and how they differ from our work. As far as we know, there is no existing work that achieves all the three design goals.

2.1 Standalone Solutions

There are many standalone solutions that aim to protect user data confidentiality. Solutions like PGP [15] (including S/MIME [37]), Gibberbot [5], TextSecure [12], SafeSlinger [41], and FlyByNight [55] provides secure messaging and/or file transfer through encryption of user data. These solutions provide good isolation from untrusted entities. However, since they are designed as standalone custom apps, they do not preserve the user experience, requiring users to adopt a new workflow on a custom app. More importantly, these solutions are not retrofittable to existing apps on the mobile platform.

Like M-Aegis, Cryptons [36] introduced a similarly strong notion of isolation through its custom abstractions. However, Cryptons assumes a completely different threat model that trusts PCS, and requires both server and client (app) modifications. Thus, Cryptons could not protect a user's communication using existing messaging apps while assuming the provider to be untrusted. We also argue that it is non-trivial to modify Cryptons to achieve the three design goals we mentioned in Sect. 1.

2.2 Browser Plugin/Extension Solutions

Other solutions that focus on protecting user privacy include Cryptocat [3], Scramble! [24], TrustSplit [40], NOYB (None of Your Business) [46], and SafeButton [53]. Some of these assume different threat models, and achieve different goals. For example, NOYB protects a user's Facebook profile data while SafeButton tries to keep a user's browsing history private. Most of these solutions try to be transparently integrated into user workflow. However, since these solutions are mostly based on browser plugins/extensions, they are not applicable to the mobile platform.

Additionally, Cryptocat and TrustSplit require new and/or independent service providers to support their functionalities. However, M-Aegis works with the existing service providers without assuming trust or requiring modification to server-side communication.

2.3 Repackaging/Rewriting Solutions

There is a category of work that repackages/rewrites an app's binary to introduce security features, such as Aurasium [68], Dr. Android [49], and others [26]. Our solution is similar to these approaches in that we can retrofit our solutions to existing apps and still preserve user experience, but is different in that M-Aegis' coverage is not limited to apps that do not contain native code. Also, repackaging-based approaches suffer from the problem that they will break app updates. In some cases, the security of such solutions can be circumvented because the isolation model is unclear, i.e. the untrusted code resides in the same address space as the reference monitor (e.g. Aurasium).

2.4 Orthogonal Work

Although our work focuses on user interaction on mobile platforms with cloud providers, we assume a very different threat model than those that focus on more robust permission model infrastructures and those that focus on controlling/tracking information flow, such as TaintDroid [38] and Airbag [67]. These solutions require changes to the underlying app, framework, or the OS, but M-Aegis does not.

Access Control Gadgets (ACG) [57] uses user input as permission granting intent to allow apps to access user owned resources. Although we made the same assumptions as ACG to capture authentic user input, ACG is designed for a different threat model and security goal than ours. Furthermore, ACG requires a modified kernel but M-Aegis does not.

Persona [23] presents a completely isolated and new online social network that provides certain privacy and security guarantees to the users. While related, it differs from the goal of M-Aegis.

Frientegrity [43] and Gyrus [48] focus on different aspects of integrity protection of a user's data.

Tor [35] is well known for its capability to hide a user's IP address while browsing the Internet. However, it focuses on anonymity guarantees while M-Aegis focuses on data confidentiality guarantees.

Off-the-record messaging (OTR) [30] is a secure communication protocol that provides perfect forward secrecy and malleable encryption. While OTR can be implemented on M-Aegis using the same design architecture to provide these extra properties, it is currently not the focus of our work.

3 System Design

3.1 Design Goals

In this section, we formally reiterate our design goals. We posit that a good solution must:

1. Offer good security by applying strong isolation from untrusted entities (defined in Sect. 3.2).
2. Preserve the user experience by providing users transparent interaction with existing apps.
3. Be easy to maintain and scale by devising a sufficiently general-purpose approach.

Above all, these goals must be satisfied within the unique set of constraints found in the mobile platform, including user experience, transparency, deployability, and adoptability factors.

3.2 Threat Model

3.2.1 In-Scope Threats

We begin with the scope of threats that M-Aegis is designed to protect against. In general, there are three parties that pose threats to the confidentiality of users' data exposed to public cloud through mobile devices. Therefore, we assume these parties to be untrusted in our threat model:

- Public cloud service (PCS) providers. Sensitive data stored in the public cloud can be compromised in several ways: 1) PCS providers can be compelled by law [21] to provide access to a user's sensitive data to law enforcement agencies [14]; 2) the business model of PCS providers creates strong incentive for them to share/sell user data with third parties [11, 22, 24, 40]; 3) PCS administrators who have access to the sensitive data may also compromise the data, either intentionally [14] or not [34]; and 4) vulnerabilities of the PCS can be exploited by attackers to exfiltrate sensitive data [47].
- Client-side apps. Since client-side apps are developed by PCS providers to allow a user to access their services, it follows that these apps are considered untrusted too.
- Middle boxes between a PCS and a client-side app. Sensitive data can also be compromised when it is transferred between a PCS and a client-side app. Incorrect protocol design/implementation may allow attackers to eavesdrop on plaintext data or perform Man-in-the-Middle attacks [39, 18, 13].

M-Aegis addresses the above threats by creating L-7.5, which it uses to provide end-to-end encryption (E2EE) for user private data. We consider the following components as our trusted computing base (TCB): the hardware, the operating system (OS), and the framework that controls and mediates access to hardware. In the absence of physical input devices (e.g. mouse and keyboard) on mobile devices, we additionally trust the soft keyboard to not leak the keystrokes of a user. We rely on the TCB to correctly handle I/O for M-Aegis, and to provide proper isolation between M-Aegis and untrusted components.

Additionally, we also assume that all the components of M-Aegis, including L-7.5 that it creates, are trusted. The user is also considered trustworthy under our threat model in his intent. This means that he is trusted to turn on M-Aegis when he wants to protect the privacy of his data during his interaction with the PCS.

3.2.2 Out of Scope Threats

Our threat model does not consider the following types of attacks. First, M-Aegis only guarantees the confidentiality of a user's data, but not its availability. Therefore, attacks that deny access to data (denial-of-service) either at the server or the client are beyond the scope of this work. Second, any attacks against our TCB are orthogonal to this work. Such attacks include malicious hardware [52], attacks against the hardware [66], the OS [50], the platform [63] and privilege escalation attacks (e.g. unauthorized rooting of device). However, note that M-Aegis can be implemented on a design that anchors its trust on trusted hardware and hypervisor (e.g. Gyrus [48], Storage Capsules [29]) to minimize the attack surface against the TCB. Third, M-Aegis is designed to prevent any direct flow of information from an authorized user to untrusted entities. Hence, leakages through all side-channels [62] are beyond the scope of this work.

Since the user is assumed to be trustworthy under our threat model to use M-Aegis correctly, M-Aegis does not protect the user against social-engineering-based attacks. For example, phishing attacks to trick users into either turning off M-Aegis and/or entering sensitive information into unprotected UI components are beyond

the scope of our paper. Instead, M-Aegis deploys best-effort protection by coloring the UI components in L-7.5 differently from that of the default app UI.

The other limitations of M-Aegis, which are not security threats, are discussed in Sect. 6.2.

3.3 M-Aegis Architecture

M-Aegis is architected to fulfill all of the three design goals mentioned in Sect. 3.1. Providing strong isolation guarantees is first. To achieve this, M-Aegis is designed to execute in a separate process, though it resides in the same OS as the target client app (TCA). Besides memory isolation, the filesystem of M-Aegis is also shielded from other apps by OS app sandbox protection.

Should a greater degree of isolation be desirable, an underlying virtual-machine-based system can be adopted to provide even stronger security guarantees. However, we do not consider such design at this time as it is currently unsuitable for mobile platforms, and the adoption of such technology is beyond the scope of our paper. The main components that make up M-Aegis are as follows.

3.3.1 Layer 7.5 (L-7.5)

M-Aegis creates a novel and conceptual layer called Layer 7.5 (L-7.5) to interpose itself between the user and the TCA. This allows M-Aegis to implement true end-to-end encryption (E2EE) without exposing plaintext data to the TCA while maintaining the TCA's original functionalities and user experience, fulfilling the second design goal. L-7.5 is built by creating a transparent window that is always-on-top. This technique is advantageous in that it provides a natural way to handle user interaction, thus preserving user experience without the need to reverse engineer the logic of TCAs or the network protocols used by the TCAs to communicate with their respective cloud service backends, fulfilling the third design goal.

There are three cases of user interactions to handle. The first case considers interactions that do not involve data confidentiality (e.g. deleting or relabeling email). Such input do not require extra processing/transformation and can be directly delivered to the underlying TCA. Such click-through behavior is a natural property of transparent windows, and helps M-Aegis maintain the look and feel of the TCA.

The second case considers interactions that involve data confidentiality (e.g. entering messages or searching encrypted email). Such input requires extra processing (e.g. encryption and encoding operations). For such cases, M-Aegis places opaque GUIs that "mimic" the GUIs over the TCA, which are purposely painted in different colors for two reasons: 1) as a placeholder for user input so that it does not leak to the TCA, and 2) for user visual feedback. Mimic GUIs for the subject and content as seen in Fig. 3 are examples of this case. Since L-7.5 is always on top, this provides the guarantee that user input always goes to a mimic GUI instead of the TCA.

The third case considers interactions with control GUIs (e.g. send buttons). Such input requires user action to be "buffered" while the input from the second case is being processed before being relayed to the actual control GUI of the TCA. For such cases, M-Aegis creates semi-transparent mimic GUIs that register themselves to absorb/handle user clicks/taps. Again, these mimic GUIs are painted with a different color to provide a visual cue to a user. Examples of these include the purple search button in the left figure in Fig. 2 and the purple send button in Fig. 3. Note that our concept of intercepting user input is similar to that of ACG's [57] in capturing user intent, but our application of user intent differs.

3.3.2 UIA Manager (UIAM)

To be fully functional, there are certain capabilities that M-Aegis requires but are not available to normal apps. First, although M-Aegis is confined within the OS' app sandbox, it must be able to determine with which TCA the user is currently interacting. This allows M-Aegis to invoke specific logic to handle the TCA, and helps M-Aegis clean up the screen when the TCA is terminated. Second, M-Aegis requires information about the GUI layout for the TCA it is currently handling. This allows M-Aegis to properly render mimic GUIs on L-7.5 to intercept user I/O. Third, although isolated from the TCA, M-Aegis must be able to communicate with the TCA to maintain functionality and ensure user experience is not disrupted. For example, M-Aegis must be able to relay user clicks to the TCA, eventually send encrypted data to the TCA, and click on TCA's button on behalf of the user. For output on screen, it must be able to capture ciphertext so that it can decrypt it and then render it on L-7.5.

M-Aegis extracts certain features from the underlying OS's accessibility framework, which are exposed to developers in the form of User Interface Accessibility/Automation (UIA) library. Using UIA, M-Aegis is not only able to know which TCA is currently executing, but it can also query the GUI tree of the TCA to get detailed information about how the page is laid out (e.g. location, size, type, and resource-id of the GUI components). More importantly, it is able to obtain information about the content of these GUI items.

Exploiting UIA is advantageous to our design as compared to other methods of information capture from the GUI, e.g. OCR. Besides having perfect content accuracy, our technique is not limited by screen size. For example,

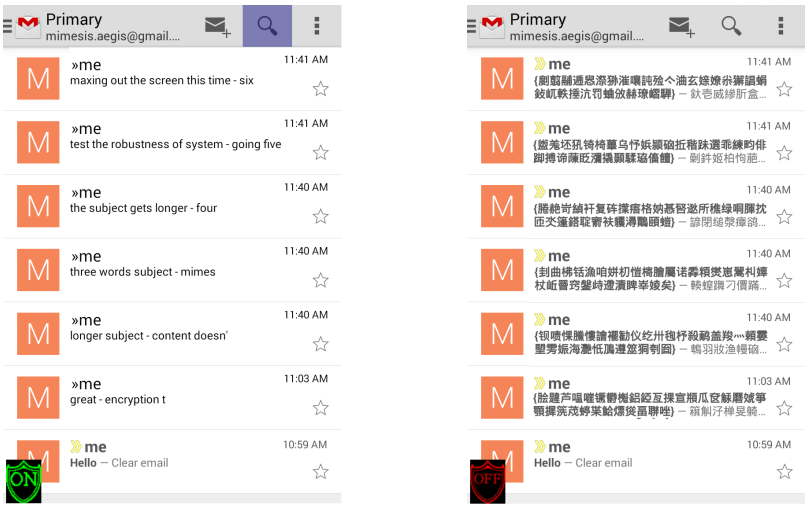

Figure 2: The figure on the left illustrates how a user perceives the Gmail preview page when M-Aegis is turned on. The figure on the right illustrates the same scenario but with M-Aegis turned off. Note that the search button is painted with a different color when M-Aegis is turned on.

even though the screen size may prevent full text to be displayed, M-Aegis is still able to capture text in its *entirety* through the UIA libraries, allowing us to comfortably apply decryption to ciphertext.

We thus utilize all these capabilities and advantages to build a crucial component of M-Aegis called the UIA manager (UIAM).

3.3.3 Per-TCA Logic

M-Aegis can be extended to support many TCAs. For each TCA of interest, we build per-TCA logic as an extension module. The per-TCA logic is responsible for rendering the specific mimic GUIs according to information it queries from the UIAM. Therefore, per-TCA logic is responsible for handling direct user input. Specifically, it decides whether the user input will be directly passed to the TCA or be encrypted and encoded before doing so. This ensures that the TCA never obtains plaintext data while user interaction is in plaintext mode. Per-TCA logic also intercepts button clicks so that it can then instruct UIAM to emulate the user's action on the button in the underlying TCA. Per-TCA logic also decides which encryption and encoding scheme to use according to the type of TCA it is handling. For example, encryption and encoding schemes for handling email apps would differ from that of messenger apps.

3.3.4 Cryptographic Module

M-Aegis' cryptographic module is responsible for providing encryption/decryption and cryptographic hash capabilities to support our searchable encryption scheme (described in detail later) to the per-TCA logic the so that M-Aegis can transform/obfuscate messages through E2EE operations. Besides standard cryptographic primitives, this module also includes a searchable encryption scheme to support search over encrypted email that works *without server modification*. Since the discussion of any encryption scheme is not complete without encryption keys, key manager is also a part of this module.

Key Manager. M-Aegis has a key manager per TCA that manages key policies that can be specific to each TCA according to user preference. The key manager supports a range of schemes, including simple password-based key derivation functions (of which we assume the password to be shared out of band) to derive symmetric keys, which we currently implement as default, to more sophisticated PKI-based scheme for users who prefer stronger security guarantees and do not mind the additional key set-up and exchange overheads. However, the discussion about the best key management/distribution policy is beyond the scope of this paper.

Searchable Encryption Scheme (EDESE). There are numerous encryption schemes that support keyword search [45, 61, 44, 31, 33, 28, 51]. These schemes exhibit different tradeoffs between security, functionality and efficiency, but *all* of them require modifications on the server side. Schemes that make use of inverted index [33] are not suitable, as updates to inverted index cannot be practically deployed in our scenario.

Since we cannot assume server cooperation (consistent with our threat model in Sect. 3.2), we designed a new searchable encryption scheme called easily-deployable efficiently-searchable symmetric encryption scheme (EDESE). EDESE is an adaptation of a scheme

proposed by Bellare et al. [25], with modifications similar to that of Goh's scheme [44] that is retrofittable to a non-modifying server scenario.

We incorporated EDESE for email applications with the following construct. The idea for the construction is simple: we encrypt the document with a standard encryption scheme and append HMACs of unique keywords in the document. We discuss the specific instantiations of encryption and HMAC schemes that we use in Sect. 4.1. To prevent leaking the number of unique keywords we add as many "dummy" keywords as needed. We present this construction in detail in the full version of our paper [54].

In order to achieve higher storage and search efficiency, we utilized a Bloom filter (BF) to represent the EDESE-index. Basically, a BF is a data structure that allows for efficient set-inclusion tests. However, such set-inclusion tests based on BFs are currently not supported by existing email providers, which only support string-based searches. Therefore, we devised a solution that encodes the positions of on-bits in a BF as Unicode strings (refer to Sect. 4.4 for details).

Since the underlying data structure that is used to support EDESE is a BF, search operations are susceptible to false positives matches. However, this does not pose a real problem to users, because the false positive rate is extremely low and is completely adjustable. Our current implementation follows these parameters: the length of keyword (in bits) is estimated to be $k = 128$, the size of the BF array is $B = 2^{24}$, the maximum number of unique keywords used in any email thread is estimated to be $d = 10^6$, the number of bits set to 1 for one keyword is $r = 10$. Plugging in these values into the formula for false positive calculation [44], i.e. $(1 - e^{-rd/B})^r$, we cap the probability of a false positive δ to 0.0003.

We formally assess the security guarantees that our construction provides. In the full version of our paper [54], we propose a security definition for EDESE schemes and discuss why the existing notions are not suitable. Our definition considers an attacker who can obtain examples of encrypted documents of its choice and the results of queries of keywords of its choice. Given such an adversary, an EDESE scheme secure under our definition should hide all partial information about the messages except for the message length and the number of common keywords between any set of messages. Leaking the latter is unavoidable given that for the search function to be transparent to encryption, the output of a query has to be a part a ciphertext. But everything else, e.g., the number of unique keywords in a message, positions of the keywords, is hidden.

Given the security definition in our full paper [54], we prove that our construction satisfies it under the standard notions of security for encryption and HMACs.

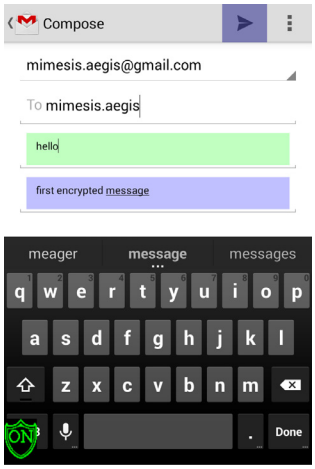

Figure 3: User still interacts with Gmail app to compose email, with M-Aegis' mimic GUIs painted with different colors on L-7.5.

3.4 User Workflow

To better illustrate how the different components in M-Aegis fit together, we describe an example workflow of a user composing and sending an email using the stock Gmail app on Android using M-Aegis:

1) When the user launches the Gmail app, the UIAM notifies the correct per-TCA logic of the event. The per-TCA logic will then initialize itself to handle the Gmail workflow.

2) As soon as Gmail is launched, the per-TCA logic will try to detect the state of Gmail app (e.g. preview, reading, or composing email). This allows M-Aegis to properly create mimic GUIs on L-7.5 to handle user interaction. For example, when a user is on the compose page, the per-TCA logic will mimic the GUIs of the subject and content fields (as seen in Fig. 3). The user then interacts directly with these mimic GUIs in plaintext mode without extra effort. Thus, the workflow is not affected. Note that essential but subtle features like spell check and autocorrect are still preserved, as they are innate features of the mobile device's soft keyboard. Additionally, the "send" button is also mimicked to capture user intent.

3) As the user finishes composing his email, he clicks on the mimicked "send" button on L-7.5. Since L-7.5 receives the user input and not the underlying Gmail app, the per-TCA logic is able to capture this event and proceed to process the subject and the content.

4) The per-TCA logic selects the appropriate encryption key to be used based on the recipient list and the predetermined key policy for Gmail. If a key cannot be found for this conversation, M-Aegis prompts the user (see Fig. 4) for a password to derive a new key. After ob-

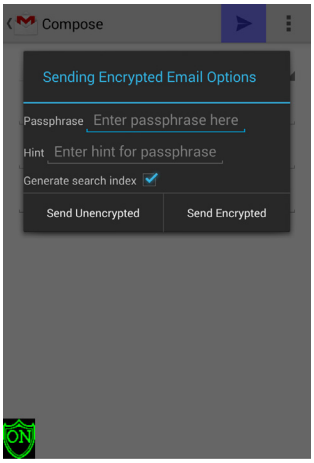

Figure 4: Password prompt when user sends encrypted mail for a new conversation.

taining the associated key for this conversation, M-Aegis will then encrypt these inputs and encode it back to text such that Gmail can consume it.

5) The per-TCA logic then requests the UIAM to fill in the corresponding GUIs on Gmail with the transformed text. After they are filled, the UIAM is instructed to click the actual "send" button on behalf of the user. This provides a transparent experience to the user.

From this workflow, it should therefore be evident that from the user's perspective, the workflow of using Gmail remains the same, because of the mimicking properties of M-Aegis.

4 Implementation and Deployment

In this section, we discuss important details of our prototype implementations. We implemented a prototype of M-Aegis using Java on Android, as an accessibility service. This is done by creating a class that extends the `AccessibilityService` class and requesting the `BIND_ACCESSIBILITY_SERVICE` permission in the manifest. This allows us to interface with the UIA library, building our UIAM. We discuss this in further detail in Sect. 4.2.

We then deployed our prototype on two Android phones from separate manufacturers, i.e. Samsung Galaxy Nexus, and LG Nexus 4, targeting several versions of Android, from Android 4.2.2 (API level 17) to Android 4.4.2 (API level 19). The deployment was done on stock devices and OS, i.e. *without* modifying the OS, Android framework, or rooting. Only simple app installation was performed. This demonstrates the ease of deployment and distribution of our solution. We have also implemented an M-Aegis prototype on Windows 7 to demonstrate interoperability and generality of approach, but we do not discuss the details here, as it is not the focus of this paper.

As an interface to the user, we create a button that is always on top even if other apps are launched. This allows us to create a non-bypassable direct channel of communication with the user besides providing visual cue of whether M-Aegis is turned on or off.

For app support, we use Gmail as an example of an email app and WhatsApp as an example of a messenger app. We argue that it is easy to extend the support to other apps within these classes.

We first describe the cryptographic schemes that we deployed in our prototype, then we explain how we build our UIAM and create L-7.5 on Android, and finally discuss the per-TCA logic required to support both classes of apps.

4.1 Cryptographic Schemes

For all the encryption/decryption operations, we use AES-GCM-256. For a password-based key generation algorithm, we utilized PBKDF2 with SHA-1 as the keyed-hash message authentication code (HMAC). We also utilized HMAC-SHA-256 as our HMAC to generate tags for email messages (Sect. 4.4.1). These functionalities are available in Java's `javax.crypto` and `java.security` packages.

For the sake of usability, we implemented a password-based scheme as the default, and we assume one password for each group of message recipients. We rely on the users to communicate the password to the receiving parties using out of band channel (e.g. in person or phone calls). For messaging apps, we implemented an authenticated Diffie-Hellman key exchange protocol to negotiate session keys for WhatsApp conversations. A PGP key is automatically generated for a user during installation based on the hashed phone number, and is deposited to publicly accessible repositories on the user's behalf (e.g. MIT PGP Key Server [10]). Further discussion about verifying the authenticity of public keys retrieved from such servers is omitted from this paper. Since all session and private keys are stored locally for user convenience, we make sure that they are never saved to disk in plaintext. They are additionally encrypted with a key derived from a master password that is provided by the user during installation.

4.2 UIAM

As mentioned earlier, UIAM is implemented using UIA libraries. On Android, events that signify something new being displayed on the screen can be detected by monitoring following the events: `WINDOW_CONTENT_CHANGED`, `WINDOW_STATE_CHANGED`,

and VIEW_SCROLLED. Upon receiving these events, per-TCA logic is informed. The UIA library presents a data structure in the form of a tree with nodes representing UI components with the root being the top window. This allows the UIAM to locate all UI components on the screen.

Additionally, Android's UIA framework also provides the ability to query for UI nodes by providing a resource ID. For instance, the node that represents Gmail's search button can be found by querying for com.google.android.gm:id/search. More importantly, there is no need to guess the names of these resource IDs. Rather, a tool called UI Automator Viewer [17] (see Sect. 4.4), which comes with the default Android SDK. Once the node of interest is found, all the other information about the GUI represented by the node can be found. This includes the exact location and size of text boxes and buttons on the screen.

M-Aegis is able to programmatically interact with various GUIs of a TCA using the function performAction(). This allows it t to click on a TCA's button on the user's behalf after it has processed the user input.

4.3 Layer 7.5

We implemented Layer 7.5 on Android as specific types of system windows, which are *always-on-top* of all other running apps. Android allows the creation of various types of system windows. We focus on two, TYPE_SYSTEM_OVERLAY and TYPE_SYSTEM_ERROR; the first is for display only and allows all tap/keyboard events to go to underlying apps. In contrast, the second type allows for user interaction. Android allows the use of any View objects for either type of window, and we use this to create our mimic GUIs, and set their size and location. We deliberately create our mimic GUIs in different colors as a subtle visual cue to the users that they are interacting with M-Aegis, without distracting them from their original workflow.

4.4 Per-TCA Logic

From our experience developing per-TCA logic, the general procedure for development is as follows:

1) Understand what the app does. This allows us to identify which GUIs need to be mimicked for intercepting user I/O. For text-based TCAs, this is a trivial step because the core functionalities that M-Aegis needs to handle are limited and thus easy to identify, e.g. buffering user's typed texts and sending them to the intended recipient.

2) Using UI Automator Viewer [17], examine the UIA tree for the relevant GUIs of a TCA and identify signatures (GUI resource IDs) for each TCA state. UI Automator Viewer allows inspection of the UIA tree through a graphical interface (as seen in Fig. 5), which reduces development time. We rely on UI components that are unique to certain states (e.g. the "send" button signifies that we are in the compose state).

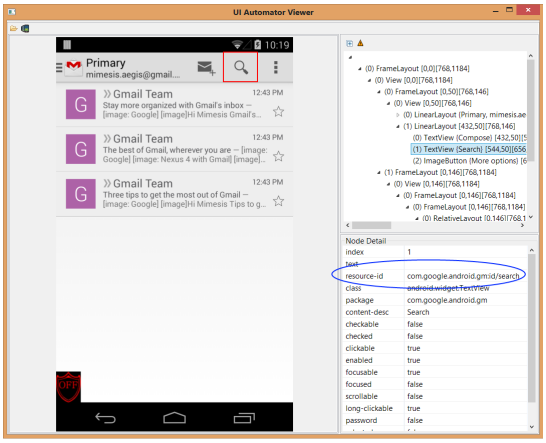

Figure 5: The UI Automator Viewer presents an easy to use interface to examine the UIA tree and determine the resource ID (blue ellipse) associated with a GUI of interest (red rectangle).

3) For each relevant GUI, we need to devise algorithms to extract either the location and content of ciphertext (for decryption and display), or the type, size, and location of GUIs we need to mimic (e.g. the subject and content boxes in the Gmail compose UI). Again, this is done through UI Automator Viewer. For example, for the Gmail preview state, we query the UIA for nodes with ID com.google.android.gm:/id/conversation_list to identify all the UIA nodes corresponding to the preview item of each individual email, and from those we can extract all ciphertext on the preview window through the UIA).

4) Create event handlers for controls we mimic on L-7.5. For the Gmail compose state, we need to listen for click/touch events for the L-7.5 "send" button and carry out the process described in Sect. 3.3.3 to encrypt the email and send the ciphertext to the underlying TCA.

5) Identify ways that each relevant state can be updated. Updates can be handled via the following method: clear L-7.5, extract all necessary information from the new state, and render again. This is equivalent to redrawing all GUIs on L-7.5 based on the detected state.

There are two details worth considering when developing per-TCA logic. First, careful consideration must be given about the type of input data fed to TCAs. Since most TCAs only accept input data in specific formats, e.g. text, they do not support the input of random byte sequences as valid data. Therefore, encrypted data must

be encoded into text format before feeding it as input to a TCA. Conventionally, base64 encoding is used for this purpose. However, base64 encoding consumes too much on-screen real estate. To overcome this, we encoded the binary encrypted data into Chinese Japanese Korean (CJK) Unicode characters, which have efficient on-screen real estate consumption. To map the binary data into the CJK plane, we process the encrypted data at the byte granularity (2^8). For each byte, its value is added to the base of the CJK Unicode representation, i.e. 0x4E00. For example, byte 0x00 will be encoded as '一', and byte 0x01 will be represented as '丁'.

Second, M-Aegis can only function correctly if it can differentiate between ordinary messages and encrypted messages. We introduce markers into the encrypted data after encoding; in particular, we wrap the subject and content of a message using a pair of curly braces (i.e. {, }).

Next, we describe implementation details that are specific to these classes of apps. We begin by introducing the format of message we created for each class. Then we discuss other caveats (if any) that are involved in the implementation.

4.4.1 Email Apps

We implemented support for Gmail on our prototype as a representative app of this category. We create two custom formats to communicate the necessary metadata to support M-Aegis' functionalities.
Subject: $\{Encode(ID_{Key}||IV||Encrypt(Subject))\}$
Content: $\{Encode(Encrypt(Content)||Tags)\}$

A particular challenge we faced in supporting decryption during the Gmail preview state is that only the beginning parts of both the title and the subject of each message are available to us. Also, the exact email addresses of the sender and recipients are not always available, as some are displayed as aliases, and some are hidden due to lack of space. The lack of such information makes it impossible to automatically decrypt the message even if the corresponding encryption key actually exists on the system.

To solve these problems, when we encrypt a message, we include a key-ID (ID_{Key}) to the subject field (as seen in the format description above). Note that since the key-ID is not a secret, it need not be encrypted. This way, we will have all the information we need to correctly decrypt the subtext displayed on the Gmail preview.

The *Tags* field is a collection of HMAC digests that are computed using the conversation key and keywords that exist in a particular email. It is then encoded and appended as part of the content that Gmail receives to facilitate encrypted search without requiring modification to Gmail's servers.

4.4.2 Messenger Apps

We implemented support for WhatsApp on our prototype as a representative app of this category. The format we created for this class of apps is simple, as seen below:
Message: $\{Encode(IV||Encrypt(Message))\}$

We did not experience additional challenges when supporting WhatsApp.

5 Evaluations

In this section, we report the results of experiments to determine the correctness of our prototype implementation, measure the overheads of M-Aegis, and user acceptability of our approach.

5.1 Correctness of Implementation

We manually verified M-Aegis's correctness by navigating through different states of the app and checking if M-Aegis creates L-7.5 correctly. We manually verified that the encryption and decryption operations of M-Aegis work correctly. We ensured that plaintext is properly received at the recipient's end when the correct password is supplied. We manually verified the correctness of our searchable encryption scheme by introducing specific search keywords. We performed search using M-Aegis and found no false negatives in the search result.

5.2 Performance on Android

The overhead that M-Aegis introduced to a user's workflow can be broken down into two factors: the additional computational costs incurred during encryption and decryption of data, and the additional I/O operations when redrawing L-7.5. We measure overhead by measuring the overall latency presented to the user in various use cases. We found that M-Aegis imposes negligible latency to the user.

All test cases were performed on a *stock* Android phone (LG Nexus 4), with the following specifications: Quad-core 1.5 GHz Snapdragon S4 Pro CPU, equipped with 2.0 GB RAM, running Android Kit Kat (4.4.2, API level 19). Unless otherwise stated, each experiment is repeated 10 times and the averaged result is reported.

For our evaluation, we only performed experiments for the setup of the Gmail app because Gmail is representative of a more sophisticated TCA, and thus indicates worst-case performance for M-Aegis. Messenger apps incur fewer overheads given their simpler TCA logic.

5.2.1 Previewing Encrypted Email

There are additional costs involved in previewing encrypted emails on the main page of Gmail. The costs are

broken down into times taken to 1) traverse the UIA tree to identify preview nodes, 2) capture ciphertext from the UIA node, 3) obtain the associated encryption key from the key manager, 4) decrypting ciphertext, and 5) rendering plaintext on L-7.5. We measure these operations as a single entity by running a macro benchmark.

For our experiment, we ensured that the preview page consists of encrypted emails (a total of 6 can fit on-screen) to demonstrate worst-case performance. We measured the time taken to perform all operations. We found, on average, it takes an additional 76 ms to render plaintext on L-7.5. Note that this latency is well within expected response time (50 - 150 ms), beyond which a user would notice the slowdown effect [60].

5.2.2 Composing and Sending Encrypted Email

We measured the extra time taken for a typical email to be encrypted and for our searchable encryption index to be built. We used the Enron Email Dataset [32] as a representation of typical emails. We randomly picked 10 emails. The average number of words in an email is 331, of which 153 are unique. The shortest sampled email contained 36 words, of which 35 are unique. The longest sampled email contains 953 words, of which 362 are unique.

With the longest sampled email, M-Aegis took 205 ms in total to both encrypt and build the search index. Note that this includes the network latency a user will perceive while sending an email, regardless of their use of M-Aegis.

5.2.3 Searching on Encrypted Emails

A user usually inputs one to three keywords per search operation. The latency experienced when performing search is negligible. This is because the transformation of the actual keyword into indexes requires only the forward computation of one HMAC, which is nearly instantaneous.

5.3 User Acceptability Study

This section describes the user study we performed to validate our hypothesis of user acceptability of M-Aegis. Users were sampled from a population of college students. They must be able to proficiently operate smart phones and have had previous experience using the Gmail app. Each experiment was conducted with two identical smart phones, i.e. Nexus 4, both running Android 4.3, installed with the stock Gmail app (v. 4.6). One of the devices had M-Aegis installed.

The set up of the experiment is as follows. We asked the user to perform a list of tasks: previewing, reading, composing, sending, and searching through email on a device that is not equipped with M-Aegis. Participants were asked to pay attention to the overall experience of performing such tasks using the Gmail app. This served as the control experiment.

Participants were then told to repeat the same set of tasks on another device that was equipped with M-Aegis. This was done with the intention that they were able to mentally compare the difference in user experience when interacting with the two devices.

We queried the participants if they found any difference in the preview page, reading, sending, and searching email, and if they felt that their overall experience using the Gmail app on the second device was significantly different.

We debriefed the participants about the experiment process and explained the goal of M-Aegis. We asked them whether they would use M-Aegis to protect the privacy of their data. The results we collected and report here are from 15 participants.

We found that no participants noticed major differences between the two experiences using the Gmail app. One participant noticed a minor difference in the email preview interface, i.e. L-7.5 did not catch up smoothly when scrolled. A different participant noticed a minor difference in the process of reading email, i.e. L-7.5 lag before covering ciphertext with mimic GUIs. There were only two participants that found the process of sending email differed from the original. When asked for details, they indicated that the cursor when composing email was not working properly. After further investigation, we determined this was a bug in Android's GUI framework rather than a fundamental flaw in M-Aegis's design.

Despite the perceived minor differences when performing particular tasks, all participants indicated that they would use M-Aegis to protect the privacy of their data after understanding what M-Aegis is. This implies that they believe that the overall disturbance to the user experience is not large enough to impede adoption.

Since we recruited 15 users for this study, the accuracy/quality of our conclusion from this study lies between 80% and 95% (between 10 and 20 users) according to findings in [42]. We intend to continue our user study to further validate our acceptability hypothesis and to continuously improve our prototype based on received feedback.

6 Discussions

6.1 Generality and Scalability

We believe that our M-Aegis architecture presents a general solution that protects user data confidentiality, which is scalable in the following aspects:

Across Multiple Cloud Services. There are two main classes of apps that provide communication services, email and messenger apps. By providing functionality for apps in these two categories, we argue that M-Aegis can satisfy a large portion of user mobile security needs. The different components of M-Aegis incur a one-time development cost. We argue that it is easy to scale across multiple cloud services, because per-TCA logic that needs to be written is minimal per new TCA. This should be evident through the five general steps highlighted in Sect. 4.4. In addition, the logic we developed for the first TCA (Gmail) serves as a template/example to implement support for other apps.

Across App Updates. Since the robustness of the UIAM construct (Sect. 4.2) gives M-Aegis the ability to track all TCA GUIs regardless of TCA state, M-Aegis is able to easily survive app updates. Our Gmail app support has survived two updates without requiring major efforts to adapt.

Resource ID names can change across updates. For example, when upgrading to Gmail app version 4.7.2, the resource ID name that identifies a sender's account name changed. Using UI Automator Viewer, we quickly discovered and modified the mapping in our TCA logic. Note that only the mapping was changed; the logic for the TCA does not need to be modified. This is because the core functionality of the updated GUI did not change (i.e., the GUI associated with a sender's account remained a text input box).

6.2 Limitations

As mentioned earlier, M-Aegis is not designed to protect users against social-engineering-based attacks. Adversaries can trick users into entering sensitive information to the TCA while M-Aegis is turned off. Our solution is best effort by providing distinguishing visual cues to the user when M-Aegis is turned on and its L-7.5 is active. For example the mimic GUIs that M-Aegis creates a different color. Users can toggle M-Aegis' button on or off to see the difference (see Fig. 2). Note that M-Aegis's main button is always on top and cannot be drawn over by other apps. However, we do not claim that this fully mitigates the problem.

One of the constraints we faced while retrofitting a security solution to existing TCAs (not limited to mobile environments) is that data must usually be of the right format (e.g. strictly text, image, audio, or video). For example, Gmail accepts only text (Unicode-compatible) for an email subject, but Dropbox accepts any type of files, including random blobs of bytes. Currently, other than text format, we do not yet support other types of user data (e.g. image, audio and video). However, this is *not* a fundamental design limitation of our system. Rather, it is because of the unavailability of transformation functions (encryption and encoding schemes) that works for the these media types.

Unlike text, the transformation/obfuscation functions in M-Aegis for other type of data may also need to survive other process steps, such as compression. It is normal for TCAs to perform compression on multimedia to conserve bandwidth and/or storage. For example, Facebook is known to compress/downsample the image uploads.

The confidentiality guarantee that we provide excludes risks at the end points themselves. For example, a poor random number generator can potentially weaken the cryptographic schemes M-Aegis applies. It is currently unclear how our text transformations will affect a server's effectiveness in performing spam filtering.

Our system currently does not tolerate typographical error during search. However, we would like to point out that this is an unlikely scenario, given that soft keyboards on mobile devices utilize spell check and autocorrect features. Again, this is not a flaw with our architecture; rather, it is because of the unavailability of encryption schemes that tolerate typographical error search without requiring server modification.

7 Conclusions

In this paper we presented *Mimesis Aegis (M-Aegis)*, a new approach to protect private user data in public cloud services. M-Aegis provides strong isolation and preserves user experience through the creation of a novel conceptual layer called *Layer 7.5 (L-7.5)*, which acts as a proxy between an app (Layer 7) and a user (Layer 8). This approach allows M-Aegis to implement true end-to-end encryption of user data while achieving three goals: 1) plaintext data is never visible to a client app, any intermediary entities, or the cloud provider; 2) the original user experience with the client app is preserved completely, from workflow to GUI look-and-feel; and 3) the architecture and technique are general to a large number of apps and resilient to app updates. We implemented a prototype of M-Aegis on Android that can support a number of popular cloud services (e.g. Gmail, Google Hangout, Facebook, WhatsApp, and Viber). Our user study shows that our system preserves both the workflow and the GUI look-and-feel of the protected applications, and our performance evaluations show that users experienced minimal overhead in utilizing M-Aegis on Android.

XRay: Enhancing the Web's Transparency with Differential Correlation

Mathias Lécuyer, Guillaume Ducoffe, Francis Lan, Andrei Papancea, Theofilos Petsios,
Riley Spahn, Augustin Chaintreau, *and* Roxana Geambasu
Columbia University

Abstract

Today's Web services – such as Google, Amazon, and Facebook – leverage user data for varied purposes, including personalizing recommendations, targeting advertisements, and adjusting prices. At present, users have little insight into how their data is being used. Hence, they cannot make informed choices about the services they choose.

To increase transparency, we developed *XRay*, the first fine-grained, robust, and scalable personal data tracking system for the Web. XRay predicts which data in an arbitrary Web account (such as emails, searches, or viewed products) is being used to target which outputs (such as ads, recommended products, or prices). XRay's core functions are service agnostic and easy to instantiate for new services, and they can track data within and across services. To make predictions independent of the audited service, XRay relies on the following insight: by comparing outputs from different accounts with similar, but not identical, subsets of data, one can pinpoint targeting through correlation. We show both theoretically, and through experiments on Gmail, Amazon, and YouTube, that XRay achieves high precision and recall by correlating data from a surprisingly small number of extra accounts.

1 Introduction

We live in a "big data" world. Staggering amounts of personal data – our as locations, search histories, emails, posts, and photos – are constantly collected and analyzed by Google, Amazon, Facebook, and a myriad of other Web services. This presents rich opportunities for marshaling big data to improve daily life and social well-being. For example, personal data improves the usability of applications by letting them predict and seamlessly adapt to future user needs and preferences. It improves business revenues by enabling effective product placement and targeted advertisements. Twitter data has been successfully applied to public health problems [36], crime prevention [44], and emergency response [22]. These beneficial uses have generated a big data frenzy, with Web services aggressively pursuing new ways to acquire and commercialize it.

Despite its innovative potential, the personal data frenzy has transformed the Web into an opaque and privacy-insensitive environment. Web services accumulate data, exploit it for varied and undisclosed purposes, retain it for extended periods of time, and possibly share it with others – *all without the data owner's knowledge or consent*. Who has what data, and for what purposes is it used? Are the uses in the data owners' best interests? Does the service adhere to its own privacy policy? How long is data used after its owner deletes it? Who shares data with whom?

At present, users lack answers to these questions, and investigators (such as FTC agents, journalists, or researchers) lack robust tools to track data in the ever-changing Web to provide the answers. Left unchecked, the exciting potential of big data threatens to become a breeding ground for data abuses, privacy vulnerabilities, and unfair or deceptive business practices. Examples of such practices have begun to surface. In a recent incident, Google was found to have used institutional emails from ad-free Google Apps for Education to target ads in users' personal accounts [18, 37]. MySpace was found to have violated its privacy policy by leaking personally identifiable information to advertisers [25]. Several consumer sites, such as Orbitz and Staples, were found to have adjusted their product pricing based on user location [29, 43]. And Facebook's 2010 ad targeting was shown to be vulnerable to micro-targeted ads specially crafted to reveal a user's private profile data [23].

To increase transparency and provide checks and balances on data abuse, we argue that new, robust, and versatile tools are needed to effectively track the use of personal data on the Web. Tracking data in a *controlled environment*, such as a modified operating system, language, or runtime, is an old problem with a well-known solution: taint tracking systems [12, 16, 7, 48]. However, is it possible to track data in an *uncontrolled environment*, such as the Web? Can robust, generic mechanisms assist in doing so? What kinds of data uses are trackable and what are not? How would the mechanisms scale with the amount of data being tracked?

As a first step toward answering these questions, we built *XRay*, a personal data tracking system for the Web.

XRay correlates designated data *inputs* (be they emails, searches, or visited products) with data *outputs* results (such as ads, recommended products, or prices). Its correlation mechanism is service agnostic and easy to instantiate, and it can track data use within and across services. For example, it lets a data owners track how their emails, Google+, and YouTube activities are used to target ads in Gmail.

At its core, XRay relies on a *differential correlation* mechanism that pinpoints targeting by comparing outputs in different accounts with similar, but not identical, subsets of data inputs. To do so, it associates with every personal account a number of *shadow accounts*, each of which contains different data subsets. The correlation mechanism uses a simple Bayesian model to compute and rank scores for every data input that may have triggered a specific output. Intuitively, if an ad were seen in many accounts that share a certain email, and never in accounts that lack that email, then the email is likely to be responsible for a characteristic that triggers the ad. The email's score for that ad would therefore be high. Conversely, if the ad were seen rarely in accounts with or lacking that email, that email's score for this ad would be low.

Constructing a practical auditing system around differential correlation raises significant challenges. Chief among them is scalability with the number of data items. Theoretically, XRay requires a shadow account for each combination of data inputs to accurately pinpoint correlation. That would suggest an *exponential number of accounts*! Upon closer examination, however, we find that a few realistic assumptions and novel mechanisms let XRay reach high precision and recall with only a *logarithmic number of accounts in number of data inputs*. We deem this a major new result for the science of tracking data-targeting on the Web.

We built an XRay prototype and used it to correlate Gmail ads, Amazon product recommendations, and YouTube video suggestions to user emails, wish lists, and previously watched videos, respectively. While Amazon and YouTube provide detailed explanations of their targeting, Gmail does not, so we manually validated associations. For all cases, XRay achieved 80-90% precision and recall. Moreover, we integrated our Gmail and YouTube prototypes so we could track cross-service ad targeting. Although several prior measurement studies [10, 47, 21, 20, 31] used methodologies akin to differential correlation, we believe we are the first to build a generic, service agnostic, and scalable tool based on it. Overall, we make the following contributions:

1. The first general, versatile, and open system to track arbitrary personal Web data use by uncontrolled services. The code is available from our Web page `https://xray.cs.columbia.edu/`.
2. The first in-depth exploration into the scalability challenges of tracking personal data on the Web.
3. The design and implementation of robust mechanisms to address scaling, including data matching.
4. System instantiation to track data on three services (Gmail, Amazon, YouTube) and across services (YouTube to Gmail).
5. An evaluation of our system's precision and recall on Gmail, Amazon, and YouTube. We show that XRay is accurate and scalable. Further, it reveals intriguing practices now in use by Web services and advertisers.

2 Motivation

This paper lays the algorithmic foundations for a new generation of scalable, robust, and versatile tools to lift the curtain on how personal data is being targeted. We underscore the need for such tools by describing potential usage scenarios inspired by real-life examples (§2.1). We do this not to point fingers at specific service providers; rather, we aim to show the many situations where transparency tools would be valuable for end-users and auditors alike. We conclude this section by briefly analyzing how current approaches fail to address these usage scenarios (§2.2).

2.1 Usage Scenarios

Scenario 1: Why This Ad? Ann often uses her Gmail ads to discover new retail offerings. Recently, she discussed her ad-clicking practices with her friend Tom, a computer security expert. Tom warned her about potential privacy implications of clicking on ads without knowing what data they target. For example, if she clicks on an ad targeting the keyword "gay" and then authenticates to purchase something from that vendor, she is unwittingly volunteering potentially sensitive information to the vendor. Tom tells Ann about two options to protect her privacy. She can either disable the ads altogether (using a system like AdBlock [1]), or install the XRay Gmail plugin to uncover targeting against her data. Unwilling to give up the convenience of ads, Ann chooses the latter. XRay clearly annotates the ads in the Gmail UI with their target email or combination, if any. Ann now inspects this targeting before clicking on an ad and avoids clicking if highly sensitive emails are being targeted.

Scenario 2: They're Targeting *What*? Bob, an FTC investigator, uses the XRay Gmail plugin for a different purpose: to study sensitive-data targeting practices by advertisers. He suspects a potentially unfair practice whereby companies use Google's ad network to collect sensitive information about their customers. Therefore, Bob creates a number of emails containing keywords such as "cancer," "AIDS," "bankruptcy," and "unemployment." He refreshes the Gmail page many times, each time recording the targeted ads and XRay's explanations

for them. The experiment reveals an interesting result: an online insurance company, TrustInUs.com, has targeted multiple ads against his illness-related emails. Bob hypothesizes that the company might use the data to set higher premiums for users reaching their site through a disease-targeted ad. He uses XRay results as initial evidence to open an investigation of TrustInUs.com.

Scenario 3: What's With The New Policy?[1] Carla, an investigative journalist, has set up a watcher on privacy policies for major Web services. When a change occurs, the watcher notifies her of the difference. Recently, an important sentence in Google's privacy policy has been scrapped:

> *If you are using Google Apps (free edition), email is scanned so we can display conceptually relevant advertising in some circumstances. ~~Note that there is no ad-related scanning or processing in Google Apps for Education or Business with ads disabled.~~*

To investigate scientifically whether this omission represents a shift in implemented policy, she obtains institutional accounts, connects them to personal accounts, and uses XRay to detect the correlation between emails in institutional accounts and ads in corresponding personal accounts. Finding a strong correlation, Carla writes an article to expose the policy change and its implications.

Scenario 4: Does Delete Mean Delete? Dan, a CS researcher, has seen the latest news that Snapchat, an ephemeral-image sharing Website, does not destroy users' images after the requested timeout but instead just unlinks them [41]. He wonders whether the reasons for this are purely technical as the company has declared (e.g., flash wearing levels, undelete support, spam filtering) [39, 38] or whether these photos, or metadata drawn from them, are mined to target ads or other products on the Website. The answer will influence his decision about whether to continue using the service. Dan instantiates XRay to track the correlation between his expired Snapchat photos and ads.

2.2 Alternative Approaches

The preceding scenarios illustrate the importance of transparency in protecting privacy across a range of use cases. *We need robust, generic auditing tools to track the use of personal data at fine granularity (e.g., individual emails, photos) within and across arbitrary Web services.* At present, no such tools exist, and the science of tracking the use of personal Web data at a fine grain is largely non-existent.

[1] In Feb. 2014, it was revealed based on court documents that Google could have used institutional emails to target ads in personal accounts [18]. In May 2014, Google committed to disable that feature [30]. Scenario 3 presents an XRay-based approach to investigate the original allegation.

Existing approaches can be broadly classified in two categories: *protection tools*, which prevent Web services' acquisition or use of personal data, and (2) *auditing tools*, which uncover Web services' acquisition or use of personal data. We discuss these approaches next; further related work is in §9.

Protection Tools. A variety of protection tools exist [11, 35, 1, 49]. For example, Ann could disable ads using an ad blocker [1]. Alternatively, she could encrypt her emails, particularly the sensitive ones, to prevent Google from using them to target ads. Dan could use a self-destructing data system, such as Vanish [14], to ensure the ephemerality of his Snapchat photos.

While we encourage the use of protection tools, they impose difficult tradeoffs that make them inapplicable in many cases. If Ann blocks all her ads, she cannot benefit from those she might find useful; if she encrypts all of her emails, she cannot search them; if she encrypts only her sensitive emails, she cannot protect any sensitive emails she neglected to encrypt in advance. Similarly, if Dan encrypts his Snapchat photos, sharing them becomes more difficult. While more sophisticated protection systems address certain limitations (e.g., searchable [5], homomorphic [15, 33], and attribute-based encryption [19], or privacy-preserving advertising [42, 13]), they are generally heavyweight [15], difficult to use [45], or require major service-side changes [15, 42, 13].

Auditing Tools. Given the limitations of protection tools, transparency is gaining increased attention [47, 12, 21]. If protecting data proves too cumbersome, limiting, or unsupportive of business needs, then users should at least be able to know: (1) *who is handling their data?*, and (2) *what is it being used for?*

Several tools developed in recent years partially address the first question by revealing where personal data flows from a local device [34, 12, 8]. TaintDroid [12] uses taint tracking to detect leakage of personal data from a mobile application to a service or third-party backend. ShareMeNot [34] and Mozilla's Lightbeam Firefox add-on [27] identify third parties that are observing user activities across the Web. These systems track personal data – such as location, sensor data, Web searches, or visited sites – *until it leaves the user's device*. Once the data is uploaded to Web services, it can be used or sold without a trace. In contrast, XRay's tracking just begins: we aim to tell users how services use their data *once they have it*.

Several new tools and personalization measurement studies partially address the second question: what data is being used for [10, 47, 21, 20, 31]. In general, all existing tools are highly specialized, focusing on specific input types, outputs, or services. No general, principled foundation for data use auditing exists, that can be applied effectively to many services, a primary

motivation for this our work. For example, Bobble [47] reveals search result personalization based on user location (e.g., IP) and search history. Moreover, existing tools aim to discover only *whether* certain types of user inputs – such as search history, browsing history, IP, etc. – influence the output. None pinpoints at fine grain *which* specific input – which search query, which visited site, or which viewed product – or combination of inputs explain which output. XRay, whose goals we describe next, aims to do just that.

3 Goals and Models

Our overarching goal is to develop the core abstractions and mechanisms for tracking data within and across arbitrary Web sites. After describing specific goals (§3.1), we narrow our scope with a set of simplifying assumptions regarding the data uses that XRay is designed to audit (§3.2) and the threats it addresses (§3.3).

3.1 Goals

Three specific goals have guided XRay's design:

Goal 1: *Fine-Grained and Accurate Data Tracking.* Detect which specific data inputs (e.g., emails) have likely triggered a particular output (e.g., an ad). While coarse-grained data use information (such as Gmail's typical statement, "This ad is based on emails from your mailbox.") may suffice at times, knowing the specifics can be revelatory, particularly when the input is highly sensitive and aggressively targeted.

Goal 2: *Scalability.* Make it practical to track significant amounts of data (e.g., past month's emails). We aim to support the tracking of hundreds of inputs with reasonable costs in terms of shadow accounts. These accounts are generally scarce resource since their creation is being constrained by Web services. While we assume that users and auditors can obtain *some* accounts on the Web services they audit (e.g., a couple dozen), we strive to minimize the number required for accurate and fine-grained data tracking.

Goal 3: *Extensibility, Generality, and Self-Tuning.* Make XRay generic and easy to instantiate for many services and input/output types. Instantiating XRay to track data on new sites should be simple, although it may require some service-specific implementation of input/output monitoring. However, XRay's correlation machinery – the conceptually challenging part of a scalable auditing tool – should be turn key and require no manual tuning.

3.2 Web Service Model

These goals may appear unsurmountable. An extremely heterogeneous environment, the Web has perhaps as many data uses as services. Moreover, data mining algorithms can be complex and proprietary. How can we abstract away this diversity and complexity to design robust and generic building blocks for scalable data tracking? Fortunately, we find that certain popular classes of Web data uses lend themselves to principled abstractions that facilitate scalable tracking.

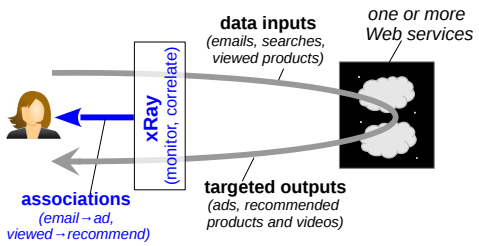

Figure 1: **XRay Conceptual View.** XRay views Web services as black boxes, monitors user *inputs* and *outputs* to/from them, and detects data use through correlation. It returns to the user or auditor *associations* of specific inputs and outputs.

Figure 1 shows XRay's simplified view of Web services. Services, and networks of services that exchange user data, are *black boxes* that receive personal data *inputs* from users – such as emails, pictures, search queries, locations, or purchases – and use them for varied purposes. Some uses materialize into *outputs* visible to users, such as ads, product or video recommendations, or prices. Others invisible to the users. XRay correlates some visible data inputs with some visible outputs by monitoring them, correlating them, and reporting strong *associations* to users. An example association is which email(s) contributed to the selection of a particular ad.

XRay relates only *strongly correlated* inputs with outputs. If an output is strongly correlated to an input (i.e., the input's presence or absence changes the output), then XRay will likely be able to detect its use. If not (i.e., the monitored input plays but a small role in the output), then it may go undetected. XRay also relates small combinations of inputs with strongly correlated outputs.

Although simple, this model efficiently addresses several types of personal data functions, including product recommendations, price discriminations, and various personalization functions (e.g., search, news). We refer to such functions generically as *targeting functions* and focus XRay's design on them.

Three popular forms of targeting are:

1. *Profile Targeting*, which leverages static or slowly evolving explicit information – such as age, gender, race, or location – that the user often supplies by filling a form. This type of targeting has been studied profusely [10, 47, 21, 20, 31]; we thus ignore it here.
2. *Contextual Targeting*, which leverages the content currently being displayed. In Gmail, this is the currently open email next to which the ad is shown. In Amazon or Youtube, the target is the product or video next to which the recommendation is shown.
3. *Behavioral Targeting*, which leverages a user's past actions. An email sent or received today can trigger an ad tomorrow; a video watched now can trig-

ger a recommendation later. Use of histories makes it harder for users to track which data is being used, a key motivation for our development of XRay.

Theoretically, our differential correlation algorithms could be applied to all three forms of targeting. From a systems perspective, XRay's design is geared towards *contextual targeting* and *a specific form of behavioral targeting*. The latter requires further attention. We observe that this broad targeting class subsumes multiple types of targeting that operate at different granularities. For example, a service could use as inputs a user's most recent few emails to decide targeting. This would be similar to an extended context. Alternatively, a service could use historical input to learn a user's coarse interests or characteristics and base its targeting on that.

XRay currently aims to disclose any targeting applied at the level of individual user data, or small combinations thereof. Our differential correlation algorithms could be applied to detect targeting that operates on a coarser granularity. However, the XRay system itself would require significant changes. Unless otherwise noted, we use *behavioral targeting* to denote the restricted form of behavioral targeting that XRay is designed to address. We formalize these restrictions in §4.2.

3.3 Threat Model

To further narrow our problem's scope, we introduce threat assumptions. We assume that data owners (users and auditors) are trusted and do not attempt to leverage XRay to harm Web services or the Web ecosystem. While they trust Web services with their data, they wish to better understand how that data is being used. Data owners are thus assumed to upload the data in clear text to the Web services.

The threat models relevant for Web services depend on the use case. For example, Scenarios 1 and 2 in §2.1 assume Google is trusted, but its users wish to understand more about how advertisers target them through its ad platform. In contrast, in Scenarios 3 and 4, investigators may have reason to believe that Web services might intentionally frustrate auditing.

This paper assumes an *honest-but-curious* model for Web services: they try to use private data for financial or functional gains, but they do not try to frustrate our auditing mechanism, e.g., by identifying and disabling shadow accounts. The service might attempt to defend itself against more general types of attacks, such as spammers or DDoS attacks. For example, many Web services constrain the creation of accounts so as to limit spamming and false clicks. Similarly, Web services may rate limit or block the IPs of aggressive data collectors. XRay must be robust to such inherent defenses. We discuss challenges and potential approaches for stronger adversarial models in §7.

4 The XRay Architecture

XRay's design addresses the preceding goals and assumptions. For concreteness, we draw examples from our three XRay instantiations: tracking email-to-ad targeting association within Gmail, attributing recommended videos to those already seen on YouTube, and identifying products in a wish list that generate a recommendation on Amazon.

4.1 Architectural Overview

XRay's high-level architecture (Figure 2) consists of three components: (1) a *Browser Plugin*, which intercepts tracked inputs and outputs to/from an audited Web service and gives users visual feedback about any input/output associations, (2) a *Shadow Account Manager*, which populates shadow accounts with inputs from the plugin and collects outputs (e.g., ads) for each shadow account, and (3) the *Correlation Engine*, XRay's core, which infers associations and provides them to the plugin for visualization. While the Browser Plugin and Shadow Account Manager are *service specific*, the Correlation Engine, which encapsulates the science of Web-data tracking, is *service agnostic*. After we describe each component, we focus on the design of the Correlation Engine.

Browser Plugin. The Browser Plugin intercepts designated inputs and outputs (i.e., *tracked inputs/outputs*) by recognizing specific DOM elements in an audited service's Web pages. Other inputs and outputs may not be tracked by XRay (i.e., *untracked inputs/outputs*). The decision of what to track belongs to an investigator or developer who instantiates XRay to work on a specific service. For example, we configure the XRay Gmail Plugin to monitor a user's emails as inputs and ads as outputs. When the Plugin gets a new tracked input (e.g., a new email), it forwards it both to the service and to the Shadow Account Manager. When the Plugin gets a new tracked output (e.g., an ad), it queries the Correlation Engine for associations with the user's tracked inputs (message `get_assoc`).

Shadow Account Manager. This component: (1) populates the shadow accounts with subsets of a user account's tracked inputs (denoted D_i), and (2) periodically retrieves outputs (denoted O_k) from the audited service for each shadow account. Both functions are service specific. For Gmail, they send emails with SMTP and call the ad API. For YouTube, they stream a video and scrape recommendations, and for Amazon, they place products in wish lists and scrape recommendations. The complexity of these tasks depends on the availability of APIs or the stability of a service's page formats. Outputs collected from the Web service are placed into a *Correlation Database* (DB), which maps shadow accounts to their input sets and output observations. Figure 2 shows a par-

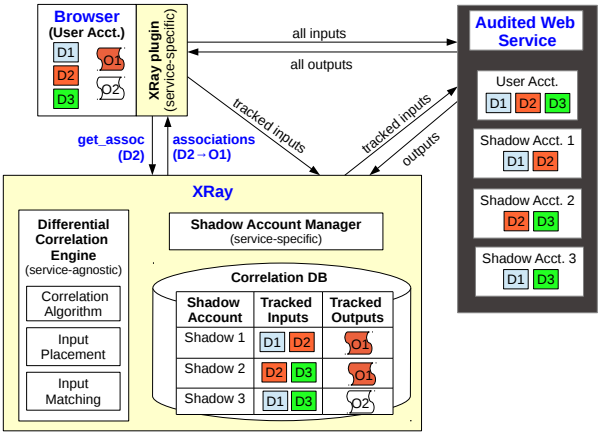

Figure 2: **The XRay Architecture.**

ticular assignment of tracked inputs across three shadow accounts. For example, Shadow 1 has inputs D_1 and D_2. The figure also shows the outputs collected for each shadow account. Output O_1 appears in Shadows 1 and 2 but not in 3; output O_2 appears in Shadow 3 only.

Differential Correlation Engine. This engine, XRay's service-agnostic "brain," leverages the data collected in the Correlation DB to infer input/output associations. When new outputs from shadow accounts are added into the Correlation DB, the engine attempts to diagnose them using a *Correlation Algorithm*. We developed several such algorithms and describe them in §4.3. This process, potentially time-consuming process, is done as a background job, asynchronously from any user request. In Figure 2, differential correlation might conclude that D_2 triggers O_1 because O_1 appears consistently in accounts with that D_2. It might also conclude that O_2 is *untargeted* given inconsistent observations. The engine saves these associations in the Correlation DB.

When the plugin makes a `get_assoc` request, the Correlation Engine looks up the specified output in its DB and returns any pre-computed association. If no output is found, then the engine replies *unknown* (e.g., if an ad never appeared in any shadow account or there is insufficient information). Periodic data collection, coupled with an online update of correlation model parameters, minimizes the number of unknown associations. Our experience shows that collecting shadow account outputs in Gmail every ten hours or so yielded few unknown ads.

While the preceding example is simple, XRay can handle complex challenges occurring in practice. First, outputs are never consistently seen across all shadow accounts containing the input they target. We call this the *limited-coverage* problem; XRay handles it by placing each data input in more shadow accounts. Second, an output may have been triggered by one of several targeted inputs (e.g., multiple emails on the same topic may cause related ads to appear), a problem we refer to as *overlapping-inputs*. This exacerbates the number of accounts needed, since it diminishes the differential signal we receive from them. XRay uses robust, service-agnostic mechanisms and algorithms to match overlapping inputs, place them in the same accounts, and detects their use as a group.

Organization. The remainder of this section describes the Differential Correlation Engine. After constructing it for Gmail, we applied it as-is for Amazon and YouTube, where it achieved equally high accuracy and scalability despite observable differences in how targeting works on these three services. After establishing notations and formalizing our assumptions (§4.2), we describe multiple correlation algorithms, which build up to our self-tuning correlation algorithm that made this adaptation convenient (§4.3). §4.4 describes our input matching.

4.2 Notation and Assumptions

We use f to denote the black-box function that represents the service (e.g., Gmail) associating inputs D_is (e.g., the emails received and sent) to targeted outputs O_ks (e.g., ads). Other inputs are either ignored by XRay, known only to the targeting system, or under no known control. We assume they are independent or fixed, captured in the randomness of f.

We assume that f decides targeting using: (1) a single input (e.g., show O_k if D_4 is in the account), (2) a conjunctive combination of inputs (e.g., show O_k if D_5 *and* D_8 are in the account), or (3) a disjunctive combination of the previous (e.g., show O_k if (D_5 *and* D_8) are in the account *or* if D_4 is in the account). We refer to conjunctive and disjunctive combinations as AND and OR combinations, respectively, and assume that their is bounded by a maximum *input size*, r. This corresponds to the preceding definition of behavioral targeting from §3.2. Contextual targeting will always be a single-input (size-one) combination.

Our goal is to decide whether f produced each output O_k as a reaction to a bounded-size combination of the D_is. We define as *untargeted* any ad that is not targeted against any combination of D_is, though in reality the ad could be targeted against untracked inputs. We denote untargeting as $D_\emptyset$, meaning that the ad is targeted against the "void" email. Our algorithms compute the most likely combination from the N inputs that explains a particular set of observations, $\vec{x}$, obtained by XRay.

We define three probabilities upon which our algorithms and analyses depend. First, the *coverage*, p_{in}, is the probability that an account j containing the input D_i targeted by a particular ad, will see that ad at least once. Second, an account j' lacking input D_i will see the ad with a smaller probability, p_{out}. Third, if the ad is not behaviorally targeted, it will appear in each account with the same probability, $p_\emptyset$. We assume that $p_{\text{in}}, p_\emptyset, p_{\text{out}}$ are

constant across all emails, ads, and time, and that p_{out} is strictly smaller than p_{in} (bounded noise hypothesis).

Finally, we consider all outputs to be independent of each other across time. §8 discusses the implications.

4.3 Correlation Algorithms

A core contribution of this paper is our service-agnostic, self-tuning differential correlation algorithm, which requires only a logarithmic number of shadow accounts to achieve high accuracy. We wished not only to validate this result experimentally, but also to prove it theoretically in the context of our assumptions. This section constructs the algorithm in steps, starting with a naïve polynomial algorithm that illustrates the scaling challenges. We then define a base algorithm using set intersections and prove that it has the desired logarithmic scaling properties; it has parameters which, if not carefully chosen, can lead to poor results. We therefore extend this base algorithm into a self-tuning Bayesian model that automatically adjusts its parameters to maximize correctness.

4.3.1 Naïve Non-Logarithmic Algorithm

An intuitive approach to differential correlation is to create accounts for every combination of inputs, gathering maximum information about their behaviors. With a sufficient number of observations, one could expect to detect which accounts, and hence which subsets of inputs, target a particular ad. Unfortunately, this method requires a number of accounts that grows *exponentially* as the number of items N to track grows. When restricting the size of combinations to r, as we do in XRay, the number of accounts needed is *polynomial* (in $O(N^r)$), or *linear* if we study unique inputs only. Even a linear number of accounts in the number N of inputs remains impractical to scale to large input sizes (e.g., a mailbox).

4.3.2 Threshold Set Intersection

We now show that it is possible to infer behavioral targeting using no more than a *logarithmic* number of accounts as a function of the number of inputs. Specifically, we prove the following theorem:

Theorem 1 *Under §4.2 assumptions, for any $\varepsilon > 0$ there exists an algorithm that requires $C \times \ln(N)$ accounts to correctly identify the inputs of a targeted ad with probability $(1-\varepsilon)$. The constant C depends on ε and the maximum size of combinations r ($O(r2^r \log(\frac{1}{\varepsilon}))$).*

To demonstrate the theorem, we define the *Set Intersection Algorithm* and prove that it has the correctness and scaling properties specified in the theorem. Given that outputs will appear more often in accounts containing the targeting inputs, the core of the algorithm is to determine the set of inputs appearing in the highest number of accounts that also see a given ad. This paper describes a basic version of the algorithm that makes some simplifying assumptions and provides a brief proof sketch. The detailed proof and complete algorithm are described in our technical report [26].

```
// Set Intersection Algo:
// Runs with each collected ad.
In: Output O_k (e.g. an ad).
Params: MIN_ACTIVE_ACCTS, THRESHOLD.
Out: Targeted input combination.
// Step 1: Compute active accounts.
A_k = the accounts that see ad O_k.
if |A_k| < MIN_ACTIVE_ACCTS
    return ∅
end
// Step 2: Create input combination hypothesis.
targeted_set = ∅
foreach input D_i do
    if (number of A_k containing D_i) / |A_k| > THRESHOLD
        targeted_set += D_i
    end
end
// Step 3: Verify it is a real combination.
if (number of A_k containing entire targeted_set) / |A_k| < THRESHOLD
    return ∅
end
// targeted_set triggered the output.
return targeted_set
```

Figure 3: **The Set Intersection Algorithm.** Can be proven to predict targeting correctly under certain assumptions with a logarithmic number of accounts.

Algorithm. The algorithm relies on a randomized placement of inputs into shadow accounts, with some redundancy to cope with imperfect coverage. We thus pick a probability, $0 < \alpha < 1$, create $C\ln(N)$ shadow accounts, and place each input D_i randomly into each account with probability α. Figure 3 shows the Set Intersection algorithm for a set of observations, $\vec{x}$. Given an output O_k collected from the user account, we compute the set of *active accounts*, A_k, as those shadow accounts that have seen the output (Step 1). We then compute the set of inputs that appear in at least a threshold fraction of active accounts; this set is our candidate for the combination being targeted by the ad (Step 2). Finally, we check that the entire combination is in a threshold fraction of the active accounts (Step 3). Theoretically, we prove that there exists a threshold for which the algorithm is arbitrarily correct with the available $C\ln(N)$ accounts. Practically, this threshold must be tuned experimentally to achieve good accuracy on every service – a key reason for our Bayesian enhancement in §4.3.3.

Correctness Proof Sketch. The proof shows that if there were targeting, every non-targeting input would have a vanishingly small probability to be in a significant fraction of the active accounts. Let us call S the set of inputs

```
// Bayesian Prediction Alg:
// Runs with each collected ad.
In: Output O_k (e.g. an ad).
Out: Targeted input.
// Compute probabilities.
foreach input D_i do
  P[D_i|x] = bayes(P[x|D_i])
end
// Compute untargeted prob.
P[D_∅|x] = bayes(P[x|D_∅])
// Return event with max prob.
return D_i with max P[D_i|x]
```

```
// Parameter Learning Alg:
// Runs periodically.
// Initialize params (arbitrary).
p_in = .7, p_out = .01, p_∅ = .1
do
  foreach output O_k do
    Run Bayesian Prediction.
  end
  Update p_in, p_out, p_∅
    from predictions.
until p_in, p_out, p_∅ converge
end
```

Figure 4: **Bayesian Correlation.** Left: Bayesian prediction algorithm for behavioral targeting. Right: typical iterative inference process to learn parameters.

contained in a significant fraction of the active accounts. Without targeting, these inputs would be present in the accounts by mere chance. Since inputs are independently distributed into the accounts, we show that the probability of S not being empty decreases exponentially with the number of active accounts (through Chernoff bounds). With targeting, we show that with high probability no other input than the explaining combination is in S, because of the bounded noise hypothesis. Appendix A.2 provides further proof details.

The proofs and algorithm included in this paper work only for conjunctive combinations (e.g., D_1 and D_2, see §4.2). The theory, however, can be extended to disjunctive combinations (e.g., (D_1 and D_2) or D_5), but the algorithm for detecting such combinations is more complex and relies on a recursive argument: if we find one combination from the disjunction, then the active accounts that include this combination define a context where the combination appears non-targeting because it is everywhere. If we recursively apply our algorithm in this context, we can detect the second combination in the disjunction, then the third, etc (see technical report [26]).

4.3.3 Self-Tuning Bayesian Algorithm

The Set Intersection algorithm provides a good theoretical foundation; however, it requires parameters be tuned and applies only to behavioral targeting, not contextual targeting. Thus, we include in XRay a more robust, self-tuning version that leverages a Bayesian algorithm to adjust parameters automatically through iterated inference. Our algorithm relies on three models: one that predicts behavioral targeting, one that predicts contextual targeting, and one that combines the two.

Behavioral Targeting. The Bayesian behavioral targeting model uses the same random assignment as the Set Intersection algorithm, and it leverages the same information from the shadow account observations, $\vec{x}$. It counts the observations x_j of ad O_k in an account j as a binary signal: if the ad has appeared at least once in account j, we count it once; otherwise we do not count it. Briefly, the Bayesian model is a simple generative model that simulates the audited service given some targeting associations (e.g., D_i triggers O_k). It computes the probability for this model to generate the outputs we do observe for every targeting association. The most likely association will be the one XRay returns.

In more detail if the ad were targeted towards D_i, then an account j containing D_i would see this ad at least once with a *coverage* probability p_{in}; otherwise, it would miss it with probability $(1-p_{\text{in}})$. An account j' without input D_i would see the ad with a smaller probability, p_{out}, missing it with probability $(1-p_{\text{out}})$. If the ad were not behaviorally targeted, it would appear in each account with the same probability, $p_\emptyset$. If we define A_k as the set of active accounts that have seen the ad, and A_i as the set of accounts that contain email D_i, then we have the following definitions for the probabilities:

$$\begin{aligned}\mathbb{P}[\vec{x}|\, D_i] = &\quad (p_{\text{in}})^{|A_i\cap A_k|}(1-p_{\text{in}})^{|A_i\cap \bar{A}_k|}\\ &\times (p_{\text{out}})^{|\bar{A}_i\cap A_k|}(1-p_{\text{out}})^{|\bar{A}_i\cap \bar{A}_k|},\\ \mathbb{P}[\vec{x}|\, D_\emptyset] = &\quad (p_\emptyset)^{|A_k|}(1-p_\emptyset)^{|\bar{A}_k|},\end{aligned}$$

where $D_\emptyset$ designates the untargeted prediction.

The preceding formula has an interesting interpretation that is visible if placed in the equivalent form:

$$\begin{aligned}\mathbb{P}[\vec{x}|\, D_i] = &\quad (p_{\text{in}})^{|A_k|}(1-p_{\text{out}})^{|\bar{A}_k|}\\ &\times \left(\frac{1-p_{\text{in}}}{1-p_{\text{out}}}\right)^{|A_i\cap\bar{A}_k|}\left(\frac{p_{\text{out}}}{p_{\text{in}}}\right)^{|\bar{A}_i\cap A_k|}\end{aligned}$$

From the point of view of the event D_i, an account found in $A_i\cap\bar{A}_k$ is a false positive (an ad was expected but was not shown). This should lower the probability, especially when the *coverage* p_{in} is close to 1. Inversely, an account found in $\bar{A}_i\cap A_k$ acts as a false negative (we observed an ad where we did not expect it), which should decrease the probability, especially when p_{out} is close to 0.

These formulas let us infer the likelihood of event D_i according to Bayes' rule: $\mathbb{P}[A|\, B] = \frac{\mathbb{P}[B|A]\times\mathbb{P}[A]}{\mathbb{P}[B]}$. Figure 4 shows two algorithms. First, the prediction algorithm (left) predicts the targeting of O_k by computing the probabilities defined above, applying Bayes' rule, and returning the input with the maximum probability. Second, the parameter learning algorithm (right) computes the variables that those probabilities depend upon (p_{in}, p_{out}, and $p_\emptyset$) using an iterative process. It repeatedly runs the prediction algorithm for all outputs and re-computes p_{in}, p_{out}, and $p_\emptyset$ based on the predictions. It stops when the variables converge (i.e., their variation from one iteration to another is small).

Contextual Targeting. Contextual targeting is more straightforward since it uses content shown next to the ad. XRay also uses Bayesian inference and defines the observations as how many times ad O_k is seen next to

email D_i. Our causal model assumes imperfect coverage: if this ad were contextually targeted towards D_i, it would occur next to that email with probability $p_{\text{in}} < 1$ and next to any other email with probability p_{out}. Alternatively, if the ad were untargeted, our model predicts it would be shown next to any email with probability $p_{\emptyset}$. Hence, $\mathbb{P}[\vec{x}|D_i] = (p_{\text{in}})^{x_i}(p_{\text{out}})^{\sum_{i' \neq i} x'_i}, \mathbb{P}[\vec{x}|D_{\emptyset}] = (p_{\emptyset})^{\sum_i x_i}$. For this model, parameters are also automatically computed by iterated inference.

Composite Model (XRay). The contextual and behavioral mechanisms were designed to detect different types of targeting. To detect both types, XRay must combine the two scores. We experimented with multiple combination functions, including a decision tree and the arithmetic average, and concluded that the arithmetic average yields sufficiently good results. XRay thus defines the *composite model* that averages scores from individual models, and we demonstrate in §6.3 that doing so yields higher recall for no loss in precision.

4.4 Input Matching and Placement

Our design of differential correlation, along with our logarithmic results for random input placement, relies on the fundamental assumption that the probability of getting an ad O_1 targeted at an input D_1 in a shadow account that lacks D_1 is vanishingly small. However, when inputs attract the same ads (a.k.a., overlapping inputs), a naive input placement can contradict this assumption. Imagine a Gmail account with multiple emails related to a Caribbean trip. If placement includes Caribbean emails in every available shadow account, related ads will appear in groups of accounts with no email object in common. XRay will thus classify them as untargeted. Our Amazon experiments showed XRay's recall dropping from 97% to 30% with overlapping inputs (§6.5).

To address this problem, XRay's Input Matching module identifies similar inputs and directs the Placement Module to co-locate them in the same shadow accounts. The key challenge is to identify similar inputs. One method is to use content analysis (e.g., keywords matching), but this has limitations. First, it is not service agnostic; one needs to reverse engineer complex and ever-changing matching schemes. Second, it is hard to apply to non-textual media, such as YouTube videos.

In XRay, we opt for a more robust, systems technique rooted in the key insight that we can deduce similar inputs from contextual targeting. Intuitively, inputs that trigger similar targeting from the Web service should attract similar outputs in their context. The Input Matching module builds and compare inputs' *contextual signatures*. Contextual signature similarity is the distance between inputs (e.g., email) in a Euclidean space, where each output (e.g., ad) is a dimension. The coordinate of an email in this dimension is the number of times the ad was seen in the context of the email. XRay then forwards close inputs to the same shadow accounts. Once the placement is done, behavioral targeting against that email's group can be inferred effectively.

This input matching mechanism differs fundamentally from any content analysis technique, such as keyword matching, because it groups inputs *the same way the Web service does*.[2] It is robust and very general: we used it on both Gmail and Amazon without changing a single line of code to change.

5 XRay-based Tools

To evaluate XRay's extensibility, we instantiated it on Gmail, YouTube, and Amazon. The engine, about 3,000 lines of Ruby, was first developed for Gmail. We then extended it to YouTube and Amazon, without any changes to its correlation algorithms. We did need to do minor code re-structuring, but the experience felt turn key when integrating a new service into the correlation machinery.

Building the full toolset required non-trivial coding effort, however. Instantiating XRay for a specific Web service is a three-step process. First, the developer instantiates appropriate data models (less than 20 code lines for our prototypes). Second, she implements a service-specific shadow account manager and plugin; care must be taken not be too aggressive to avoid adversarial service reactions. While these implementations are conceptually simple, they require some coding; our Amazon and YouTube account managers were built by two graduate students new to the project, and have around 500 lines of code. Third, the developer creates a few shadow accounts for the audited service and runs a small exploratory experiment to determine the service's coverage. XRay uses the coverage to estimate the number of shadow accounts needed for a given input size. All other parameters are self-tuned at runtime.

6 Evaluation

We evaluated XRay with experiments on Gmail, Amazon, and YouTube. While Amazon and YouTube provide ground truth for their targeting, Gmail does not. We therefore manually labeled ads on Gmail and measured XRay's accuracy, as described in §6.1 and validated in §6.2. We sought answers to four questions:

Q1 How accurate are XRay's inference models? (§6.3)
Q2 How does XRay scale with input size? (§6.4)
Q3 Can input matching manage overlap? (§6.5)
Q4 How useful is XRay in practice? (§6.6)

[2] We call this method "monkey see, monkey do" because we watch how the service groups inputs and group them similarly.

Ad Keyword	Targeted Email	Detected by XRay?	XRay Scores	# Accounts & Displays
Chaldean Poetry	Like Chaldean Poetry?	Yes	0.99, 1.0	13/13, 1588/1622
Steampunk	Fan of Steampunk?	Yes	0.99, 1.0	13/13, 888/912
Cosplay	Discover Cosplay.	Yes	0.99, 1.0	13/13, 440/442
Falconry	Learn about Falconry.	Yes	0.99, 1.0	13/13, 1569/1608

Figure 5: **Self-Targeted Ads.** Fourth column shows XRay's correlation scores X, Y, (Bayesian) Behavioral and Contextual scores, respectively. Fifth column shows raw behavioral and contextual data for interpretation: X/Y, Z/T means that the ad was seen in X active accounts that contain the targeted email out of a total of Y active accounts; the ad was shown Z times in the context of the targeted email out of a total of T times.

6.1 Methodology

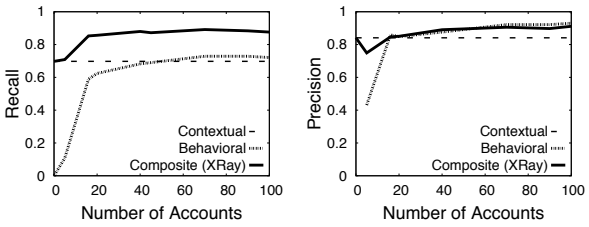
We evaluated XRay with experiments on Gmail, Amazon, and YouTube. For inputs, we created a workload for each service by selecting topics from well-defined categories relevant for that service. For Gmail and YouTube, we crafted emails and selected videos based on AdSense categories [17]; for Amazon, we selected products from its own product categories [2]. We used these categories for most of our experiments (§6.3–§6.5). We used these categories to create two types of workloads: (1) a non-overlapping workload, in which each data item belonged to a distinct category, and (2) an overlapping workload, with multiple data items per category (described in §6.5).

To assess XRay's accuracy, we needed the ground truth for associations. Amazon and YouTube provide it for their recommendations. For instance, Amazon provides a link "Why recommended?" which explicitly explains the recommendation. For Gmail, we manually labeled ads based on our personal assessment. The ads for different experiments were labeled by different people, generally project members. A non-computer scientist labeled the largest experiment (51 emails).

We evaluate two metrics: (1) *recall*, the fraction of positive associations labeled as such, and (2) *precision*, the fraction of correct associations. We define *high accuracy* as having both high recall and high precision.

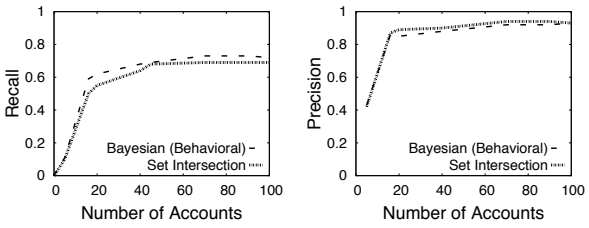
6.2 Sanity-Check Experiment

To build intuition into XRay's functioning, we ran a simple sanity-check experiment on Gmail. Recall that, unlike Amazon and YouTube, Gmail does not provide any ground truth, requiring us to manually label associations, a process that can be itself faulty. Before measuring XRay's accuracy against labeled associations, we checked that XRay can detect associations for our own ads, whose targeting we control. For this, we strayed away from the aforementioned methodology to create a highly controlled experiment. We posted four Google AdWords campaigns targeted on very specific keywords (Chaldean Poetry, Steampunk, Cosplay, and



(a) **Recall** (b) **Precision**

Figure 6: **Bayesian Model Accuracy.** Recall and precision for each of the three Bayesian models vs. shadow account number, using the Bayesian algorithm. XRay needed 16 accounts to reach the "knee" with high recall and precision.



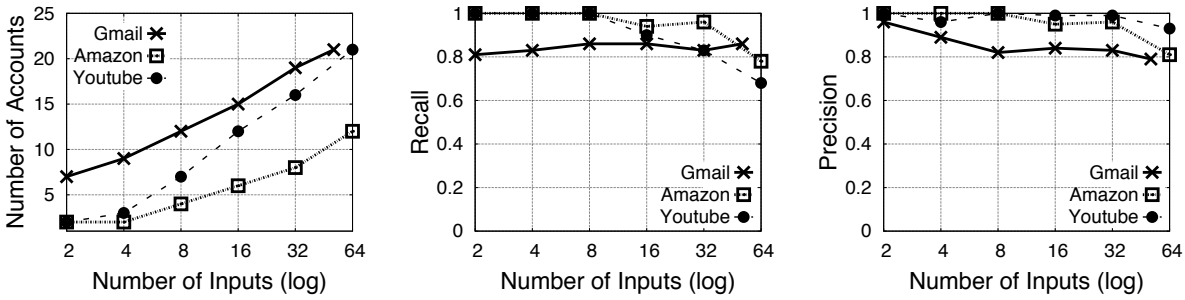
(a) **Recall** (b) **Precision**

Figure 7: **Bayesian vs. Set Intersection Comparison.** Recall and precision for detecting *behavioral* targeting with each algo.

Falconry), crafted an inbox that included one email per keyword, and used XRay to recover the associations between our ads and those emails. In total, we saw our ads 1622, 912, 442, and 1608 times, respectively, across all accounts (shadows and master). Figure 5 shows our results. After one round of ad collection (which involved 50 refreshes per email), XRay correctly associated all four ads with the targeted email. It did so with very high confidence: composite model scores were 0.99 in all cases, with very high scores for both contextual and behavioral models. The figure also shows some of the raw contextual/behavioral data, which provides intuition into XRay's perfect precision and recall in this controlled experiment. We next turn to evaluating XRay in less controlled environments, for which we use the workloads and labeling methodology described in §6.1.

6.3 Accuracy of XRay's Inference Models (Q1)

To assess the accuracy of XRay's key correlation mechanisms (Bayesian behavioral, contextual, and composite), we measured their recall and precision under non-overlapping workloads. Figures 6(a) and 6(b) show how these two metrics varied with the number of shadow accounts for a 20-email experiment on Gmail. The results indicate two effects. First, both contextual and behavioral models were required for high recall. Of the 193 distinct ads seen in the user account, 121 (62%) were targeted, and XRay found 109 (90%) of them, a recall we deem high. Of the associations XRay found, 37% were found by only one of the models: 15



(a) **Scalability with Input Size** (b) **Recall with Input Size** (c) **Precision with Input Size**

Figure 8: **Scalability.** (a) Number of accounts required to achieve the knee accuracy for varied numbers of inputs. (b), (c) Recall/precision achievable with the number of accounts in (a). Behavioral uses the Bayesian algorithm.

by the contextual model only, and 24 by the behavioral model only. Thus, both models were necessary, and composing them yielded high recall. Our Amazon and YouTube experiments (which provide ground truth) yielded very similar results: on a 20-input experiment, we reached over 90% recall and precision with only 8 and 12 accounts, respectively.

Second, the composite model's recall exhibited a knee-shaped curve for increasing shadow account numbers, with a rapid improvement at the beginning and slow growth thereafter. With 16 accounts, XRay exceeded 85% recall; increasing the number of accounts to 100 yielded a 1.9% improvement. Precision also remained high (over 84%) past 16 accounts. We define the *knee* as the minimum number of accounts needed to reap most of the achievable recall and precision.

We also wished to compare the accuracy of the Bayesian algorithm, which conveniently self-tunes its parameters, to the parameterized Set Intersection algorithm. We manually tuned the latter as best as we could. Figures 7(a) and 7(b) show the recall and precision for detecting behavioral targeting with the two methods for a non-overlapping workload. The two algorithms performed similarly, with the Bayesian staying within 5% of the manually tuned algorithm. We also tested the algorithms on an Amazon dataset, and using a version of the Set Intersection algorithm with empirical optimizations. The conclusion holds: the Bayesian algorithm, with self-tuned parameters, performs as well as the Set Intersection technique with manually tuned parameters. We focus the remainder of this evaluation on the Bayesian algorithm.

6.4 Scalability of XRay with Input Size (Q2)

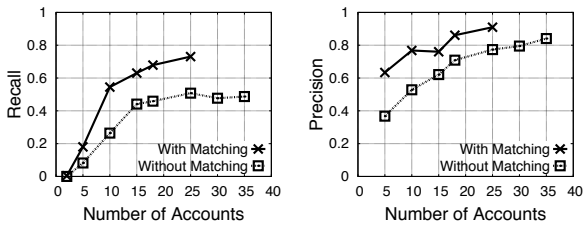
A main contribution of this paper is the realization that, under certain assumptions, the number of accounts needed to achieve high accuracy for XRay scales logarithmically with the number of tracked inputs. We have proven that under certain assumptions, the Set Intersection algorithm scales logarithmically. This theoretical result is hard to extend to the Bayesian algorithm, so we evaluated it experimentally by studying three metrics with growing input size: the number of accounts required to reach the recall knee and the value of recall/precision at this knee. Figures 8(a), 8(b) and 8(c) show the corresponding results for Gmail, YouTube and Amazon. For Gmail, the number of accounts necessary to reach the knee increased less than 3-fold (from 8 to 21) as input size increased more than 25-fold (from 2 to 51). For Amazon and YouTube, the increases in accounts were 6- and 8-fold respectively, for a 32-fold increase in input size. In general, the roughly linear shapes of the log-x-scale graphs in Figure 8(a) confirm the logarithmic increase in the number of accounts required to handle different inputs. Figure 8(b) and 8(c) confirm that the "knee number" of accounts achieved high recall and precision (over 80%).

What accounts for the large gap between the number of accounts needed for high accuracy in Gmail versus Amazon? For example, tracking a mere two emails in Gmail required 8 accounts, while tracking two viewed products in Amazon needed 2 accounts. The distinction corresponds to the difference in coverage exhibited by the two services. In Gmail, a targeted ad was typically seen in a smaller fraction of the relevant accounts compared to a recommended product in Amazon. XRay adapted its parameters to lower coverage automatically, but it needed more accounts to do so.

Overall, these results confirm that our theoretical scalability results hold for real-world systems given carefully crafted, non-overlapping input workloads. We next investigate how more realistic overlapping input workloads challenge the accuracy of our theoretical models and how input matching – a purely systems technique – helps address this challenge.

6.5 Input Matching Effectiveness (Q3)

To evaluate XRay's accuracy with overlapping inputs, we infused our workloads with multiple items from the same category. (e.g., multiple emails targeting the



(a) **Recall** (b) **Precision**

Figure 9: **Input Matching effectiveness.** Behavioral (Bayesian) recall and precision in Gmail with overlapping inputs, with and without Matching.

same topic on Gmail and multiple products in the same category in Amazon). For the Gmail experiments, we (as users) could not tell when Gmail targeted a specific email from a group of similar emails. We therefore ran two different types of experiments. First, a controlled, albeit unrealistic, one for Gmail. We replicated various emails *identically* in a user's inbox: 1 email was replicated 4 times, 2 emails 3 times, 4 emails 2 times, and 12 were single, for a total of 30 emails. This end-of-a-spectrum workload demonstrates how matching works ideally. XRay matched *all* redundant emails correctly. More importantly, Figures 9(a) and 9(b) show XRay's precision/recall with and without matching-aware placement for XRay's behavioral model, the only model improved by matching. Without input matching, XRay struggled to find differential signals: even with 35 shadow accounts for a 30-email experiment, recall was only 48%. With input matching, XRay's correlation model drew a stronger signal from each account and attained close to 70% recall for 16 accounts.

Second, for Amazon, we created a more realistic overlapping workload by selecting three *distinct* products in each of six product categories (e.g., from the Outdoor & Cycling category, we selected a helmet, pedals, and shoes). With a total workload of 18 products, XRay's input matching matched all but one item (shoes) into its correct group. With the new grouping, XRay's recall improved by a factor of 3 (from 30% to 93%) compared to the no-matching case for 18 products with 10 accounts; precision was 2.6 times higher (from 34% to 88%).

These results demonstrate that XRay's matching scheme is both portable across Web services and essential for high accuracy with overlapping workloads.

6.6 Anecdotal Use Experience (Q4)

To gain intuition into XRay's practical value, we ran a small-scale, anecdotal experiment that fished for Gmail ads targeted against a few specific topics. We created emails focused on topics such as cancer, Alzheimer, depression, HIV, race, homosexuality, pregnancy, divorce, and debt. Each email consisted of keywords closely related to one topic (e.g., the depression-related email included *depression*, *depressed*, and *sad*; the homosexuality email included *gay*, *homosexual*, and *lesbian*). We then launched XRay's Gmail ad collection and examined the targeting associations. We acknowledge that a much larger-scale experiment is needed to reach statistically-meaningful conclusions. Hence, we relate our experience by example.

Topic	Targeted Ads	XRay Scores	# Accounts & Displays
Alzheimer	Black Mold Allergy Symptoms? Expert to remove Black Mold.	0.99, 0.05	9/9, 61/198
	Adult Assisted Living. Affordable Assisted Living.	0.99, 0.99	8/8, 12/14

Figure 10: **Example of Targeted Ads.** Columns three and four show the same data as columns four and five in Figure 5.

Figure 10 shows ads that XRay associated with each topic, with its confidence scores. Conservatively, we only consider ads with high scores. We make two observations. First, our small-scale experiment confirms that it is possible to target sensitive topics in users' inboxes. All disease-related emails, except for the HIV one, are strongly correlated with a number of ads. A "Shamanic healing" ad appears exclusively in accounts containing the depression-related email, and many times in its context; ads for assisted living services target the Alzheimer email; and a Ford campaign to fight breast cancer targets the cancer email. Race, homosexuality, pregnancy, divorce, and debt also attract plenty of ads. For example, the pregnancy email is strongly targeted by an ad for baby-shower invitations (shown in the figure), maternity- and lactation-related ads (not shown), and, interestingly, a number of ads for general-purpose clothing

(shown). As another example, the debt email is strongly targeted by a car dealership ad that entices the targeted users to take a Toyota test drive using a $50 gift offering. Discussing the morality of targeting such sensitive topics is beyond our statute, however we believe that the lack of transparency, coupled with sensitive-topic targeting, opens users to subtle dangers, a topic we discuss next.

Second, for many ads, the association with the targeted email is not obvious at all. Nothing in the "Shamanic healing" ad suggests targeting against depression; nothing in the general-purpose clothing ads suggest targeting against pregnancy; and nothing in the "Cedars hotel" ad suggests an orientation toward the homosexuality email. If no keyword in the ad suggests relation with sensitive topics, a user clicking on the ad may not realize that they could be disclosing private information to advertisers. Imagine an insurance company wanted to gain insight into pre-existing conditions of its customers before signing them up. It could create two ad campaigns – one that targets cancer and another youth – and assign different URLs to each campaign. It could then offer higher premium quotes to visitors who come through the cancer-related ads to discourage them from signing up while offering lower premium quotes to those who come through youth-related ads. We believe that the potential for this attack illustrates the urgent need for increased transparency in ad targeting.

6.7 Summary

Our evaluation results show that XRay supports fine-grained, accurate data tracking in popular Web services, scales well with the size of data being tracked, is general and flexible enough to work efficiently for three Web services, and robustly uses systems techniques to discover associations when ad contents provide no indication of them. We next discuss how XRay meets its last goal: robustness against honest-but-curious attackers.

7 Security Analysis

As stated in §3.3, two threat models are relevant for XRay and applicable to different use cases. First, an *honest-but-curious* Web service does not attempt to frustrate XRay, but it could incorporate defenses against typical Web attacks, such as DDoS or spam, that might interfere with XRay's functioning. Second, a *malicious service* takes an adversarial stand toward XRay, seeking to prevent or otherwise disrupt its correlations. Our current XRay prototype is robust against the former threat and can be extended to be so against the latter. In either case, third-party advertisers can attempt to frustrate XRay's auditing. We discuss each threat in turn.

Non-Malicious Web Services. Many services incorporate protections against specific automated behaviors. For example, Google makes it hard to create new accounts, although doing so remains within reach. Moreover, many services actively try to identify spammers and click fraud. Gmail includes sophisticated spam filtering mechanisms, while YouTube rate limits video viewing to prevent spam video promotion. Finally, many services rate limit access from the same IP address.

XRay-based tools must be aware of these mechanisms and scale back their activities to avoid raising red flags. For example, our prototype for Gmail, YouTube, and Amazon rate limit their output collection in the shadow accounts. Moreover, XRay's very design is sensitive to these challenges: by requiring as few accounts as possible, we minimize: (1) the load on the service imposed by auditing, and (2) the amount of input replication across shadow accounts. Moreover, XRay's workloads are often atypical of spam workloads. Our XRay Gmail plugin sends emails from one to a few other accounts, while spam is sent from one account to many other accounts.

Malicious Third-Party Advertisers. Third-party advertisers have many ways to obfuscate their targeting from XRay, particularly if it may arouse a public outcry. First, an advertiser could purposefully weaken its targeting by, for example, targeting the same ad 50% on one topic and 50% on another topic. This weakens input/output correlation and may cause XRay to infer untargeting. However, it also makes the advertisers' targeting less effective and potentially more ambiguous if their goal is to learn specific sensitive information about users. Second, an advertiser might target complex combinations of inputs that XRay's basic design cannot discover. Our accompanying technical report shows an example of how advertisers might achieve this [26]. It also extends our theoretical models so they can detect targeting on linear combinations with only a constant factor increase in the number of accounts. We plan to incorporate and evaluate these extensions in a future prototype.

Malicious Web Services. A malicious service could identify and disable shadow accounts. Identification could be based on abnormal traffic (successive reloads of email pages), data distribution within accounts (several accounts with subsets of one account), and perhaps more. XRay could be extended to add randomness and deception (e.g., fake emails, varying copies). More importantly, a collaborative approach to auditing, in which users contribute their ads and input topics in an privacy-preserving way is a promising direction for strengthening robustness against attacks. Web services cannot, after all, disable legitimate user accounts to frustrate auditing. We plan to pursue this direction in future work.

8 Discussion

XRay takes a significant step toward providing data management transparency in Web services. As an initial effort, it has a number of limitations. First, both the Set

Intersection and Bayesian algorithms assume independent targeting across accounts and over time. In reality, ad targeting is not always independent across either. For example, advertisers set daily ad budgets. When the budget runs out, an ad can stop appearing in accounts mid-experiment even though it has the targeted attributes. The system might incorrectly assume that no targeting is taking place, when it could resume the next day. XRay takes reduced coverage into account, but differences between ads can let some targeting pass unnoticed. XRay does not currently account for these dependencies, but estimating their impact is an important goal for future work.

Second, we assume that targeting noise is bounded and smaller than the targeting signal. While this condition seems to hold on the evaluated services, other services making more local decisions may be harder to audit. For example, Facebook might target ads based on friends' information, potentially creating noise that is as high as the targeting signal. A future solution might imitate the social network in shadow accounts.

Third, XRay uses Web services atypically. To the best of our knowledge, it does not violate any terms of service. It does, however, collect ads paid for by advertisers to detect correlation. Ad payment is per impression and pay per click. The former is vastly less expensive than the latter [32]. XRay creates false impressions only but never clicks on ads. A back-of-the-envelope calculation using impression pricing from [32] of $0.6/thousand impressions reveals that XRay's cost should be minimal: at most 50 cents per ad for our largest experiments.

Despite these limitations, XRay has proven itself useful for many needs, particularly in an auditing context. An auditor can craft inputs that avoid many of these limitations. For example, emails can be written to avoid as much overlap as possible and keep the size of inputs used for targeting within reasonable bounds. We hope that XRay's solid correlation components will streamline much-needed investigations – by researchers, journalists, or the FTC – into how personal data is being used.

9 Related Work

While §2.2 covered Web data protection and auditing related works, we next cover other related topics. Our work relates to recent efforts to measure various forms of personalization, such as search [21, 47], pricing [31], and ad discrimination [40]. They generally employ a methodology similar in spirit to differential correlation, but their goals differ from ours. They aim to quantify *how much* output is personalized and what *type* of information is used overall. In contrast, XRay seeks to provide fine-grained diagnosis of which *input data* generates which personalized results. Through its scaling mechanisms – unique in the personalization and data tracking literature – XRay scales well even when the relevant inputs are many and unknown in advance.

Our work also relates to a growing body of research measuring advertising networks. These networks, notably complex and difficult to crawl [3], are rendered opaque by the need to combat click fraud [9], and have been shown to be susceptible to leakage [24] and profile reconstruction attacks [6]. As for other personalization, prior studies focused mostly on macroscopic trends (e.g., What fraction of ads are targeted?) [3] or qualitative trends (e.g., Which ads are targeted toward gay males?) [20]. Various studies showed traces – but not a prevalence – of potential abuse through concealed targeting [20] and data exchange between services [46]. These works primarily focus on display advertising, and each distinguishes contextual advertising using a specific classifier with semantic categories obtained from Google's Ad Preferences Managers or another public API [28].

XRay departs significantly from these works. First, since it entirely ignores the content and even the domain of targeting, it is readily applied as-is to ads in Gmail, product recommendations, and videos. Second, while previous methods label ads as "behavioral" in bulk once other explanations fail [28], XRay remains grounded on positive evidence, and determines to *which* inputs an output should be attributed. Third, XRay's mechanisms to avoid exponential input placement and deal with overlapping inputs are unprecedented in the Web-data-tracking context. While they resemble *black box* software testing [4], the specific targeting assumption we leverage have, to our knowledge, no prior equivalent.

10 Conclusions

The tracking of personal data usage poses unique challenges. XRay shows for the first time that accurate, *fine-grained* tracking need not compromise portability and scalability. For users who care about *which* piece of their data has been targeted, it offers a unique level of precision and protection. Our work calls for and promotes the best practice of voluntary transparency, while at the same time empowering investigators and watchdogs with a significant new tool for increased vigilance.

A Proof of Theorem 1

A.1 Targeting functions, Axioms and Core Family

A *combination* $\mathscr{C}$ of order r, also called r_combination, is a subset of r elements among the N inputs.

Each given ad is associated with a *targeting function* defined as a mapping f from any subset $\mathscr{C}$ of the N inputs into $\{0,1\}$, where $f(\mathscr{C}) = 1$ denotes that an account containing $\mathscr{C}$ as inputs should be targeted. By convention, untargeted ads are associated with the null function $f(.) = 0$. Any targeting function f satisfies two axioms:

- **monotonicity**: $\mathscr{C} \subseteq \mathscr{C}' \implies f(\mathscr{C}) \leq f(\mathscr{C}')$.
- **input-sensitivity**: $\exists \mathscr{C}, \mathscr{C}'$ s.t. $f(\mathscr{C}) = 0, f(\mathscr{C}') = 1$.

Monotonicity simply reflects that an account with strictly more interest or hobbies should in theory be relevant to more ads, and never to less. Input sensitivity prevents the degenerate case where a targeting function is constant.

A *family* S of size l is any collection of l distinct combination. The *order* of this family is defined as the largest order of a combination it contains. For any family S, one can define a targeting function that takes value 1 whenever the subset contains at least one combination in S. Indeed, as shown in [26], the converse is true:

Lemma 1 *For each monotone, input-sensitive targeting function there exists a unique family S satisfying:*

(i) S has size l and order r and it explains *f, which means $f(\mathscr{C}) = 1$ holds if and only if $\exists \mathscr{C}' \in S, \mathscr{C}' \subseteq \mathscr{C}$.*

(ii) No family of size $l' < l$ explains f.

(iii) No family of order $r' < r$ explains f.

Hence, associated with each ad and therefore each targeting function is a unique family of input combination that are targeted, called the ad's *core family*, and we now sketch why it is correctly identified by our algorithm.

A.2 Algorithm and Correctness

For any family of subsets S and fraction $0 \leq x \leq 1$, we say a subset of inputs $\mathscr{C}$ is an x_intersecting subset of S if x subsets in S have at least one input in $\mathscr{C}$. Our proof exploits an original connection between small intersecting subsets (that can be found efficiently) to show how they can reveal a core family. One way to understand why is the following: say, for instance, that the targeting function f takes value 1 exactly when one of the inputs within $\mathscr{C}$ is found in the account. Then $\mathscr{C}$ is exactly the union of inputs found in the core family and intersects all accounts within scope, i.e., forms a large fraction of those receiving the ad.

The key property to explain our algorithm is random subsets. We can show under the conditions of the theorem that there exists $0 < x < 1$ that satisfies two properties related to the inputs of accounts receiving the ads: (1) if targeting does not occur, then with a large probability we cannot find a subset of l inputs that meets at least a fraction x of the accounts seeing the ad, and (2) if targeting does occur, we have accounts receiving the ads for various reasons, within and outside the targeting scope. But we can show with high probability that at least a fraction x of them are within scope and hence must include one combination in the core family. Since with each core family of size l one can associate an intersecting subset that contains at most l elements, checking the existence of such a subset reveals the presence of targeting.

This explains why an algorithm can qualitatively conclude whether targeting occurs or not, but it does not explain how the core family can be computed. However, leveraging stronger results of random subsets allows to apply the same rule recursively, offering multiple ways to determine exactly the core family even with a polynomial number of operations.

More formally, we define: A random *Bernoulli subset*, denoted by $B(n,p)$, is a subset such that any of n elements is contained with probability p independently of all others. A random *Bernoulli family* of size m is a collection of m independent Bernouilli subsets. We first show property (1) above more formally:

Lemma 2 *Let $x > 0$, $s \in \mathbb{N}$, $p < 1 - (1-x)^{\frac{1}{s}}$, and a Bernouilli family $B_1(n,p), B_2(n,p), \ldots, B_m(n,p)$. For any $\varepsilon > 0$ and polynomial P of degree $\leq r$, there exists $A > 0$ such that with probability $\left(1 - \frac{\varepsilon}{P(n)}\right)$ no x_intersection subset exists of size s whenever we have:*

$$m \geq A \cdot ((s+r)\ln(n) + \ln(1/\varepsilon)) .$$

To prove property (2), we need to bound, among accounts receiving an ad, the fraction that is outside the scope of targeting but still receives the ads because $p_{\text{out}} > 0$. Formally, we have:

Lemma 3 *Let $x > 0$, $\alpha > 0$, and a core family of size l and order r p_{in}, p_{out} where we have $p_{out}/p_{in} < \frac{1-x}{x}\frac{\alpha^r}{1-\alpha^r}$. Let $\mathscr{C}$ be a combination of order r.*

For any $\varepsilon > 0$ and polynomial P of degree $\leq r$, there exists $A > 0$ such that with probability $(1 - \varepsilon/P(n))$ the following holds: Among accounts containing $\mathscr{C}$ and receiving the ad, at least x fraction of them is within the targeting scope whenever we have:

$$m \geq A \cdot (r\ln(n) + \ln(1/\varepsilon)) .$$

The two lemmas above (proved in [26]) can be combined whenever α satisfies the inequality for p in the first lemma, which shows that an algorithm can detect the presence of targeting whenever $p_{\text{out}}/p_{\text{in}} < \frac{1-x}{x}\frac{(1-(1-x)^{\frac{1}{l}})^r}{1-(1-(1-x)^{\frac{1}{l}})^r}$.

A naive exponential algorithm could be used to exhaustively search for a core family using this brick. We also show that a polynomial algorithm can refine this analysis to compute the core family at the expense of a more complex recursion in [26].

An Internet-Wide View of Internet-Wide Scanning

Abstract

While it is widely known that port scanning is widespread, neither the scanning landscape nor the defensive reactions of network operators have been measured at Internet scale. In this work, we analyze data from a large network telescope to study scanning activity from the past year, uncovering large horizontal scan operations and identifying broad patterns in scanning behavior. We present an analysis of who is scanning, what services are being targeted, and the impact of new scanners on the overall landscape. We also analyze the scanning behavior triggered by recent vulnerabilities in Linksys routers, OpenSSL, and NTP. We empirically analyze the defensive behaviors that organizations employ against scanning, shedding light on who detects scanning behavior, which networks blacklist scanning, and how scan recipients respond to scans conducted by researchers. We conclude with recommendations for institutions performing scans and with implications of recent changes in scanning behavior for researchers and network operators.

1 Introduction

Internet-wide scanning is a powerful technique used by researchers to study and measure the Internet and by attackers to discover vulnerable hosts *en masse*. It is well known that port scanning is pervasive — including both large horizontal scans of a single port and distributed scanning from infected botnet hosts [5, 14, 15, 28, 39, 45]. However, the past year saw the introduction of two high-speed scanning tools, ZMap [19] and Masscan [23], which have shifted the scanning landscape by reducing the time to scan the IPv4 address space from months to minutes.

In this study, we examine the practice of Internet-wide scanning and explore the impact of these radically faster tools using measurement data from a large network telescope [13, 37, 46]. We analyze scan traffic from the past year, develop heuristics for recognizing large horizontal scanning, and successfully fingerprint ZMap and Masscan. We present a broad view of the current scanning landscape, including analyzing who is performing large scans, what protocols they target, and what software and providers they use. In some cases we can determine the identity of the scanners and the intent of their scans.

We find that scanning practice has changed dramatically since previous studies from 5–10 years ago [5,39,45]. Many large, likely malicious scans now originate from bullet-proof hosting providers instead of from botnets. Internet-scale horizontal scans have become common. Almost 80% of non-Conficker probe traffic originates from scans targeting $\geq$1% of the IPv4 address space and 68% from scans targeting $\geq$10%.

To understand how and why people are conducting scans, we attempt to identify individual large-scale scanning operations. We find that researchers are utilizing new scanning tools such as ZMap to cull DDoS attacks and measure distributed systems, but we also uncover evidence that attackers are using these tools to quickly find vulnerable hosts. In three case studies, we investigate scanning behavior following the disclosure of the OpenSSL Heartbleed vulnerability [36], vulnerabilities in Linksys routers, and vulnerabilities in NTP servers. In each instance, the vast majority of probe traffic originated from large, single-origin scanners. For the Linksys and OpenSSL vulnerabilities, we observed attackers applying ZMap from international bullet-proof hosting providers to complete full scans of the IPv4 address space within 24 hours of public vulnerability disclosure.

We also investigate the defensive mechanisms employed by network operators to detect and respond to scanning. Even in the most favorable case for detection — when repeated, aggressive scan traffic originates from a single IP address and would be trivial to fingerprint — we find that only a minuscule fraction of organizations respond by blocking the probes. When probes are blocked, it is often after operators inadvertently find evidence of scanning during other maintenance, rather than through

automated detection. This may indicate that the vast majority of network operators do not regard scanning as a significant threat. It also validates many recently published research studies based on Internet-wide scanning, as dropped traffic and exclusion requests appear to have minimal impact on study results.

Our findings illustrate that Internet-wide scanning is a rapidly proliferating methodology among both researchers and malicious actors. Maintaining its enormous utility for defensive security research while simultaneously protecting networks from attack is a difficult challenge. Network operators need to be aware that large vulnerability scans are taking place within hours of disclosure, but they should remember that blindly blocking all networks responsible for scanning may adversely impact defensive research. Future work is needed to develop mechanisms for differentiating between benign and malicious scans. In the mean time, we recommend close cooperation between researchers and network operators.

2 Previous Work

Most similar to our work is a study in 2004 by Pang et al. [39], who performed one of the first comprehensive analyses of Internet background radiation. Their study covers many aspects of background traffic, including the most frequently scanned protocols. However, the scanning landscape has changed drastically in the last decade—the Conficker worm [40], a major source of probe traffic, appeared in 2008, and ZMap [19] and Masscan [23] were released in 2013.

In 2007, Allman et al. [5] briefly described historical trends in scan activity between 1994 and 2006. Wustrow et al. [45] again studied Internet background radiation in 2010. They noted an increase in scan traffic destined for SSH (TCP/22) and telnet (TCP/23) in 2007, as well as increased scanning activity targeting port 445 (SMB over IP) in 2009 due to Conficker. We note a different set of targeted services and other changes in scanning dynamics since that time. Czyz et al. [14] explored background radiation in the IPv6 address space. Their work briefly touches on the presence of ICMPv6 probe traffic, but otherwise does not investigate scanning activity; we focus on the IPv4 address space.

There exists a large body of work that focuses on detecting distributed botnet scanning [22, 24, 29, 31, 43]. However, barring few exceptions, this phenomenon has remained largely hypothetical. In one exception, Javid and Paxson [28] unearthed slow but persistent SSH brute-force attacks in 2013. Similarly, Dainotti et al. analyzed distributed botnet scanning in 2011.

Real-world responses to horizontal scanning have not been previously studied. We briefly discussed reactions to our own scanning in prior work [19], but we perform a more in-depth analysis now. Leonard et al. [32] similarly describe the complaints they received when attempting to build an Internet scanner; however, our analysis is based on a much larger data set. In addition, we perform experiments to detect instances where networks block scan probes without notice.

The dynamics of performing studies on IPv4 darknet traffic have been formally documented by both Moore et al. [37] and Cooke et al. [13]. We utilize both studies when performing calculations in this work.

3 State of Scanning

In order to understand current scanning behavior, we analyzed traffic received by a large darknet over a 16-month period. We find that large-scale horizontal scanning—the process of scanning a large number of hosts on a single port—is pervasive and that, excluding Conficker, almost 80% of scan traffic originates from large scans targeting >1% of the IPv4 address space. We find evidence that many scans are being conducted by academic researchers. However, a large portion of all scanning targets services associated with vulnerabilities (e.g. Microsoft RDP, SQL Server), and the majority of scanning is completed from bullet-proof hosting providers or from China. In this section, we describe the dynamics of these scans, including identifying the services targeted, the sources of the scans, and the largest scanning operations.

3.1 Dataset and Methodology

Our dataset consists of all traffic received by a darknet operated at Merit Network for the period from January 1, 2013 to May 1, 2014. The darknet is composed of 5.5 million addresses, 0.145% of the public IPv4 address space. During this period, the darknet received an average of 1.4 billion packets, or 55 GB of traffic, per day. For non-temporal analyses, we focus on January 2014.

In order to distinguish scanning from other background traffic, we define a scan to be an instance where a source address contacted at least 100 unique addresses in our darknet (.0018% of the public IPv4 address space) on the same port and protocol at a minimum estimated Internet-wide scan rate of 10 packets per second (pps). In the case of TCP, we consider only SYN packets.

While we cannot know for sure whether a particular scan covers the entire IPv4 address space, the darknet does not respond to any incoming packets, and the majority of its parent /8 does not host any services. As such, we expect that hosts that send repeated probes to the darknet are scanning naïvely and are likely targeting a large portion of the address space.

Detecting scans Assuming a random uniform distribution of targets, the probability that a single probe packet will be detected can be modeled by a geometric distribution and the number of packets observed by our darknet modeled by a binomial distribution [37]. A scanner probing random IPv4 addresses at the slowest rate we try to detect (10 pps) will appear in our darknet with 99% confidence within 311 seconds and with 99.9% confidence within 467 seconds. We estimate the number of packets sent to the entire IPv4 address space by approximating the binomial distribution with a normal distribution.

We process the darknet traffic using libpcap [27] and apply a single-pass algorithm to identify scans. We expire scans that do not send any packets in more than 480 seconds and record scans that reach at least 100 darknet addresses before expiring. We combine scans originating from sequential addresses in a routed block, as ZMap allows users to scan from a block of addresses. We perform geolocation using the MaxMind GeoIP dataset [35].

Fingerprinting scanners We investigate open-source scanners and fingerprint the probes generated by ZMap [19] and Masscan [23]. In ZMap, the IP identification field is statically set to 54321. In Masscan, probes can be fingerprinted using the following relationship:

$$\text{ip\_id} = \text{dst\_addr} \oplus \text{dst\_port} \oplus \text{tcp\_seqnum}$$

Because the IP ID field is only 16 bits and has a non-negligible chance of randomly being either of these values, we only consider scans in which all packets match one of the fingerprints. We find no easily identifiable characteristics for Nmap [33] probes.

3.2 Scan Dynamics

We detected 10.8 million scans from 1.76 million hosts during January 2014. Of these, 4.5 million (41.7%) are TCP SYN scans targeting less than 1% of the IPv4 address space on port 445 and are likely attributable to the Conficker worm [40]. Excluding Conficker traffic, the scans are composed of 56.4% TCP SYN packets, 35.0% UDP packets, and 8.6% ICMP echo request packets. Only 17,918 scans (0.28%) targeted more than 1% of the address space, 2,699 (0.04%) targeted more than 10%, and 614 (0.01%) targeted more than 50% (see Figure 5). However, after excluding Conficker traffic, we note that 78% of probe traffic is generated by scans targeting ≥1% of the IPv4 address space, 62% by scans targeting ≥10%, and 30% by scans targeting ≥50% (see Figure 4). In other words, while there is a relatively small number of large scans (0.28%), nearly 80% of scan traffic is generated by these scans.

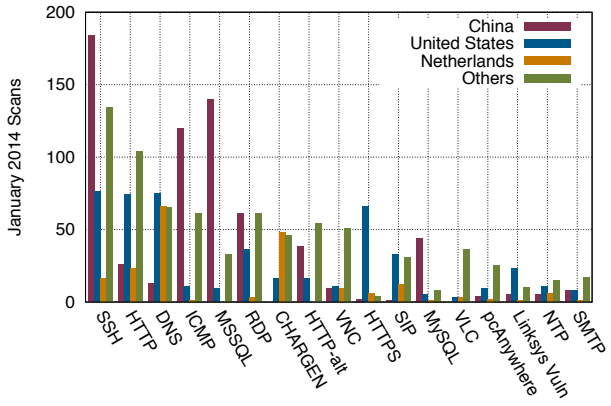

Figure 1: **Large scans (≥10%) by origin country** — Many countries have distinct scanning profiles. For example, the vast majority of MSSQL scanning takes place in China.

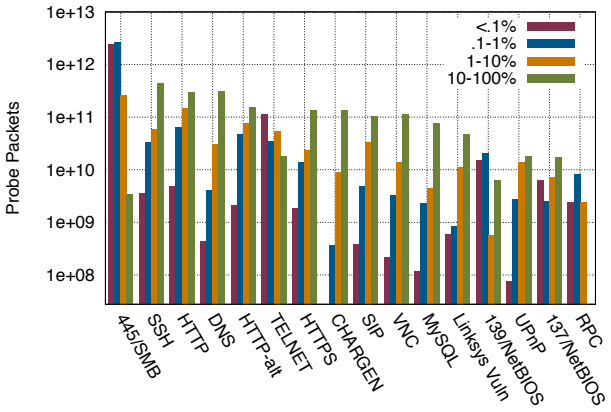

Figure 2: **Targeted ports by scan size** — Small scans target different protocols than large scans. For example, the bulk of port 445 scanning occurs in small scans, whereas port 22 is targeted by larger scans.

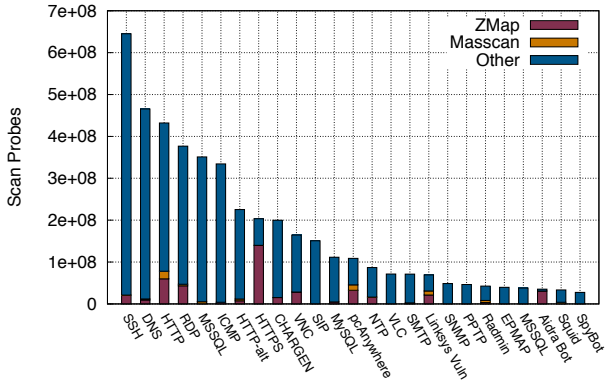

Figure 3: **Large scans (≥10%) by software** — We fingerprint ZMap and Masscan probes and present the breakdown of large scans that use these scanners.

3.3 Targeted Services

Close to half of all scan traffic (48.9%) targets NetBIOS (TCP/445)—5.4 trillion SYN probes in January 2014 alone. Of these packets, 95.1% originate from small scans—scans targeting <10% of the IPv4 address space—and are likely attributable to Conficker [40, 45]. We note that small scans show different characteristics than large scans. For example, while SSH is the most targeted service in large scans, it is the seventh most targeted in small scans, accounting for only 1.3% of scan traffic.

For the most part, the protocols being targeted are not surprising, although they have shifted from previous studies in 2004 and 2010—we show the differences in Table 3. In both large and small scans, there appear to be a mix of protocols frequently associated with vulnerability scanning (e.g. Microsoft RDP, telnet, Microsoft SQL server, and VNC) as well protocols frequently studied by academic researchers (e.g. HTTP, HTTPS, SSH). We show the differences in Figure 2 and the breakdown of frequently targeted services in Tables 1 and 2.

Despite the fact that most scans originate from large international hosting providers, countries display differences in targeted protocols—particularly China, which performs regular scans against SSH, SQL Server, and Microsoft RDP. For example, while Microsoft Remote Desktop Protocol (RDP) is the fourth most scanned protocol, 77% of scans and 76% of probe packets originate from China. The second most active country (United States) is responsible for only 5.4% of probe traffic. A similar pattern emerges for ICMP echo request scans, MySQL and SSH. We show the differences by country for the top ports in Figure 1.

3.4 Scan Sources

While large scans originate from 68 countries, 76% of scan traffic originates from only five countries: China, the United States, Germany, the Netherlands, and Russia. We list the top countries that performed horizontal scans in Table 4 and the CDF in Figure 7.

While the United States and China have large allocations of address space, Germany and the Netherlands do not. In order to understand why a disproportionate amount of scan traffic is originating from smaller countries, we consider the ASes from which scans are being completed. We find that scans targeting ≥10% of the IPv4 address space occur from only 350 ASes (Figure 8). We manually classify the top 100 ASes, finding that 49 are dedicated hosting services or collocation centers, 31 are Internet service providers, 4 are academic institutions, 3 are corporations, and 13 are unidentifiable networks in China.

In the case of the Netherlands, 93% of probe traffic originates from five hosting providers: Ecatel Network,

2004 [39]	2010 [45]	2014
HTTP (80)	SMB-IP (445)	SMB-IP (445)

Table 2: **Commonly targeted services for large scans (targeting $\geq$10% of the IPv4 address space)**

LeaseWeb, WorldStream, Datacenter, Nedzone, and TransIP. We note that Ecatel was one of the hosting providers that Hurricane Electric stopped peering with in 2008 due to spam traffic and malware hosting [12]. In Germany, PlusServer was responsible for 45% of probe traffic. In the United States, scanning was present from 440 ASes, but a small handful of hosting providers were responsible for 39% of scan traffic[1]. We list the hosting providers and collocation centers responsible for the most scan traffic in Table 5.

3.5 Regularly Scheduled Scans

We investigate the 25 most aggressive scanners and find several examples of both academic research scans and likely malicious groups performing repeated scans. In many of the cases where scans were performed from an academic network, researchers provided information on the purpose of their scanning. However, most scans take place from bullet-proof hosting providers or from China and provide no identifying information.

The academic and non-profit scans primarily focus on protocols used for DDoS amplification and studying cryptographic ecosystems (e.g. HTTPS and SSH). All of the groups we identified explained the purpose of their scanning and allow operators to request exclusion. Similarly, several security companies also completed scans. The Shodan Search Engine [34] was the only security group that we were able to detect that did not provide information over the web on scan addresses.

The University of Michigan performs regular ZMap scans for HTTPS hosts in order to track the certificate authority ecosystem [18, 19, 25, 47]; their data is available online at https://scans.io [17]. Ruhr-Universität Bochum completes weekly scans on ports 53, 80, 123, 137, 161, and 1900 in order to measure amplification attacks [42]. The Shadow Server Open Resolver Scanning Project [4] performs daily scans for DNS servers (UDP/53); their scanning machines are hosted by AOL. One of their hosts generated the most probes of any source in our sample — an estimated 97 billion packets in January 2014 alone. Similarly, the Open Resolver Project [3] completes weekly scans for DNS (UDP/53) and NTP (UDP/123) servers. All these institutions provide information on scan intent and how to request exclusion on a simple website at the scan source IPs.

Shodan completed 2,294 scans targeting 53 ports, sending an estimated 209 billion probes from six servers[2] in January 2014. The scans most frequently targeted ports 443, 80, 53, 32764, 1900, 23, 623, 27017, 161, and 137. Errata Security executed 89 scans of common ports using their Masscan tool. Rapid7 performed 13 scans of common ports using ZMap; their datasets are publicly available at https://scans.io [17].

There are two daily ICMP echo request scans from Guangzhou, China that jointly target an average estimated 77% of the IPv4 address space[3]. The hosts only appear to be used for these ICMP scans. A second host in

[1] CariNet (13.0%), SingleHop (11.4%), Hosting Solutions International (4.37%), Versaweb, LLC (3.46%), Psychz Networks (2.2%), Amazon.com (2.1%), and Leaseweb USA (2.0%)

[2] 198.20.69.98, 198.20.69.74, 198.20.70.114, 66.240.192.138, 71.6.5.200, and 71.6.167.142

[3] 113.108.2.117, 159.253.146.141, 220.177.198.034, and 59.46.161.130

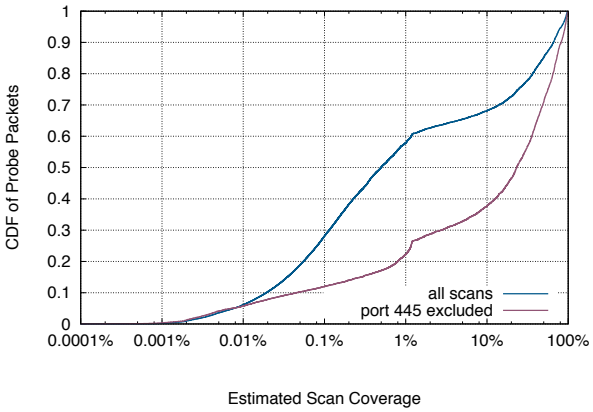

Figure 4: **CDF of scan traffic** — 40% of probes originated from scans targeting ≥1% of the IPv4 space and 30% from scans targeting ≥10%.

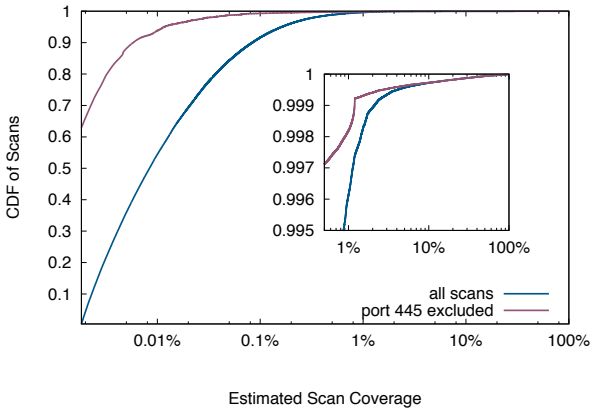

Figure 5: **CDF of scan coverage** — 45.5% of scans achieved 0.01% coverage, 8.37% achieved 0.1% coverage, and 0.38% achieved ≥1% coverage.

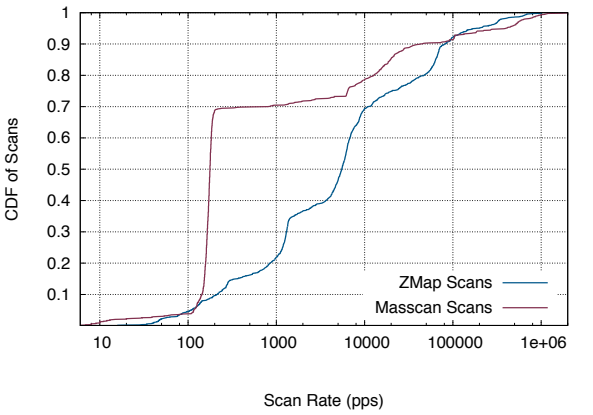

Figure 6: **CDF of scan rate** — The fastest scans operated at 2.2 Mpps (about 1.5 Gbps). However, less than 10% of scans exceeded 100 Mbps.

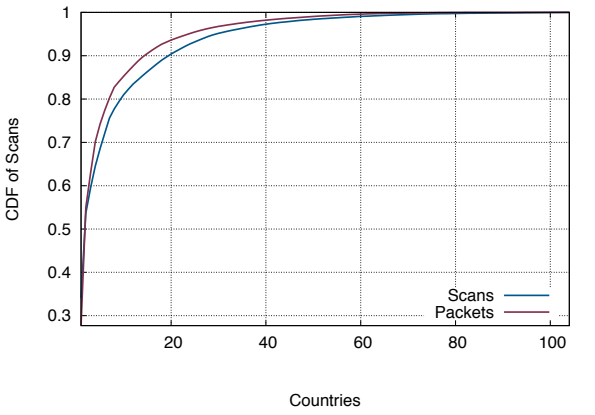

Figure 7: **CDF of scanning countries** — 76% of scans targeting ≥10% of the IPv4 address space originated from only five countries.

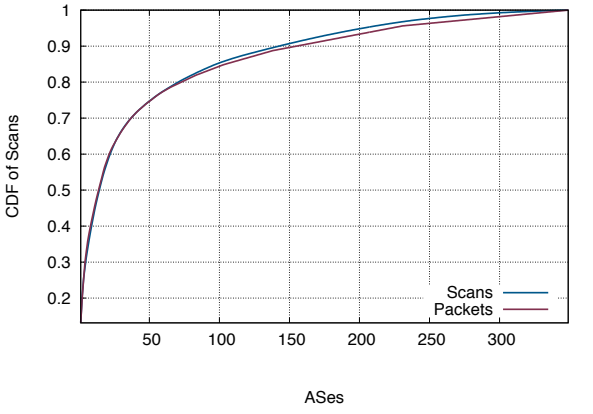

Figure 8: **CDF of scanning ASes** — Scans targeting ≥10% of the address space originated from only 350 ASes, many of them large hosting providers.

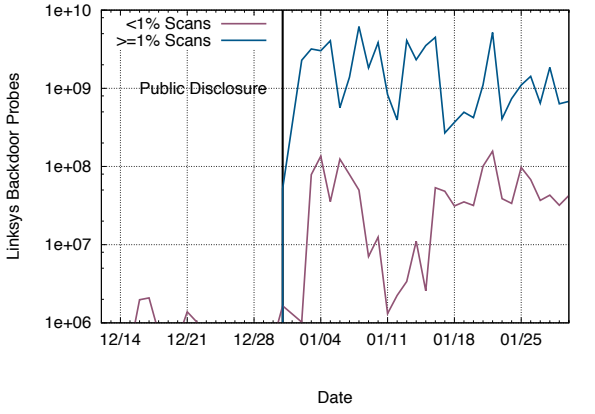

Figure 9: **Linksys backdoor** — Widespread scanning of port 32764 started within hours of the disclosure of a Linksys backdoor on that port.

Guangzhou (113.108.21.16) performs regular daily SYN scans of TCP/0, and a host in Changzhi (218.26.89.179) performs similar scans targeting SSH (TCP/22). We note that while TCP/0 is reserved, it is frequently used for fingerprinting network stacks and because it is not possible to block the port on some firewalls.

The remaining hosts in the top 25 most active scanners repeatedly scanned well-known ports and were hosted from large hosting providers in Germany, Iceland, Romania, Poland, Russia, and China. None of the hosts provided any identifying information in WHOIS records, reverse DNS records, or websites.

3.6 ZMap and Masscan Usage

The majority of scans targeting $\geq$10% of the IPv4 address space used neither ZMap nor Masscan. However, as scan coverage increases, the probability that a scanner uses ZMap steeply increases. ZMap was utilized for 133 (21.7%) of the 614 scans of more than 50% of the IPv4 address space in January 2014; Masscan was used for 21 (3.4%). Of the 242 ZMap scans targeting $\geq$10% of the address space, 70 (30%) targeted HTTP (TCP/80) and HTTPS (TCP/443) and were conducted by academic institutions and other clearly identifiable researchers. We show a breakdown of what scans used various scanners in Figure 3.

3.7 Estimated Scan Rate

In order to estimate the resources that scanners have available, we consider the estimated scan rate observed from ZMap and Masscan scans. We choose to utilize these as our metric for scan rate because the randomization algorithms are approximately uniformly random. We find that hosts are scanning between 13 pps and 1.02 million pps using ZMap and between 5 pps and 2.2 million pps — slightly more than 1.5 Gbps — using Masscan. While both tools support scanning at over 1 Gbps, all but a handful of scans were operated at much lower speeds. As shown in Figure 6, more than 90% of scans operate at under 100 Mbps, and over 70% are operated at under 10 Mbps.

4 Case Studies

Recent advances in high-speed scanning have altered the security landscape, making it possible for attackers to complete large-scale scans for vulnerable hosts within hours of a vulnerability's disclosure. In this section, we analyze scanning related to three recent vulnerabilities that affected Linksys routers, OpenSSL, and NTP servers. We find that likely attackers are taking advantage of new tools: they have started to use ZMap and Masscan from bullet-proof hosting providers instead of using distributed botnet scans. In the cases of the Linksys backdoor and the Heartbleed vulnerability, attackers began scans within 48 hours of public disclosure. We note that while conducting single-origin scans from bullet-proof hosting providers may lower the burden for attackers, it may also allow defenders to more easily detect and block scanning activity and identify the malicious actors.

4.1 Linksys Backdoor

In late December 2013, Eloi Vanderbeken disclosed a backdoor in common Cisco, Linksys, and Netgear home and small business routers [44]. The backdoor allowed full, unauthenticated, remote access to routers over an undocumented ephemeral port, TCP/32764. While there was previously only negligible traffic to the port, traffic spiked on January 2, 2014 when news sources began to cover the story [1,11,21]. There remained an average, sustained 1.98 billion estimated probe packets and 99.55 GB of traffic per day through the end of January (Figure 9).

After the disclosure, 22 hosts completed 43 scans targeting port 32764 on $\geq$1% of the IPv4 address space. Shodan [34] started scanning on December 31, 2013, within 48 hours of the disclosure, and continued to scan throughout January, approximately daily. Within one week, security consulting groups began scanning: Errata Security on January 7, M5 Computer Security on January 13, and Rapid7 on January 22. Two academic institutions, Katholieke Universiteit Leuven and Naukowa i Akademicka Sieć Komputerowa completed scans on January 3 and 6, respectively. Between January 14–16, two Chinese hosts (AS4808/China169 Beijing Province Network) completed scans. The remaining scans were performed from dedicated hosting providers[4]. No identifying information was found on any of the scanning hosts.

All non-Shodan scans utilized ZMap (71%) or Masscan (29%). Surprisingly, 98% of the probes targeting port 32764 were part of large scans targeting $\geq$1% of the IPv4 space, and 79% of probes were part of scans targeting $\geq$10%. In other words, scan traffic was not from a large number of distributed botnets hosts, but rather a small number of high-speed scanners.

While we cannot definitively determine the intent of the hosts in colocation centers, several of the providers have reputations for hosting malware and spammers, and for turning a blind eye to malicious behavior [12]. Assuming that customers of these providers are malicious, this implies that attackers completed comprehensive scans within 48 hours of disclosure using ZMap and Masscan from bullet-proof hosting providers.

4.2 Heartbleed Vulnerability

The Heartbleed Bug is a vulnerability in the OpenSSL cryptographic library [7] that was discovered in March 2014 and publicly disclosed on April 7, 2014 [36]. The vulnerability allows attackers to remotely dump arbitrary private data (e.g. cryptographic keys, usernames, and passwords) from the memory of many popular servers that support TLS, including Apache HTTP Server and nginx [36].

In the week following the disclosure, we detected 53 scans from 27 hosts targeting HTTPS. In comparison, in the week prior to the disclosure, there were 29 scans from 16 hosts. Unlike the Linksys vulnerability, there was not a sustained increase in scanning behavior. However, scan traffic was temporarily more than doubled for several days following the public disclosure.

While we do not know whether the scanners intended to exploit the vulnerability, we can detect which hosts began scanning for the first time following the disclosure. Of the 29 HTTPS scans seen prior to the disclosure, seven were daily scans from the University of Michigan, one was executed as part of Rapid7's SSL Sonar Project, and one belonged to the Shodan Project. A Chinese host (218.77.79.34) also performed daily scans. The remaining scans were operated out of bullet-proof hosting providers in the US, Great Britain, Poland, France, Iceland, and the Netherlands; none of them provided any identifying information.

Only 5 of the 27 hosts found scanning after the disclosure had previously been seen scanning on port 443, and only 3 had performed any scanning in 2014. The only recognizable organizations scanning in the week following the disclosure were the University of Michigan, Technische Universitaet Muenchen, Rapid7, Errata Security, and Nagravision. The remainder of the scans were completed from China and bullet-proof hosting providers. Within 24 hours of the vulnerability release, scanning began from China — 20 of the 53 scans (38%) originated from China. The remaining scans occurred from Rackspace, Cyberdyne, SingleHop, CariNet, Ecatel, myLoc, and Amazon EC2. 74% of the scans used ZMap; 21% used Masscan. Only three scans (6%) used other software.

4.3 NTP DDoS Attacks

Network Time Protocol (UDP/123) is a protocol that allows servers to synchronize time. In December 2013, attackers began to use NTP to perform denial-of-service amplification, in a similar way to how DNS had been abused in the past. Traffic from NTP servers began to rise around December 8, 2013 [2] and in February 2014, attackers attempted to DDoS a Cloudflare customer with over 400 Gbps of NTP traffic — one of the largest ever DDoS attacks [41].

The scanning behavior surrounding NTP is similar to what we observed for the Linksys backdoor and the Heartbleed vulnerability. Specifically, 97.3% of probe traffic destined for NTP was part of large scans (targeting $>1\%$), rather than from distributed botnet scanning. In January 2014, 29 scans from 19 hosts targeted NTP (UDP/123); 8 of the hosts used ZMap; 1 used Masscan. Three groups completed regular scans: Ruhr-Universitaet Bochum completed weekly scans, Shodan performed daily scans, and Errata Security completed one scan.

Three hosts in China completed full scans. The remaining 14 scans occurred from otherwise anonymous hosts in several hosting providers, including Ecatel, OVH Systems, FastReturn, Continuum Data Centers, and ONLINE S.A.S. One of the IPs hosts a website for the "Openbomb Drone Project" and also hosts the website http://ra.pe; the scan from the host only achieved 3% coverage; another one of the IPs hosts a site stating "#yolo"; one server had a reverse PTR record of "lulz".

As with the other vulnerabilities, there is no way to ascertain the intent of the scanners with certainty. However, the names and sites hosted on the IPs do not instill confidence that the hosts are maintained by responsible researchers rather than attackers.

5 Defensive Measures

In the previous two sections, we showed that Internet-wide scanning is widespread and that likely-attackers are scanning for vulnerabilities within 48 hours of disclosure. However, it is equally important to consider the reactions and defenses of those being scanned. Not only does this help us understand the defensive ecosystem, it also provides important data to calibrate the results from scanning research. In this section, we analyze networks' reactions to scanning, including which networks detect scan activity, drop traffic from repeat scanners, and report perceived network misuse.

Despite the fact that a large number of scans are occurring from unique source IPs and could be easily detected and blocked by network intrusion detection systems, we find that only a minuscule number of organizations block scan traffic or request exclusion. Our scan subnet at the University of Michigan is responsible for the third most aggressive scanning campaign on the Internet, yet we find that only 0.05% of the IP space is inaccessible to it. Similarly, only 208 organizations have requested that we exclude their networks from our scans, reducing the IPv4 address space for study by only 0.15%.

We further uncover evidence that networks are not detecting scans proactively, but are instead stumbling upon scans after *years* of consistent scanning — most likely during other troubleshooting or maintenance. While this lack of attention paints a dismal picture of current defensive

measures, the lack of blocking and exclusion also validates many of the recent research studies that utilize active Internet-wide measurements [8–10, 16, 18–20, 25, 26, 30, 38, 42, 47], as blacklisting does not appear to significantly bias scan results.

5.1 Detecting Blocked Traffic

In order to detect networks that are dropping scan traffic, we completed simultaneous ZMap scans from our scan subnet at the University of Michigan (141.212.121.0/24) and from a subnet that had never previously been used for scanning at the Georgia Institute of Technology. These scans took place on Wednesday, February 5, 2014 between 1:00 PM EST and 23:20 EST.

While our subnet at Michigan is used for multiple ongoing scanning effort, it has primarily been used for scanning the HTTPS ecosystem [18]. Between April 2012 and February 2014, we completed 390 scans on port 443 (HTTPS). The Michigan subnet was responsible for the third most scan traffic in January 2014. The scanning hosts all have corresponding DNS PTR records, WHOIS entries, and a simple website that describes our scanning, the data we collect, recent publications, and how to request exclusion from future research scans [19]. Despite these steps, we expected that some fraction of networks had detected our scanning and opted to silently drop traffic from our subnet.

For the simultaneous scans, we chose to scan port 443 at 100,000 pps in order to compare against our historical data on HTTPS. Both hosts used Ubuntu 12.04 and ZMap 1.2.0, and both had access to a full 1 Gbps of upstream bandwidth. We performed the two scans using ZMap, selecting identical randomization seeds such that the probes from both subnets arrive at approximately the same time.

There exists the likely possibility that some hosts were lost due to random packet drop and not intentional blocking—previous measurements on our network have shown a packet loss rate of approximately 3% [19]. In order to ensure that missing hosts are inaccessible due to blacklisting and not dropped packets, we immediately completed a secondary scan from the Michigan subnet, sending three SYN probes to each missing host, and removing hosts that were missed due to random packet drop. Previous work shows that sending three packets achieves a 99.4% success-rate [19].

We analyzed the set of hosts that appeared in scans from the "clean" subnet at Georgia Tech but not in scans from the "dirty" subnet at Michigan. We aggregate inaccessible hosts by routed block and find that there are two categories of missing hosts: (1) entire routed blocks that drop all traffic and (2) sporadic hosts and small networks belonging to large ISPs that are generally unidentifiable.

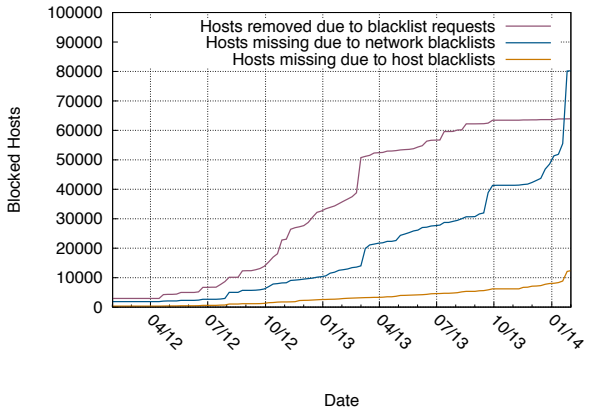

Figure 10: **Impact of blacklisting on HTTPS results** — The impact of external blacklisting and requests to be excluded from scans continue to grow over time rather than plateau.

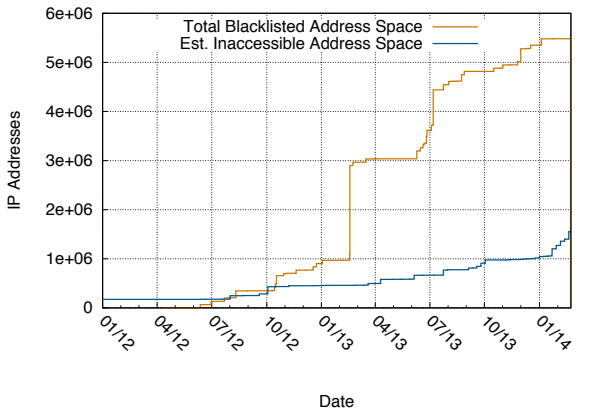

Figure 11: **Estimated impact** — We estimate inaccessible address space based on the total size of inaccessible routed blocks.

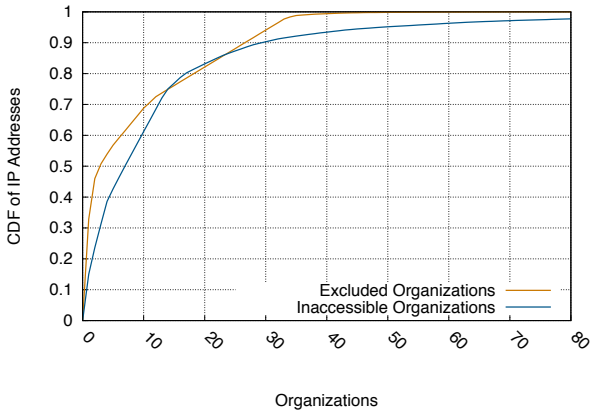

Figure 12: **CDF of blacklisting organizations** — 60% of inaccessible IPs were due to only 10 organizations.

We consider any routed block with more than three hosts in the clean subnet's scan and zero responses from the dirty subnet's scan to have blocked traffic. We find that 99,484 hosts from 612 routed blocks, 198 ASes, and 194 organizations belong to first category; 67,687 hosts belong to the second.

However, these numbers do not represent the total address space that is inaccessible to the dirty subnet, but rather the difference in hosts that respond on port 443. In order to estimate the total inaccessible address space, we consider the size of the routed blocks that appear to drop all traffic and find that these routed blocks comprise a total of 1.55 million addresses. In aggregate with the individual addresses that dropped scan traffic, we find a total of 1.62 million addresses (0.05% of the public IPv4 address space) are no longer accessible. We note that this is a lower bound of inaccessible address space as many of the individual IP addresses that we were unable to classify may represent larger, inaccessible networks. However, ultimately, only a minuscule number of organizations are detecting and blocking scan traffic.

It is important to consider not just the raw number of hosts that are inaccessible, but also the impact on the research that was being conducted by Internet-scale scanning — in our case, what percentage of the HTTPS ecosystem we are unable to measure. We compare the number of unavailable hosts to the most recent results in our HTTPS dataset, which contained TLS handshakes with 27.9 million hosts. The 167,171 inaccessible hosts would have resulted in a 0.4%–0.6% change in the result set, depending on the number of unavailable hosts that successfully completed a TLS handshake.

5.2 Organizations Blocking Scan Traffic

We identify and categorize the organizations that own each of the inaccessible routed blocks (Table 7). We note that this categorization is skewed towards organizations that are large enough to control an entire AS. Unfortunately, when attempting to classify individual IPs that blacklisted addresses, we find that most do not expose any identifying information.

As shown in Figures 10 and 11, the removal of a small number organizations resulted in large changes in the aggregate inaccessible address space — only ten organizations[5] are responsible for 60% of dropped traffic (Figure 12).

We note a bias in the countries that have blocked traffic, which we show in Table 10. However, we note that when considering the percentage of blacklisted addresses per

Russia	4	8,192	0.01%

Table 10: **Inaccessible hosts by country** — We geolocate the routed blocks that are no longer accessible to scanning hosts.

country, a different pattern emerges, because the removal of a single AS can greatly impact the availability within the region. For example, while only one organization in Nigeria blacklisted our subnet, this single rule blocked more than 1% of the country's IP space. A similar situation appears in Portugal, Ireland, Luxembourg, Honduras, Argentina, and Lithuania.

5.3 Organizations Requesting Exclusion

Another indicator of scan detection can be found in the scan exclusion requests that we receive. Over the course of our HTTPS scanning, we have received 208 exclusion requests—resulting in the removal of 5.4 million addresses from our study—0.15% of the public IPv4 address space. Of the excluded hosts, 1.46 million (28%) had previously been seen hosting HTTPS. In comparison, only 1% of IPv4 hosts respond on port 443. We present the types of organizations that have requested exclusion in Table 8 and countries in Table 9. As with the organizations that dropped scan traffic, the majority of requests originated from the United States. We only received four requests from Asia and Africa: one each from Taiwan, India, South Africa, and Japan.

In our prior work [19], we suggest that researchers post a website that explains the purpose of their scanning and that they coordinate with their local network administrators. In order to understand whether this information was useful to network operators and to revise our recommendations, we tracked how network operators contacted us. We find that almost 60% of emails were sent directly to our research team via the site hosted on the scan IPs, 17% were sent to the WHOIS abuse contact, and 12% were sent to our institution's security office (e.g. security@umich.edu). We show a breakdown of contact points in Table 6.

Our informational page has been viewed by 6,600 unique users with an average of 357 visitors per month. More than 90% of visitors used common web browsers (Chrome, Firefox, Internet Explorer, Safari, or Opera). Viewers primarily geolocated to the United States, Germany, United Kingdom, Canada, and Japan. The ratio of page views to complaints (approximately 1:30) suggests that many organizations are cognizant of our scanning activity and do not object to it.

5.4 Blacklisting Scope

While we expected that a small number of organizations would block our scan hosts, it is not immediately clear what network segment organizations would block. We scanned from an additional, unrelated /24 in our institutional AS and found that 38,648 (39%) of the hosts that we could not reach on port 443 are also unavailable from the unrelated /24 in our AS. In other words, 39% of organizations that blocked our dirty subnet blocked the entire /16 in which our scan subnet is located or blocked our entire AS. In terms of estimated total inaccessible address space, 338,944 addresses (18.7% of the addresses inaccessible in our scan subnet) are possibly unavailable from the entire AS.

5.5 Temporal Analysis of Scan Detection

We initially hypothesized that our scanning would cause observant networks to immediately blacklist our network or contact our research team. If this were the case, we would expect that network exclusion requests would plateau after several scans. Instead, we find that organizations are slowly continuing to blacklist our scan subnet or request exclusion more than two years after we began regular scanning. In order to estimate when users detected scanning and blacklisted the scan subnet, we analyzed our historical data on the HTTPS ecosystem and recorded the last time any IP address in each routed block responded.

As shown in Figure 10, there is no plateau in the number of blacklisted hosts or in the number of organizations that have requested removal. Instead, we find that organizations continue to freshly notice the scanning behavior and to blacklist us or request exclusion. Further, more than half of the organizations began starting dropping traffic after more than a year of daily scans. We suspect that the organizations that request exclusion or begin blocking traffic years later are not proactively noticing scan traffic, but rather happening upon log entries during other maintenance and troubleshooting.

5.6 Scan Detection Mechanisms

In order to understand how organizations detect scans, we categorized the emails requesting exclusion or alerting us of potential abuse. In 64 cases (31%), network operators included evidence that was copied directly from log files or otherwise explained how they detected our scanning.

In 50% of cases, network operators noticed scans in their firewall or IDS logs. However, in 22% of reports, operators did not detect scanning in a firewall, but rather in their web logs (primarily Apache or nginx), and in 16% of cases, administrators noticed our scanning as our HTTPS handshake appeared to be a malformed handshake in SSH or OpenVPN logs. We show a breakdown of detection mechanisms in Table 11.

5.7 Revised Recommendations

We further emphasize the importance of researchers serving an informational webpage given the high percentage of users who used this to find contact information and the high number of views by network operators. We also recommend that researchers notify the owners of

Detection Mechanism	Organizations	
Firewall logs	22	(34%)
Web server logs	14	(22%)
Intrusion detection system (IDS) logs	10	(16%)
Invalid SSH or OpenVPN handshake	10	(16%)
Public blacklists	2	(3%)
Other	6	(9%)

Table 11: **Scan detection methods** — We classify the type of evidence included in email requests to be excluded in order to understand how organizations detect scanning.

various other email accounts at the institution including postmaster and administrator, in addition to institutional help desks, departmental administrators, and IT officials.

We add the additional recommendation that researchers publish the subnet being used for their research. This allows organizations that decide to drop traffic a mechanism to blacklist the correct subnet instead of dropping traffic from the entire institution.

6 Future Work

While we shed light on the broad landscape of large horizontal scans, there remain several open questions surrounding scan detection and defensive mechanisms.

Correlating distributed scanners It remains an open research problem to detect and correlate distributed scanning events. While we are able to estimate broad patterns in scanning behavior, we excluded scanners that operate at under 10 pps or targeted fewer than 100 hosts in our darknet. This likely excludes slow, massively distributed scans [6, 15]. While there has been previous research on detecting distributed scanning, little work has applied these to darknet data, in order to understand the slow scans that are taking place. Similarly, our darknet is primarily composed of contiguous address space, which may be avoided by some operations. It reamains an open issue to analyze distributed network telescopes to determine whether attackers are avoiding large blocks of consistently unresponsive address space.

IPv6 scanning In this work, we focused on scanning within the IPv4 address space. Scanning the IPv6 address space efficiently remains an open problem, as does analyzing existing IPv6 scanning behavior.

Vertical scanning Our study focused on horizontal scanning — scanning a single port across a large number of hosts. We note that during this investigation, we also stumbled upon several cases of large vertical scanning operations, which deserve further attention.

Exclusion standards Blacklisting by external organizations indicates a lack of communication between researchers and network operators. This misalignment has lead to organizations dropping all traffic from institutional ASes, which may have other adverse impacts. There currently exists no standard for system operators to request exclusion. Further work is needed to develop a standard similar to HTTP's robots.txt to facilitate this communication.

Determining intent Given that the majority of scanning takes place from large hosting providers, it is oftentimes difficult to discern the intent of the scanner beyond scanned protocol. Follow-up work is necessary to determine the follow-up actions of these scanners. Given that these large scans are happening from a small number of hosts, it may be possible to determine owners and track from where these attacks are originating. Automated mechanisms for signaling benign intent (such as centrally maintained whitelists) could help network operators distinguish between harmful and beneficial instances of wide-scale scanning.

Understanding defensive reactions We find that a minuscule number of organizations are dropping scan traffic. However, it is unclear whether other organizations are aware of and deliberately permit this research-focused traffic, or whether they are entirely unaware of it. More investigation is needed to understand the attentiveness of these organizations.

7 Conclusion

In this work, we analyzed the current practice of Internet-wide scanning, finding that large horizontal scanning is common and is responsible for almost 80% of non-Conficker scan traffic. We analyzed who is scanning and what services they are targeting noting differences from previously reported results. Ultimately, we find that researchers and attackers are both taking advantage of new scanning tools and hosting options — adapting to new advances in technology in order to further reduce the burden for finding vulnerabilities. While the landscape of scanning is evolving, defenders have remained sluggish in detecting and responding to even the most obvious scans.

Acknowledgments

We thank Paul Royal, Adam Allred, and their team at the Georgia Institute of Technology, as well as Thorsten Holz, Christian Rossow, and Marc Kührer at Ruhr-Universität Bochum for facilitating scans from their institutions. We similarly thank the exceptional sysadmins at the University of Michigan for their help and support throughout this project. This research would not have been possible without Kevin Cheek, Chris Brenner, Laura Fink, Paul

Howell, Don Winsor, and others from ITS, CAEN, and DCO. The authors thank Michael Kallitsis and Manish Karir of Merit Network for helping facilitate our darknet analysis. We additionally thank David Adrian, Brad Campbell, Jakub Czyz, Jack Miner III, Pat Pannuto, Eric Wustrow, and Jing Zhang. This work was supported in part by the Department of Homeland Security Science and Technology Directorate under contracts D08PC75388, FA8750-12-2-0235, and FA8750-12-2-0314; the National Science Foundation under contracts CNS-0751116, CNS-08311174, CNS-091639, CNS-1111699, CNS-1255153, and CNS-1330142; and the Department of the Navy under contract N000.14-09-1-1042.

Abstract

While Apple iOS has gained increasing attention from attackers due to its rising popularity, very few large scale infections of iOS devices have been discovered because of iOS' advanced security architecture. In this paper, we show that infecting a large number of iOS devices through botnets is feasible. By exploiting design flaws and weaknesses in the iTunes syncing process, the device provisioning process, and in file storage, we demonstrate that a compromised computer can be instructed to install Apple-signed malicious apps on a connected iOS device, replace existing apps with attacker-signed malicious apps, and steal private data (e.g., Facebook and Gmail app cookies) from an iOS device. By analyzing DNS queries generated from more than half a million anonymized IP addresses in known botnets, we measure that on average, 23% of bot IP addresses demonstrate iOS device existence and Windows iTunes purchases, implying that 23% of bots will eventually have connections with iOS devices, thus making a large scale infection feasible.

1 Introduction

As one of the most popular mobile platforms, Apple iOS has been successful in preventing the distribution of malicious apps [23, 32]. Although botnets on Android and jailbroken iOS devices have been discovered in the wild [40, 42, 43, 45, 54], large-scale infections of non-jailbroken iOS devices are considered extremely difficult for many reasons.

First, Apple has powerful revocation capabilities, including removing any app from the App Store, remotely disabling apps installed on iOS devices, and revoking any developer certificate. This makes the removal of malicious apps relatively straightforward once Apple notices them.

Second, the mandatory code signing mechanism in iOS ensures that only apps signed by Apple or certified by Apple can be installed and run on iOS devices. This significantly reduces the number of distribution channels of iOS apps, forcing attackers to have their apps signed by a trusted authority.

Third, the Digital Rights Management (DRM) technology in iOS prevents users from sharing apps among arbitrary iOS devices, which has a side effect of limiting the distribution of malicious apps published on the App Store. Although recent studies show that malicious apps can easily bypass Apple's app vetting process and appear in the Apple App Store [26, 36, 51], lacking the ability to self-propagate, these malicious apps can only affect a limited number of iOS users who *accidentally* (e.g., by chance or when tricked by social-engineering tactics) download and run them. Specifically, to run an app signed by Apple, an iOS device has to be authenticated by the Apple ID that purchased the app. For example, suppose we use an Apple ID_A to download a copy of a malicious app from the App Store and later we install this copy on an iOS device that is bound to Apple ID_B. This copy cannot run on the iOS device that is bound to Apple ID_B because of the failure of DRM validation. On iOS 6.0 or later, when launching this app, iOS will pop up a window (Figure 1) to ask the user to re-input an Apple ID and a password. If the user cannot input the correct Apple ID (i.e., Apple ID_A) and the corresponding password, iOS refuses to run the app.

In this paper, we show that despite these advanced security techniques employed by iOS, **infecting a large number of non-jailbroken iOS devices through botnets is feasible**. Even though iOS devices are designed for mobile use, they often need to be connected to personal computers via USB or Wi-Fi for many reasons, such as backup, restore, syncing, upgrade, and charging. We find that the USB and Wi-Fi communication channels between iOS devices and computers are not well protected. Consequently, a compromised computer (i.e., a bot) can be easily instructed to install malicious apps onto its connected iOS devices and gain access to users'

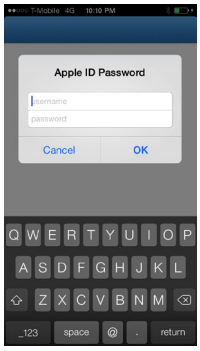

Figure 1: User attempting to run an app downloaded by a different Apple ID on his iOS device needs to first enter the correct Apple ID and password.

private data without their knowledge. In this paper, connected iOS devices refer to those that are plugged into a computer through USB cable or have Wi-Fi syncing enabled. Note that if Wi-Fi syncing is enabled, the iOS device will automatically sync with a paired computer when they are on the same network.

The feasibility of a large scale infection is facilitated by two main problems that we have discovered in our research. The first is a previously unknown design flaw in the iTunes syncing mechanism (including both USB and Wi-Fi based syncing), which makes the iTunes syncing process vulnerable to Man-in-the-Middle (MitM) attacks. By exploiting this flaw, attackers can first download an Apple-signed malicious app (e.g., a Jekyll app [51]) using their Apple ID and then remotely instruct a compromised computer to install the attacker's copy on a connected iOS device, completely bypassing DRM checks. In other words, an attacker can have a malicious app of his own choosing run on a user's iOS device without the user ever seeing an authentication pop-up window.

Coupled with botnet infrastructures, this exploit enables large scale delivery of arbitrary Apple-signed apps. This has two serious security implications. First, it challenges the common belief that the Apple App Store is the sole distributor of iOS apps. Instead of relying on tricking a user into downloading apps from the App Store, attackers can now push copies of their app onto a victim's device. Even if an app has been removed from the App Store, attackers can still deliver it to iOS users. Second, this expolit challenges the common belief that the installation of iOS apps must be approved by the user. Attackers can surreptitiously install any app they downloaded onto victim's device.

The second security issue we discovered is that an iOS device can be stealthily provisioned for development through USB connections. This weakness allows a compromised computer to arbitrarily remove installed third-party apps from connected iOS devices and install any app signed by attackers in possession of enterprise or individual developer licenses issued by Apple. This weakness leads to many serious security threats. For example, attackers can first remove certain targeted apps (such as banking apps) from iOS devices and replace them with malicious apps that look and feel the same. As a result, when a victim tries to run a targeted app, they actually launch the malicious app, which can trick the user to re-input usernames and passwords. We originally presented this attack [31] in 2013 and Apple released a patch in iOS 7 that warns the user when connecting iOS devices to a computer *for the first time*. However, this patch does not protect iOS devices from being stealthily provisioned by a compromised computer that the user already trusts.

In addition to injecting apps into iOS devices, attackers can also leverage compromised computers to obtain credentials of iOS users. Specifically, since many iOS developers presume that the iOS sandbox can effectively prevent other apps from accessing files in their apps' home directories, they store credentials in plaintext under their apps' home directories. For example, the Starbucks app was reported to save usernames and passwords in plaintext. Starbucks thought the possibility of a security exploit to steal the plaintext passwords was "very far fetched" [8]. However, once an iOS device is connected to a computer, all these files are accessible by the host computer. Consequently, malware on the computer can easily steal the plaintext credentials through a USB connection. In our work, we found that the Facebook and Gmail apps store users' cookies in plaintext. By stealing and reusing the cookies from connected iOS devices, attackers can gain access to the victims' accounts remotely.

While it is known that a host computer can partially access the file system of a connected iOS device, we point out that it leads to security problems, especially when attackers control a large number of personal computers. Considering that there are many apps dedicated to iOS, this problem may allow attackers to gain credentials that are not always available on PCs.

To quantitatively show that botnets pose a realistic threat to iOS devices, we also conduct a large scale measurement study to estimate how many compromised computers (i.e., bots) could connect with iOS devices. Intuitively, given the immense popularity of iOS devices and compromised Windows machines, we presume that many people are using iOS devices connected to compromised computers. However, to the best of our knowledge, there exists no previous work that can provide large scale measurement results.

By analyzing DNS queries generated from 473,506

Infection Type	Root Cause	Connection Type
Install malicious apps signed by Apple	Man-in-the-Middle attacks against syncing	USB or Wi-Fi
Install malicious apps signed by attackers	Stealthy provisioning of devices	USB
Steal private data (e.g., Facebook and Gmail apps's cookies)	Insecure storage of cookies	USB

Table 1: Infection Summary.

anonymized IP addresses[1] that were involved in known botnets on 10/12/2013 in 13 cities of two large ISPs in the US, we identified 112,233 IP addresses that had App Store purchase traffic issued by iTunes on Windows, as well as network traffic generated by iOS devices. This implies that the iOS users in the 112,233 home networks were purchasing items in the App Store from compromised Windows PCs on the same day. We make the following assumption: if iTunes is installed on a user's personal computer and is also used to purchase some item from the App Store, the user will eventually connect his or her iOS device(s) to it either via USB or Wi-Fi. Based on this assumption, we estimate that iOS devices in the 112,233 IP addresses could be infected via a connected computer. In other words, 23% of bots in our measured botnet could be used to infect iOS devices.

A broader implication of our study is that it may raise concerns about the security of mobile two-factor-authentication schemes [13]. In such schemes, a mobile phone is used as a second factor of authentication for transactions initiated on a potentially compromised PC. A fundamental assumption made by such schemes is that the "two factors" (i.e., the PC and the phone) are very hard to be reliably and simultaneously compromised (and linked to the same user) by an adversary. This assumption is reasonable if the PC and the phone are exposed to independent attack vectors. However, as shown in this paper, since a large number of users would connect mobile phones to their PCs, the PC itself becomes an attack vector to the phone. As such, the aforementioned assumption becomes dubious. An attacker who already controls the PC can now use it as a stepping stone to inject malware into the phone, and thus can control both factors. As a result, the attacker can easily launch attacks described in [21, 39] to defeat mobile two-factor-authentication schemes[2].

In summary, the main contributions of our work are:

- We discover a design flaw in the iTunes syncing process, and present a Man-in-the-Middle attack that enables attackers to run any app downloaded by their Apple ID on iOS devices that are bound to different Apple IDs, bypassing DRM protections. Based on the MitM attack, we present a way to deliver Apple-signed malicious apps such as Jekyll apps to iOS users.

- We point out the security implications of the stealthy provisioning process and insecure credential storage, and demonstrate realistic attacks, such as replacing installed apps in the iOS device with malicious apps and stealing authentication cookies of the Facebook and Gmail apps.

- We show that a large scale infection of iOS devices is a realistic threat and we are the first to show quantitative measurement results. By measuring iTunes purchases and iOS network traffic generated from IP addresses involved in known botnets, we estimate that on average, 23% of all bot population have connections with iOS devices.

Table 1 summaries the attacks. We have made a full disclosure to Apple and notified Facebook and Google about the insecure storage of cookies in their apps. Apple acknowledged that, based on our report, they have identified several areas of iOS and iTunes that can benefit from security hardening.

The rest of the paper is organized as follows. In Section 2, we demonstrate installation of Apple-signed malicious apps without violating DRM checks. In Section 3, we demonstrate replacing targeted apps with attacker-signed malicious apps. In Section 4, we demonstrate theft of private data (e.g., Facebook and Gmail apps' cookies) from iOS devices. In Section 5, we describe our measurement techniques that indicate large scale infection is feasible. Finally, we provide related work, discussion, and a conclusion.

2 Delivery of Apple-Signed Malicious Apps

This section discusses how a compromised computer can be instructed to install Apple-signed malicious apps on iOS devices. We explore the iOS DRM technology and iTunes syncing process in Section 2.1, present a Man-in-the-Middle attack in Section 2.2, and discuss how to bypass iOS DRM validations in Section 2.3.

[1]The original IP addresses were hashed into anonymized client IDs in our dataset. We performed our measurement over five days of DNS query data, and we used statistics from one day as an example here. We use IP address and client ID interchangeably.

[2]The ultimate defeat of mobile two-factor-authentication schemes will depend on what capabilities the injected mobile malware has. We further discuss it in Section 6.

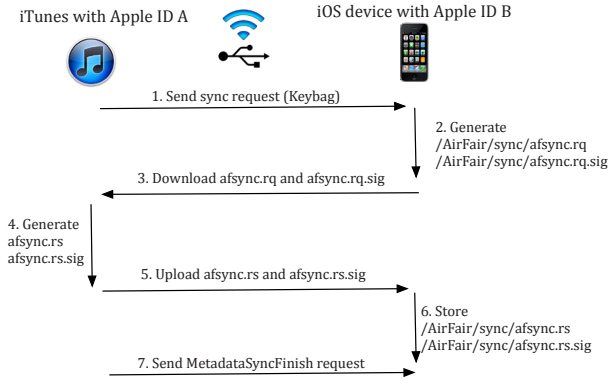

Figure 2: iTunes can sync apps to an iOS device with a different Apple ID.

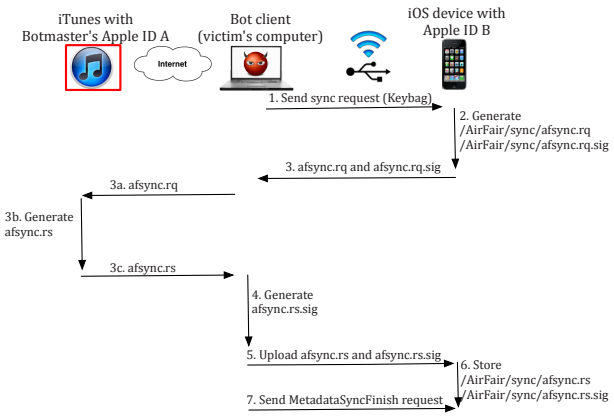

Figure 3: The Man-in-the-Middle against the syncing.

2.1 Fairplay DRM and iTunes Syncing

Apple utilizes a DRM (Digital Rights Management) technology called Fairplay to prevent piracy of iOS apps. All apps in the App Store are encrypted and signed by Apple. To run an app downloaded from the App Store, iOS will 1) verify an app's code signature, 2) perform DRM validation and decrypt the executable file, and 3) run the decrypted code. As a result, a copy of an app purchased by Apple ID_A cannot run on other iOS devices bound to other Apple IDs, because of the failure of DRM validation in step 2.

Although Apple does not disclose any technical details about the Fairplay DRM technology, we found a way to bypass it based on the following key observations.

- **Observation 1: Different Apple IDs will receive the same encrypted executable files for different copies of the same app**. After purchasing an app, an iOS user will receive a file with the `.ipa` extension from the App Store. The `ipa` file is in compressed zip format. We can retrieve the contents of an app package by decompressing the `ipa` file. The following shows the typical structure of an app directory (taking the Twitter app as an example).

```
/iTunesArtwork
/iTunesMetadata.plist
/Payload/Twitter.app/Twitter
...
/Payload/Twitter.app/SC_Info/Twitter.sinf
/Payload/Twitter.app/SC_Info/Twitter.supp
...
```

  Although the whole `ipa` package is unique for each Apple ID, we noticed that the encrypted executable files inside these `ipa` files are the same. Different copies of the same app purchased by different Apple IDs sharing same encrypted executable files implies that **the final decryption of the executables is irrelevant to Apple IDs**[3].

- **Observation 2: Apps purchased by different Apple IDs can run on the same iOS device under certain circumstances**. We found that iTunes can sync apps in its app library to iOS devices through USB or Wi-Fi connections, even if the iOS devices are bound to different Apple IDs. Specifically, when an iOS device with Apple ID_B is connected to iTunes with Apple ID_A, iTunes can still sync apps purchased by Apple ID_A to the iOS device, and authorize the device to run the apps. As a result, apps purchased by both Apple ID_A and Apple ID_B can run on the iOS device.

In particular, we reverse engineered the iTunes authorization process, i.e., how iTunes authorizes an iOS device with a different Apple ID to run its apps. We briefly present the workflow here.

First, iTunes sends a `Keybag` sync request to the iOS device (Step 1 in Figure 2). We refer the readers to [29] for detailed use of "Keybags" in iOS. For example, a keybag named Escrow is used for iTunes syncing and allows iTunes to back up and sync without requiring the user to enter a passcode.

Next, the iOS device generates an authorization request file `/AirFair/sync/afsync.rq` and corresponding signature file `/AirFair/sync/afsync.rq.sig` (Step 2 in Figure 2). Upon retrieving these two files from the iOS device (Step 3), iTunes generates an authorization response file `afsync.rs` and corresponding signature file `afsync.rs.sig` (Step 4).

iTunes then uploads the authorization response and signature files (`afsync.rs` and `afsync.rs.sig`) to the iOS device (Step 5). The iOS device stores the two files

[3] We further explain this in Section A.1

in the directory `/AirFair/sync/` and updates its internal state (Step 6).

Finally, iTunes sends a request to the iOS device to finish the syncing process (Step 7). After that, all apps in the iTunes app library can directly run on the iOS device without showing the pop-up window similar to Figure 1, even though iTunes and the iOS device are bound to different Apple IDs.

2.2 Remote Authorization

By reverse engineering the iTunes executables, we identified the functions in iTunes that are used to generate the `afsync.rs` and `afsync.rs.sig` (i.e., Step 4 in Figure 2). Based on these findings, we realized that by launching a Man-in-the-Middle-style attack, iTunes can remotely authorize an iOS device, without requiring physical connections between iTunes and the iOS device.

Figure 3 shows the remote authorization process in which iTunes is running on a remote computer (iTunes with Botmaster's Apple ID) and an iOS device is connected to a local computer (i.e., the bot client) through a USB cable or Wi-Fi connection. The local computer acts as a middleman.

First, the local computer, as instructed by the botmaster, sends a `Keybag` syncing request to a connected iOS device (Step 1 in Figure 3). After receiving the request, the iOS device generates the authorization request and signature file (Step 2), and transfers them to the local computer (Step 3). However, unlike the traditional iTunes authorization process, the local computer does not directly produce the authorization response file. Instead, it sends the authorization request file `afsync.rq` to a remote computer where iTunes is running (Step 3a). Upon receiving `afsync.rq`, the remote computer can force its local iTunes to handle the authorization request file as if it were from a connected iOS device, generate the authorization response file `afsync.rs` (Step 3b), and then send `afsync.rs` back (Step 3c).

Next, the local computer further produces the signature file `afsync.rs.sig` by using local iTunes code (Step 4). Note that the signature file is a keyed hash value of the response file using the connection session ID as the key. The signature file could also be generated by the remote iTunes if the local computer transfers the connection session ID to the remote iTunes in Step 3a. Furthermore, the local computer uploads `afsync.rs` received from the remote iTunes and `afsync.rs.sig` to the connected iOS device (Step 5). Step 6 and Step 7 in Figure 3 are the same as those in Figure 2.

The end result is that the iOS device connected to a local computer obtains authorization to run apps purchased by the iTunes instance running on a remote computer.

2.3 Delivery of Jekyll Apps

Background. Our previous work [51] demonstrated that malicious third-party developers can easily publish malicious apps on the App Store. It also implemented a proof-of-concept malicious app named Jekyll that can carry out a number of malicious tasks on iOS devices, such as posting tweets and dialing any number. Other research also demonstrated malicious keylogger apps on iOS 7.0.6 [55]. However, a key limitation of these apps is that attackers have to passively wait for iOS users to download the apps and thus affect only a limited number of iOS users.

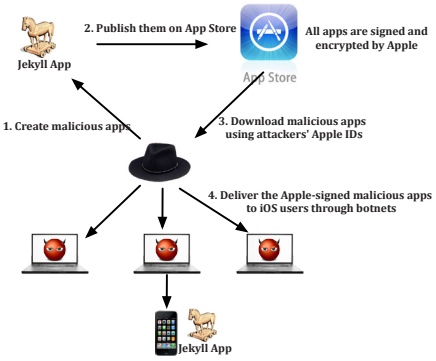

Figure 4: Deliver Jekyll apps to iOS devices.

Delivery Process. Figure 4 illustrates the high level workflow of the attack. First, attackers create Jekyll-like malicious apps using methods proposed in [51] and publish them on the App Store (Step 1 & 2 in Figure 4). Next, attackers download Jekyll-like apps from the App Store using Apple IDs under their control (Step 3). Finally, attackers deliver the downloaded apps to compromised computers and instruct them to install the downloaded apps to connected iOS devices.

Since Jekyll [51] has been removed from the App Store, we reused the copy of the app downloaded by our testing accounts. By using the remote authorization technique we described in Section 2.2, we successfully made our copy of Jekyll run on iOS devices bound to different Apple IDs without triggering DRM violations. The attack demonstrates that even if an app has been removed from the App Store, attackers can still distribute their own copies to iOS users. Although Apple has absolute control of the App Store, attackers can leverage MitM to build a covert distribution channel of iOS apps.

3 Delivery of Attacker-Signed Apps

In this section, we present how the USB interface can be exploited to install arbitrary apps that are signed by attackers. The iOS mandatory code signing mechanism ensures that only apps signed by trusted authorities can

run on iOS devices. Apple allows developers to install apps into iOS devices through a process called device provisioning, which delegates code signing to iOS developers. This was originally intended for developers to either test their apps on devices or for enterprises to do in-house app distribution. Unfortunately, we found that this process can be abused to install malicious apps into iOS devices.

3.1 Provisioning Process

Preparation. A provisioning profile is a digital certificate that establishes a chain of trust. It describes a list of iOS devices that are tied to an Apple ID, using the Unique Device Identifier (UDID) of each device. After sending the UDID of an iOS device to Apple, a provisioning profile is produced for installation on the device. Once installed, apps created and signed by the Apple ID that created the provisioning profile can be successfully executed in a provisioned iOS device. Although a device's UDID is considered sensitive information, it is straightforward for compromised machines to obtain the UDID of a connected iOS device because an iOS device exposes its UDID through the USB device descriptor header field.

Installing Provisioning Profiles. Conventionally, the provisioning process is transparently done when one is using Xcode (Apple's IDE). However, we found that the installation of provisioning profiles can also be done by directly sending requests to a service running on iOS devices called `com.apple.misagent`, launched via the `lockdownd` service [33]. Specifically, by crafting requests of the following key value pairs encapsulated in plist format [1]: <`MessageType`, `Install`>, <`Profile`, the provisioning profile to be installed>, and <`ProfileType`, `Provisioning`>, we can stealthily install a provisioning profile in a USB-connected iOS device [33].

Installing and Removing Apps. The removal of an app is done by issuing an `Uninstall` command and app-id to a service on the device called `com.apple.mobile.installation_proxy`. The installation of an app is done by issuing an `Install` command and app-id to the same service, with the addition of the path to where the app package resides on the computer [33]. Note that using the `com.apple.mobile.installation_proxy` service to install or remove apps also works for non-provisioned iOS devices.

3.2 Attack Examples

As we will present in Section 5.7, we discovered that 4,593 (4%) of 112,233 potential victims queried mobile banking domains in a day (10/12/2013), implying that these devices are likely to have mobile banking apps installed. We implemented a proof-of-concept program that can check whether a plugged-in iOS device has banking apps installed and replaces them with malicious apps that look and feel the same, but trick the user to re-input usernames and passwords.

4 Stealing Credentials

In this section, we demonstrate that in addition to injecting apps into iOS devices, attackers can also leverage bots to steal credentials of iOS users.

4.1 Background

Cookie as Credential. Due to the common architecture of backend servers, the most frequently used credential types in the iOS app model are HTTP cookies [17] and OAuth Tokens [25, 27]. We focus on cookies, as they generally provide a full set of privileges for a particular app, whereas OAuth credentials are utilized to provide limited permissions.

Many iOS apps (such as Facebook and Gmail) use cookies as their authentication tokens. After first login to these apps, a cookie is generated by the server, transmitted to the device, and stored locally. Later, this cookie is presented to the server for accessing its contents via APIs (mostly `RESTful` HTTP).

The locations of the stored cookies are determined by the library that processes HTTP requests. The most commonly used library is called `NSURLConnection` [15], which is provided by the default iOS SDK. In addition, many third-party HTTP libraries [49, 50] are built on top of `NSURLConnection`. As a result, these libraries store the cookies in the same fixed locations as `NSURLConnection`. After analyzing the `NSURLConnection` library, we found that all cookies are stored inside an app's home folder by default.

Due to sandbox-based isolation, accessing files inside directories of other apps is prohibited in iOS. Since all cookies are stored separately per app, unless attackers can bypass the sandbox, a cookie can only be accessed by the corresponding app itself. Thus, storing cookies in each app directory is widely used by third-party developers and is considered to be hard to exploit [8].

4.2 Threat from the PC

This assumed difficulty of exploitation is incorrect when USB-based attacks are considered in the threat model. From a USB connection, a host computer can connect to an iOS device not only through the iTunes sync protocol, but also via the Apple File Connection (AFC) protocol [46]. AFC is designed to access media

files (e.g., images taken from the camera, recorded audio, or music files) through the USB cable. Furthermore, there exists a service maintained by `lockdownd` called `com.apple.mobile.house_arrest`, which provides access to iOS app directories through the AFC protocol. As a result, a computer has full USB-based access to the contents of `/private/var/mobile/Applications/*`.

Attacks. Credentials can be accessed via the `Cookie.binarycookies` file within an app's directory using AFC. Both the httpOnly cookie that is protected from JavaScript access and secure cookies that are only transferred through HTTPS connections can be recovered. Applying these cookies to the same apps in different devices allows attackers to log-in to the services of their victims.

Real Examples. As a proof of concept, we implemented a tool that can retrieve the cookies of Facebook and Gmail apps from a USB-connected iOS device, and transfer them to another computer.

By using these stolen cookies, we successfully logged in as the victim via the web services for both Facebook and Gmail. Although we only demonstrated the attacks against Facebook and Gmail, we believe that our finding affects a number of third-party apps that store cookies in the way similar to the Facebook and Gmail apps.

5 Measurement

In this section, we describe the methodology and datasets we use to determine a lower bound of the coexistence of iOS devices, App Store purchases made from Windows iTunes, and compromised Windows machines in home networks, with a goal to quantitatively show that a large number of users are likely to connect iOS devices to infected personal computers.

5.1 Overview

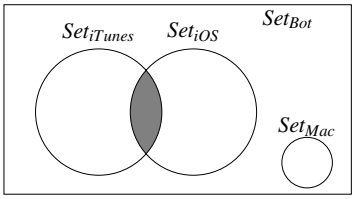

Figure 5: $(Set_{bot} - Set_{Mac}) \cap Set_{iOS} \cap Set_{iTunes}$ is the estimation of iOS devices that can be connected with bots.

Due to NAT, there are usually multiple machines (such as Windows machines, mobile phones, and Mac machines) behind a single client ID (i.e., an anonymized IP address). In our measurement, we used different fingerprints to determine the client IDs (CIDs) that produce network traffic generated by iOS devices, App Store purchases from Windows iTunes, and compromised Windows machines.

Identified as \ Truth	CID has Mac	CID has no Mac
CID has a Mac	True Positive	False Positive
CID has no Mac	False Negative	True Negative

Table 2: Definition of false positive and false negative.

First, we quantified the population of compromised Windows machines (i.e., bots) using a labeled C&C domains dataset (see Section 5.3). Since we only used C&C domains from Windows malware families, we are confident that all CIDs (Set_{bot} in Figure 5) have Windows machines. Next, within Set_{bot}, we further measured how many CIDs contain network traffic generated from iOS devices. Since there is an overlap of DNS queries from Mac OS X and queries from iOS, we excluded CIDs with Mac OS X traffic (Set_{Mac} in Figure 5). We used a set of iOS fingerprint domain names to identify a lower bound of CIDs containing iOS devices (Set_{iOS} in Figure 5). Then, we estimated how many iOS devices in Set_{iOS} are likely to be connected to a Windows machine. Since there is no unique DNS query generated when an iOS device is connected to a Windows machine either via USB or Wi-Fi, we assumed that if users have purchased an item from the App Store using Windows iTunes, they will eventaully connect iOS devices to a Windows machine. We estimated a lower bound of CIDs with Windows iTunes (Set_{iTunes} in Figure 5). Finally, the intersection of Set_{iOS} and Set_{iTunes} is our measurement result (shaded area in Figure 5).

We use false positives and false negatives to evaluate our methodology. They are defined in Table 2, using identification of Set_{Mac} as an example. If a CID has a Mac but we identify it as without a Mac, it is a false negative. On the other hand, if a CID does not have a Mac but we identify it as with a Mac, it is a false positive. The definition of false positive and false negative are similar to identifying Set_{iOS} and Set_{iTunes}. Since we want to be conservative about the size of $Set_{iTunes} \cap Set_{iOS}$, we accept false positives for Set_{Mac}, false negatives for Set_{iOS} and false negatives for Set_{iTunes}. However, we want to have small or zero false negatives for Set_{Mac} as well as false positives for Set_{iOS} and Set_{iTunes}.

5.2 Datasets

All datasets are provided by Damballa, Inc [3].

DNS Query Dataset. We obtained DNS traffic from two large ISPs in the US, collected in 13 cities for five days[4] in October 2013. A-type DNS queries from all clients to the Recursive DNS Servers of the ISPs were

[4] 10/12/2013, 10/24/2013, 10/27/2013, 10/28/2013, 10/30/2013.

captured by a sensor in each city, and then de-duplicated every hour to be stored. Each record in the dataset is a tuple of sensor ID, hourly timestamp, anonymized CID, query count, queried domain, and resolved IP address of the domain. The CID is a hash of original client IP address. The hash is performed to preserve client IP anonymity, and at the same time to retain a one-to-one mapping property. The query count denotes the number of times that client queried the particular domain and resolved IP pair in the hour. On average, we observed 54 million client IDs, 62 million queries, and 12 billion records daily from 13 sensors in total.

ISP Clients. Most CIDs in the two ISPs are home networks. Only few are small businesses. Since 99.5% of CIDs queried fewer than 1,000 distinct valid domains daily, we identified those as representative of home network users[5].

DHCP Churn. Because of long DHCP lease times (one week) and specific DHCP renewal policies (e.g., a modem's IP address will only be changed if some other modem has acquired the IP address after lease expiration) from the two large ISPs, the DHCP churn rate is very low in the networks we measured. Consequently, we consider a single CID as the same home in a given day. This is different than that of a botnet's perspective, where the bots could reside in any network [48].

Passive DNS Database. We collected and built a passive DNS database for the same days, from the same locations as the DNS query dataset to provide visibility of other types of DNS records. The database contains tuples of date, sensor ID, queried domain, query type, resolved data, and query count. Since there are only A-type records in the DNS query dataset, if there is a CNAME chain [38] for the domain name we want to measure, we use the passive DNS database to reconstruct the CNAME chain to determine the mapping of the domain we are interested in to the eventual returned A record. For example, the CNAME chain for Apple's iMessage server `static.ess.apple.com` is shown in Table 3. The final A-type domain for `static.ess.apple.com` is `e2013.g.akamaiedge.net`. If we want to know how many CIDs queried `static.ess.apple.com` in a day, we first examine the passive DNS database for that day to reconstruct all possible CNAME chains to `e2013.g.akamaiedge.net`. Next, we make sure that only `static.ess.apple.com` resolved into `static.ess.apple.com.edgekey.net`, and only `static.ess.apple.com.edgekey.net` resolved into `e2013.g.akamaiedge.net`. Finally, we measure `e2013.g.akamaiedge.net` in DNS query dataset.

HTTP Dataset. We utilized technology provided by Damballa to collect HTTP headers related to iOS and Windows iTunes, as well as those related to domain names of our selection. If User Agent strings related to iOS or Windows iTunes appeared in an HTTP header, or if any selected domain name was in the "Host" field of an HTTP request, we collected the request and corresponding response headers. The time frame for all HTTP headers we obtained is from 10/18/2013 to 11/11/2013. Since the HTTP data is not always available for all CIDs in our DNS query dataset, we only used the HTTP dataset to obtain ground truth for evaluating our approach.

Labeled C&C Domains We acquired all command and control (C&C) domain names for botnets that Damballa is tracking. The threat researchers in Damballa labeled those C&C domains using various methods, including static and dynamic analyses of malware, several public blacklists, historical DNS information, etc. We only picked malware families for Windows for the purpose of this measurement, since we wanted to avoid Mac OS X as much as possible.

`static.ess.apple.com. 3600 IN CNAME static.ess.apple.com.edgekey.net.`
`static.ess.apple.com.edgekey.net. 21600 IN CNAME e2013.g.akamaiedge.net.`
`e2013.g.akamaiedge.net. 20 IN A 23.73.152.93`

Table 3: CNAME chain for static.ess.apple.com.

5.3 Bot Population

First, we used labeled C&C domains to find CIDs containing infected Windows machines in the DNS query dataset. If a CID queried any C&C domain in a day, we consider it as having a bot at home for that day. During the five days in October, we observed 442,399 to 473,506 infected CIDs daily, with an average of 459,326. In particular, there were 473,506 infected CIDs on 10/12/2013. We use statistics from 10/12/2013 as an example below to explain how we determine the population of iOS devices and Windows iTunes.

5.4 Excluding Client IDs with Mac OS X

We utilized unique software update traffic to fingerprint Mac OS X. Apple lists five domain names related to OS X software update services [16]:

`swscan.apple.com`, `swquery.apple.com`, `swdist.apple.com`
`swdownload.apple.com`, `swcdn.apple.com`

Mac OS X is set to automatically check for security updates daily since version 10.6 [14] and to check for general software updates daily since version 10.8 [19]. We assume that if there is any Mac OS X within a CID, there must be a query to at least one of the five domains every day. According to [11], the percentage of OS X versions later than or including 10.6 is 95%. This assumption gives us a low false negative rate. To

[5] We explain why we use 1,000 as the threshold in Section A.2

evaluate the false positives of this approach, we verified using the HTTP dataset (See Table 5). We were able to collect HTTP headers for three of the five domain names. 3,530 headers for `swdist.apple.com`, 9,643 headers for `swscan.apple.com`, and 18,649 headers for `swcdn.apple.com` were observed. Among 115 unique (Source IP, User Agent string) pairs for `swdist.apple.com`, 114 User Agent strings were from Mac OS X, and one was from Mozilla, which gives us a $\frac{1}{115}$ false positive rate. Similarly, nine out of 3,884 pairs of (Source IP, User Agent string) for `swscan.apple.com` were false positives. We identified

Weather App	`apple-mobile.query.yahooapis.com`
Stocks App	`iphone-wu.apple.com`
Location Service	`gs-loc.apple.com` `iphone-wu.apple.com`

Table 4: Domains for finding iOS devices.

6,966 (1.50%) of 473,506 infected CIDs with Mac OS X on 10/12/2013. It is lower than the market share of Mac OS X since we only looked for CIDs infected with Windows malware. After excluding Mac OS X, we have 466,540 bot CIDs without Mac OS X, i.e., Set_{bot}-Set_{Mac}.

5.5 iOS Device Population

We used unique domains from two default apps and one service in iOS (the Weather app, Stocks app, and Location Services) to get a lower bound of CIDs containing iOS devices. We obtained these domains in Table 4 by capturing and analyzing network traffic when Weather, Stock, and Location Services were used in a controlled network environment. We also used the HTTP dataset for evaluation. As Table 5 shows, within all (Source IP, User Agent string) pairs that requested the three domains, all User Agent strings were from either iOS or Mac OS X. There were no User Agent strings from other operating systems. Since we have already excluded CIDs with Mac OS X traffic in the previous step, domains in Table 4 can be used to fingerprint iOS without introducing any false positives. However, if a user did not use Weather, Stocks, or Location Services in the day, it is a false negative.

Of 466,540 CIDs without Mac OS X traffic on 10/12/2013, 142,907 (Set_{iOS}) queried any of the three domains, indicating 30.63% of observed Windows bots have iOS devices in the same home network.

5.6 Windows iTunes Population

After we identified infected CIDs containing iOS devices, we further analyzed how many of these have iTunes installed in infected Windows. The biggest challenge here is that there is no unique domain name that can effectively fingerprint Windows iTunes, because Windows iTunes traffic is similar to the traffic generated by the App Store for iOS.

Fortunately, we found that because of the Apple Push Notification Service [2], iOS devices need to constantly query a certain domain name for push server configurations. Based on this feature, we define **iOS heartbeat DNS queries** as DNS queries that an iOS device always makes as long as it is connected to the Internet.

To pinpoint Windows iTunes, our observation is that if we observe App Store purchases but do not find iOS heartbeat DNS queries, then the purchases must originate from iTunes. Next, we describe how we identify the iOS heartbeat DNS queries and App Store purchase queries.

5.6.1 App Store Purchase

To fingerprint App Store purchases, we experimented with several App Store purchases in both Windows iTunes and iOS. By analyzing PCAP traces of these purchases, we discovered that domain names of the pattern `p*-buy.itunes.apple.com` is related to a purchase, where * denotes numbers. We used the HTTP dataset to check this pattern (See Table 5). 487 HTTP headers were collected from 10/26/2013 to 10/29/2013. From the 119 (Source IP, User Agent string) pairs, we confirmed that this pattern comes from the purchase of apps in either iOS or iTunes.

5.6.2 iOS Heartbeat DNS Queries

To discover iOS heartbeat DNS queries, we first collected all domains in the "Host" field of HTTP requests containing iOS-related and Windows iTunes-related User Agent strings from the HTTP dataset. Next, we examined domains that received a large number of requests, and concluded that the domain name `init-p01st.push.apple.com` is constantly queried for Apple push server configurations and certificates from iOS, but queried much less often by Windows iTunes.

Apple does not disclose how often iOS devices query their push server. To confirm our observed queries were iOS heartbeats, we utilized the following three methods.

1. HTTP Traffic Analyses: 8,990 HTTP headers were gathered for `init-p01st.push.apple.com`, from 10/18/2013 to 10/31/2013. By inspecting the distribution of "max-age" values of the Cache-Control field in the HTTP response headers, we were able to know the intended cache policy for the push server certificate in the response. For iOS, the observed max-age values were from 338s to 3,600s; for APSDaemon.exe (part of Windows iTunes), values ranged from 131,837s to 1,295,368s. Compared to Windows, iOS caches the push server certificate for a shorter time, with one hour maximum. Consequently, iOS devices must

Domain	Time Frame	HTTP headers	(Source IP, UA)	iOS	Mac	Mozilla	Other
swdist.apple.com	10/24-11/04/2013	3,530	115	0	114	1	0
swscan.apple.com	10/24-11/04/2013	9,643	3,884	0	3,875	9	0
swcdn.apple.com	10/19-11/11/2013	18,649	613	0	140	473	0
iphone-wu.apple.com	10/18-11/04/2013	17,606	1,772	1,174	598	0	0
apple-mobile.query.yahooapis.com	10/22-11/02/2013	16,808	3,018	2,999	19	0	0
gs-loc.apple.com	10/22-11/04/2013	2,380	561	367	182	0	0
p*-buy.itunes.apple.com	10/26-10/29/2013	487	119	-	-	-	App Store
init-p01st.push.apple.com	10/18-10/31/2013	8,990	-	-	-	-	-

Table 5: Ground truth of fingerprint domain names.

query `init-p01st.push.apple.com` when the cache expires.

2. Reverse Engineering: We also reverse engineered the push service daemon process `apsd` in iOS located at `/System/Library/PrivateFrameworks/ApplePushService.framework/`. We found that the URL `http://init-p01st.push.apple.com/bag` is used to set up the push-server's configuration path in the class `APSEnvironmentProduction` through the method `setConfigurationURL`. Furthermore, in another private framework called `PersistentConnection`, we found that the maximum length of time this connection can last is set to 1,800s by `setMaximumKeepAliveInterval(1800.0)`. This means iOS devices must re-send an HTTP request to get push server configurations at least every 1,800s. Moreover, the final A-type domain from `init-p01st.push.apple.com` has a TTL of 20s. As a result, every time the HTTP request is made, there must be a DNS query for the A-type domain.

3. Idle iPod Touch Experiment: We set up an iPod Touch to never auto-lock, connected it to a WiFi hotspot, and left it idle for 35.5 hours. During this period, there were 150 DNS queries to `init-p01st.push.apple.com` in total. Average query interval was 859s, with a maximum value of 1,398s and a minimum value of 293s. The maximum query interval is consistent with our 1,800s result via reverse engineering.

Our findings show that as long as an iOS device is connected to the Internet, it constantly queries `init-p01st.push.apple.com` for push service configurations, with query intervals shorter than an hour. Each query interval is determined by both the HTTP Cache-Control value and an enforced maximum interval value. The query interval for `init-p01st.push.apple.com` from iTunes is much longer. The reason for this query interval difference may be that iOS devices are more mobile than PCs. As an iOS device moves, it might need a push server closer to its current location, to ensure small push service delay.

Given the unique fingerprint for App Store purchases and a unique iOS heartbeat query pattern, we inferred a lower bound of Windows iTunes by estimating the number of CIDs that queried `p*-buy.itunes.apple.com` but did not query `init-p01st.push.apple.com` in the hour before and after the purchase query. If the Windows iTunes happened to query `init-p01st.push.apple.com` within those two hours, or if the user did not purchase anything in the iTunes App Store, it would be a false negative, since we cannot recognize Windows iTunes even though it exists. However, there are no false positives. Note that we cannot use `init-p01st.push.apple.com` to estimate the number of iOS devices for two reasons: i) Windows iTunes can query this domain; ii) the final A-type domain of `init-p01st.push.apple.com` can come from multiple original domain names[6]. Therefore, by removing CIDs that queried `init-p01st.push.apple.com` in the small time window, we exclude a larger set of CIDs that purchased from within iOS, resulting in a lower bound for Windows iTunes estimation.

On 10/12/2013, from the 142,907 infected CIDs with iOS devices, we further identified 112,233 CIDs with Windows iTunes purchases on the same day, i.e., $Set_{iTunes} \cap Set_{iOS}$. This indicates that 112,233 (23.70%) of CIDs have both iOS devices and Windows iTunes, but no Mac OS X within the home network.

5.7 Mobile Banking Traffic

The iOS devices behind bot CIDs with Windows iTunes are potential victims of our attacks. To estimate the percentage of those devices that may have banking apps installed, we chose mobile domains from eight banks (Citibank, Wells Fargo, PNC, Bank of America, Suntrust, Bank of the West, and U.S. Bank), and examined how many of those iOS devices queried them. We discovered that 4,593 (4%) of 112,233 potential victims queried mobile banking domains on 10/12/2013. This indicates that these devices are likely installed with mobile banking apps that could be replaced with fake mobile banking apps once they are infected, as discussed in Section 3.

[6]This is the only fingerprint domain name we used whose final A-type domain could be resolved from multiple different domain names.

5.8 Result Summary

We used the methodology described in this section to measure the number of iOS devices that can be potentially infected using the MitM attack described in Section 2, with five days of DNS query data. The results are summarized in Table 7. On average, we identified 459,326 bots daily. For 30% of bots, there exist iOS devices used from the same CID; and for 23% of all bots, there are both Windows iTunes installed and an iOS device used. Statistics for individual botnets as tracked by Damballa are presented in Table 6. For example, if the botmaster of botnet α bundled our attacks into their payload, there would be 75,714 potential victims in 13 cities, within the networks we monitor.

Botnet	Size	$Set_{bots} \cap Set_{iOS} \cap Set_{iTunes}$	Percentage
α	287,055	75,714	26.38%
β	69,895	12,517	17.91%
γ	49,138	10,216	20.79%
δ	16,236	3,232	19.91%
ε	13,732	2,662	19.39%
ε	5,024	1,182	23.53%
ζ	4,554	944	20.73%
η	4,377	929	21.22%
θ	4,231	834	19.71%
ϑ	4,067	806	19.82%

Table 6: Statistical analysis of the top 10 botnets with highest number of infected CIDs on 10/12/2013.

Date	Set_{bots}	$Set_{bots} \cap Set_{iOS}$	$Set_{bots} \cap Set_{iOS} \cap Set_{iTunes}$
10/12	473,506	142,907 (30.63%)	112,233 (23.70%)
10/24	452,003	134,838 (29.83%)	104,225 (23.06%)
10/27	442,399	134,271 (30.35%)	104,075 (23.53%)
10/28	461,144	138,793 (30.10%)	105,056 (22.78%)
10/30	467,579	141,242 (30.21%)	102,795 (21.98%)

6 Related Work

USB Attack Vector. The USB interface has been demonstrated to be an attack vector for mobile devices for some years [18, 31, 35, 52]. Z. Wang and A. Stavrou [52] studied attacks that take advantage of USB interface connectivity and presented three attack examples on Android platforms that spread infections from phone to phone, from phone to computer, and from computer to phone. The work in [31, 35] further demonstrated that these USB based attacks can take place through USB charging stations or chargers. It is worth noting that infecting connected mobile devices from the PC has happened in the real world. Symantec has found malware samples on Windows that can inject malicious apps to USB-connected Android devices [6].

Our work is the first to show measurement results that indicate a large number of users are likely to connect iOS devices to compromised computers, potentially leading to a large scale infection of iOS devices. We hope that our measurement results could drive Apple and other mobile manufacturers to redesign the security model of USB connections, and remind app developers to securely store credentials. In addition, while most previous works focus on Android, we present various attacks against non-jailbroken iOS devices that can be launched via USB or Wi-Fi connections.

Attacks Against iOS. In recent years, more attacks against the iOS platform have been observed As one of the most representative attacks, jailbreaking is the process of obtaining root privilege and removing certain limitations (such as code signing) on iOS devices by exploiting vulnerabilities in the kernel, the boot loader, and even the hardware [37]. Since most jailbreaking tools [22, 30] deliver the exploits through a USB connection, attackers could also take advantage of these jailbreaking tools to root USB-connected iOS devices. In this case, attackers can easily inject malicious apps with the ability to read and send SMS (e.g., [5]), which will allow for more advanced attacks against SMS-based two factor authentication schemes [21, 39].

Many researchers have shown that the App Store cannot prevent publishing of malicious apps [26, 36, 51]. They also proposed defenses [20, 53] for jailbroken devices. As previously mentioned, these malicious apps could only affect a limited number of iOS users who downloaded them. Our research describes the means to deliver malicious apps to a significant number of iOS devices and could significantly amplify the threat of iOS-based malware.

Many works focus on reverse engineering iOS and its protocols. Researchers analyzed the iMessage protocol and proposed Man-in-the-Middle attacks [44]. Requiem [47] reverse engineered the Apple Fairplay DRM protection algorithm for music, movies, and eBooks, and can bypass Fairplay to decrypt protected media files. However, Requiem does not support Apple Fairplay DRM protection for apps in the App Store. The libimobiledevice project [33] enables a computer to communicate with USB-connected iOS devices without requiring iTunes, such as syncing music and video to the device and managing SpringBoard icons and installed apps. However, libimobiledevice does not contain the iTunes authorization process (Section 2.1). In other words, libimobiledevice can install an app purchased by Apple ID_A to an iOS device bound to Apple ID_B, but the app cannot successfully run due to the failure of DRM validations. In comparison, we analyzed the iTunes authorization process, and found a way to bypass the DRM validations. This can allow attackers to deliver malicious apps downloaded by their Apple IDs to different iOS devices.

Mobile OS Fingerprint. To fingerprint mobile OSes in a multi-device network environment, the User Agent field of the HTTP header, DHCP request header fields, Organization Unique Identifier (OUI, i.e., the first 3-bytes of a MAC address), or a combination of these were commonly used [12, 24, 28, 34, 41]. Unfortunately, it is not scalable to collect these data in ISP-level networks. Furthermore, it is common for each client IP in a cellular network to represent only one device. In ISP networks, many client IPs represent a NAT endpoint. To cope with the complexity caused by multiple devices per client IP in ISP networks, we used unique domains from two default apps and one service within iOS to measure the number of iOS devices. We also found a domain name related to the push service with a unique query frequency that allowed us to determine the presence or absence of an iOS device for a given client IP.

7 Discussion

7.1 Accuracy of the Measurement

We emphasize that the goal of our measurement study is to show that there is a large number of users who are likely to connect their iOS devices to compromised computers, which we argue may lead to a large scale infection of iOS devices through botnets. There are many reasons that may lead to underestimations in our measurement, which implies that even more iOS devices could be infected by the botnets that we monitor. For example, in our measurement, we did not consider cellular traffic and the case that people often have multiple iOS devices in their household.

Next, we discuss the potential reasons that may result in overestimations and analyze why they are unlikely to happen in our dataset.

Multiple Windows machines. The data we have only allows us to determine what *type* of devices are behind an IP address, but not how many of each. Thus, it is possible that there are multiple Windows machines behind an IP. In the case that there are multiple Windows machines and not all of them are infected, we may have an overestimated infection number since iOS devices could be connected to only the uninfected computers. To reduce this risk of overestimation, we excluded IPs that queried more than 1,000 unique domains in a day because these IPs are likely to be a gateway with many users. On the other hand, we can expect that within a small environment, if one Windows machine in a NAT environment is infected, it is likely that all Windows machines will eventually be infected. This is because 1) most likely all the Windows machines in the network are managed in a similar manner, and have the same level of updates and defenses, thus share the same vulnerabilities, and 2) it is likely that there is some kind of communication or data sharing (e.g., using the same Wi-Fi network or a USB thumb drive) between the machines.

Mobility of iOS devices. Due to the mobility of iOS devices, it is possible that the same iOS device appears in different "infected" IP addresses, which leads to an overestimation of the number of potential iOS victims. However, we argue that this is extremely unlikely in our dataset because the overestimation can only happen when the same iOS device is present behind different NAT-networks in the same ISP, and the NATs have infected computers that make purchases from Windows iTunes in the same day.

7.2 Mitigation and Prevention

Since Apple has remote removal and revocation abilities, they have complete mediation over what app can run on an iOS device. However, due to a significant number of apps on the App Store and the lack of runtime monitors on iOS devices, malicious apps are only detected when the users perceive adverse effects of the malicious apps. As a result, many iOS users may have already been affected by such attacks before the manually-triggered revocations and removal are applied. We have observed many Android botnets [42, 43] even though Google also has remote app removal ability [4]. In addition, this ability cannot prevent an attack that steals a user's cookies (as discussed in Section 4).

Since we only tested a few devices in the attack presented in Section 2, we cannot confirm whether Apple is able to impose a limit on the number of iOS devices that can be authorized per Apple ID. However, since registering an Apple ID only requires a valid email address, attackers can easily prepare a number of Apple IDs and use them to distribute malicious apps. Nonetheless, we still suggest that Apple should monitor the anomalous Apple IDs that deliver purchased apps to excessive number of devices. In addition, we advocate that iOS should warn the user when an app purchased by a different Apple ID is to be installed.

The attack in Section 3 relies on iOS developer licenses. An individual iOS developer license can only register up to 100 iOS devices, which prevents large scale exploitation. However, Apple has the enterprise developer license program, which allows provisioning of an arbitrary number of iOS devices. Although the application for an Enterprise iOS Developer License is arguably very difficult because one would require a Dun & Bradstreet (D-U-N-S) number, we have observed a lot of real world cases of abusing enterprise licenses, such as distributing pirated iOS apps [10], running GBA emulators [9], and delivering jailbreak exploits [7]. It is also

possible for attackers to obtain such licenses through infected machines under their control, rather than applying for one. As result, we suggest that iOS should warn the user when a provisioning profile is installed or prompts the user the first time an app is run that is signed by an unknown provisioning profile.

To prevent the malicious PC from stealing cookies through the USB connection, third-party developers should be aware that plaintext credentials could be easily leaked through the USB interface and store the credentials in a secure manner.

8 Conclusion

This paper discussed the feasibility of large scale infections of non-jailbroken iOS devices. We demonstrated three kinds of attacks against iOS devices that can be launched by a compromised computer: delivering Apple-signed malicious apps, delivering third-party developer signed malicious apps, and stealing private data from iOS devices. Furthermore, by analyzing DNS queries generated from more than half a million IP addresses in known botnets, we measured that on average, 23% of bots are likely to have USB connections to iOS devices, potentially leading to a large scale infection.

A Appendices

A.1 Fairplay

The code segments of iOS apps on the App Store are encrypted with AES-128. Specifically, rather than using a single pair of key and IV (Initialization Vector) per app, each 4K bytes (i.e., memory page size) of the code segment of an app are encrypted with a unique pair of key and IV. These keys and IVs are also encrypted and stored in an `supp` file that is inside the `SC_Info` folder within the app archive. Upon loading an encrypted app into memory, iOS will derive the decryption keys and IVs from the `supp` file, the `sinf` file that is also inside the `SC_Info` folder, and the `sidb` file that resides

under `/private/var/mobile/Library/FairPlay/iTunes_Control/iTunes/`. A heavily obfuscated kernel module `FairPlayIOKit` and a heavily obfuscated user space daemon `fairplayd` are involved in this process.

Furthermore, this user space daemon `fairplayd` is also involved in the generation of `afsync.rq` and `afsync.rq.sig` mentioned in Section 2.2. After receiving the syncing request from a PC, the air traffic control service `atc` running in iOS devices will communicate with `fairplayd` through Mach messages to generate `afsync.rq` and `afsync.rq.sig`.

A.2 Measurement

Exclude small business networks. We plotted the cumulative distribution for number of distinct valid domains queried from all CIDs in a day in Figure 6. Some CIDs queried a lot more than 2,000 distinct domains in a day, e.g., 25,138,224. However, we only show in Figure 6 until 2,000 unique domains in the x-axis. The CDF curve grows extremely slowly after 1,000 unique domains, and 99.5% of CIDs queried fewer than 1,000 unique domains in a day. Therefore, we only use CIDs that queried fewer than 1,000 distinct valid domains per day in our experiment.

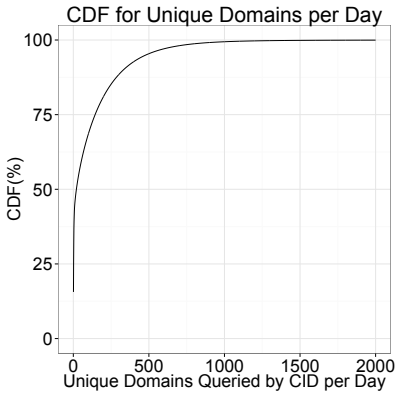

Figure 6: Cumulative distribution for number of distinct valid domains queried from all CIDs, on 10/12/2013.

A Large-Scale Analysis of the Security of Embedded Firmwares

Abstract

As embedded systems are more than ever present in our society, their security is becoming an increasingly important issue. However, based on the results of many recent analyses of individual firmware images, embedded systems acquired a reputation of being insecure. Despite these facts, we still lack a global understanding of embedded systems' security as well as the tools and techniques needed to support such general claims.

In this paper we present the first public, large-scale analysis of firmware images. In particular, we unpacked 32 thousand firmware images into 1.7 million individual files, which we then statically analyzed. We leverage this large-scale analysis to bring new insights on the security of embedded devices and to underline and detail several important challenges that need to be addressed in future research. We also show the main benefits of looking at many different devices at the same time and of linking our results with other large-scale datasets such as the ZMap's HTTPS survey.

In summary, without performing sophisticated static analysis, we discovered a total of 38 previously unknown vulnerabilities in over 693 firmware images. Moreover, by correlating similar files inside apparently unrelated firmware images, we were able to extend some of those vulnerabilities to over 123 different products. We also confirmed that some of these vulnerabilities altogether are affecting at least 140*K* devices accessible over the Internet. It would not have been possible to achieve these results without an analysis at such wide scale.

We believe that this project, which we plan to provide as a firmware unpacking and analysis web service[1], will help shed some light on the security of embedded devices.

[1] `http://firmware.re`

1 Introduction

Embedded systems are omnipresent in our everyday life. For example, they are the core of various Common-Off-The-Shelf (COTS) devices such as printers, mobile phones, home routers, and computer components and peripherals. They are also present in many devices that are less consumer oriented such as video surveillance systems, medical implants, car elements, SCADA and PLC devices, and basically anything we normally call *electronics*. The emerging phenomenon of the Internet-of-Things (IoT) will make them even more widespread and interconnected.

All these systems run special software, often called *firmware*, which is usually distributed by vendors as *firmware images* or *firmware updates*. Several definitions for *firmware* exist in the literature. The term was originally introduced to describe the CPU microcode that existed "somewhere" between the hardware and the software layers. However, the word quickly assumed a broader meaning, and the IEEE Std 610.12-1990 [6] extended the definition to cover the *"combination of a hardware device and computer instructions or computer data that reside as read-only software on the hardware device"*.

Nowadays, the term *firmware* is more generally used to describe the software that is embedded in a hardware device. Like traditional software, embedded devices' firmware may have bugs or misconfigurations that can result in vulnerabilities for the devices which run that particular code. Due to anecdotal evidence, embedded systems acquired a bad security reputation, generally based on case by case experiences of failures. For instance, a car model throttle control fails [47] or can be maliciously taken over [21, 55]; a home wireless router is found to have a backdoor [48, 7, 44], just to name a few recent examples. On the one hand, apart from a few works that targeted specific devices or software versions [39, 27, 63], to date there is still no large-scale security analysis of firmware images. On the other hand,

manual security analysis of firmware images yields very accurate results, but it is extremely slow and does not scale well for a large and heterogeneous dataset of firmware images. As useful as such individual reports are for a particular device or firmware version, these alone do not allow to establish a general judgment on the overall state of the security of firmware images. Even worse, the same vulnerability may be present in different devices, which are left vulnerable until those flaws are rediscovered independently by other researchers [48]. This is often the case when several *integration vendors* rely on the same subcontractors, tools, or SDKs provided by *development vendors*. Devices may also be branded under different names but may actually run either the same or similar firmware. Such devices will often be affected by exactly the same vulnerabilities, however, without a detailed knowledge of the internal relationships between those vendors, it is often impossible to identify such similarities. As a consequence, some devices will often be left affected by known vulnerabilities even if an updated firmware is available.

1.1 Methodology

Performing a large-scale study of the security of embedded devices by actually running the physical devices (i.e., using a dynamic analysis approach) has several major drawbacks. First of all, physically acquiring thousands of devices to study would be prohibitively expensive. Moreover, some of them may be hard to operate outside the system for which they are designed — e.g., a throttle control outside a car. Another option is to analyze existing online devices as presented by Cui and Stolfo [29]. However, some vulnerabilities are hard to find by just looking at the running device, and it is ethically questionable to perform any nontrivial analysis on an online system without authorization.

Unsurprisingly, static analysis scales better than dynamic analysis as it does not require access to the physical devices. Hence, we decided to follow this approach in our study. Our methodology consists of collecting firmware images for as many devices and vendors as possible. This task is complicated by the fact that firmware images are diverse and it is often difficult to tell firmware images apart from other files. In particular, distribution channels, packaging formats, installation procedures, and availability of meta-data often depend on the vendor and on the device type. We then designed and implemented a distributed architecture to unpack and run simple static analysis tasks on the collected firmware images. However, the contribution of this paper is not in the static analysis techniques we use (for example, we did not perform any static *code* analysis), but to show the advantages of an horizontal, large-scale exploration. For this reason, we implemented a correlation engine to compare and find similarities between all the objects in our dataset. This allowed us to quickly "propagate" vulnerabilities from known vulnerable devices to other systems that were previously not known to be affected by the same vulnerability.

Most of the steps performed by our system are conceptually simple and could be easily performed manually on a few devices. However, we identified *five major challenges* that researchers need to address in order to perform large scale experiments on thousands of different firmware images. These include the problem of building a representative dataset (Challenge A in Section 2), of properly identifying individual firmware images (Challenge B in Section 2), of unpacking custom archive formats (Challenge C in Section 2), of limiting the required computation resources (Challenge D in Section 2), and finally of finding an automated way to confirm the results of the analysis (Challenge E in Section 2). While in this paper we do not propose a complete solution for all these challenges, we discuss the way and the extent to which we dealt with some of these challenges to perform a systematic, automated, large-scale analysis of firmware images.

1.2 Results Overview

For our experiments we collected an initial set of `759,273` files (totaling `1.8TB` of storage space) from publicly accessible firmware update sites. After filtering out the obvious noise, we were left with `172,751` potential firmware images. We then sampled a set of `32,356` firmware candidates that we analyzed using a private cloud deployment of `90` worker nodes. The analysis and reports resulted in a `10GB` database.

The analysis of sampled files led us to automatically discover and report 38 new vulnerabilities (fixes for some of these are still pending) and to confirm several that were already known [44, 48]. Some of our findings include:

- We extracted private RSA keys and their self-signed certificates used in about 35,000 online devices (mainly associated with surveillance cameras).
- We extracted several dozens of hard-coded password hashes. Most of them were weak, and therefore we were able to easily recover the original passwords.
- We identified a number of possible backdoors such as the `authorized_keys` file (which lists the SSH keys that are allowed to remotely connect to the system), a number of hard-coded `telnetd` credentials affecting at least 2K devices, hard-coded web-login admin credentials affecting at least 101K de-

vices, and a number of backdoored daemons and web pages in the web-interface of the devices.
- Whenever a new vulnerability was discovered (by other researchers or by us) our analysis infrastructure allowed us to quickly find related devices or firmware versions that were likely affected by the same vulnerability. For example, our *correlation techniques* allowed us to correctly extend the list of affected devices for variations of a `telnetd` hard-coded credentials vulnerability. In other cases, this led us to find a vulnerability's root problem spread across multiple vendors.

1.3 Contributions

In summary this paper makes the following contributions:

- We show the advantages of performing a large-scale analysis of firmware images and describe the main challenges associated with this activity.
- We propose a framework to perform firmware collection, filtering, unpacking and analysis at large scale.
- We implemented several efficient static techniques that we ran on 32,356 firmware candidates.
- We present a correlation technique which allows to propagate vulnerability information to similar firmware images.
- We discovered 693 firmware images affected by at least one vulnerability and reported 38 new CVEs.

2 Challenges

As mentioned in the previous section, there are clear advantages of performing a wide-scale analysis of embedded firmware images. In fact, as is often the case in system security, certain phenomena can only be observed by looking at the global picture and not by studying a single device (or a single family of devices) at a time.

However, large-scale experiments require automated techniques to obtain firmware images, unpack them, and analyze the extracted files. While these are easy tasks for a human, they become challenging when they need to be fully automated. In this section we summarize the five main challenges that we faced during the design and implementation of our experiments.

Challenge A: Building a Representative Dataset

The embedded systems environment is heterogeneous, spanning a variety of devices, vendors, architectures, instruction sets, operating systems, and custom components. This makes the task of compiling a *representative* and *balanced* dataset of firmware images a difficult problem to solve.

The real market distribution of a certain hardware architecture is often unknown, and it is hard to compare different classes of devices (e.g., medical implants vs. surveillance cameras). Which of them need to be taken into account to build a representative firmware dataset? How easy is it to generalize a technique that has only been tested on a certain brand of routers to other vendors? How easy is it to apply the same technique to other classes of devices such as TVs, cameras, insulin pumps, or power plant controllers?

From a practical point of view, the lack of centralized points of collection (such as the ones provided by antivirus vendors or public sandboxes in the malware analysis field) makes it difficult for researchers to gather a large and well triaged dataset. Firmware often needs to be downloaded from the vendor web pages, and it is not always simple, even for a human, to tell whether or not two firmware images are for the same physical device.

Challenge B: Firmware Identification

One challenge often encountered in firmware analysis and reverse engineering is the difficulty of reliably extracting meta-data from a firmware image. For instance, such meta-data includes the vendor, the device product code and purpose, the firmware version, and the processor architecture, among many other details.

In practice, the diversity of firmware file formats makes it harder to even recognize that a given file downloaded from a vendor website is a firmware at all. Often firmware updates come in unexpected formats such as *HP Printer Job Language* and *PostScript* documents for printers [24, 23, 27], *DOS executables* for BIOS, and *ISO images* for hard disk drives [72].

In many cases, the only source of reliable information is the official vendor documentation. While this is not a problem when looking manually at a few devices, extending the analysis to hundreds of vendors and thousands of firmware images automatically downloaded from the Internet is challenging. In fact, the information retrieval process is hard to automate and is error prone, in particular for certain classes of meta-data. For instance, we often found it hard to infer the correct version number. This makes it difficult for a large-scale collection and analysis system to tell which is the latest version available for a certain device, and even if two firmware images corresponded to different versions for the same device. This further complicates the task of building an unbiased dataset.

Challenge C: Unpacking and Custom Formats

Assuming the analyst succeeded in collecting a representative and well labeled dataset of firmware images, the next challenge consists in locating and extracting important functional blocks (e.g., binary code, configuration files, scripts, web interfaces) on which static analysis routines can be performed.

While this task would be easy to address for traditional software components, where standardized formats for the distribution of machine code (e.g., PE and ELF), resources (e.g., JPEG and GZIP) and groups of files (e.g., ZIP and TAR) exist, embedded software distribution lacks standards. Vendors have developed their own file formats to describe flash and memory images. In some cases those formats are compressed with non-standard compression algorithms. In other cases those formats are obfuscated or encrypted to prevent analysis. Monolithic firmware, in which the bootloader, the operating system kernel, the applications, and other resources are combined together in a single memory image are especially challenging to unpack.

Forensic strategies, like file *carving*, can help to extract known file formats from a binary blob. Unfortunately those methods have drawbacks: On the one hand, they are often too aggressive with the result of extracting data that matches a file pattern only by chance. On the other hand, they are computationally expensive, since each unpacker has to be tried for each file offset of the binary firmware blob.

Finally, if a binary file has been extracted that does not match any known file pattern, it is impossible to say if this file is a data file, or just another container format that is not recognized by the unpacker. In general, we tried to unpack at least until reaching uncompressed files. In some cases, our extraction goes one step further and tries to extract sections, resources and compressed streams (e.g., for the ELF file format).

Challenge D: Scalability and Computational Limits

One of the main advantages of performing a wide-scale analysis is the ability of correlating information across multiple devices. For example, this allowed us to automatically identify the re-use of vulnerable components among different firmware images, even from different vendors.

Capturing the global picture of the relationship between firmware images would require the one-to-one comparison of each pair of unpacked files. Fuzzy hashes (such as sdhash [62] and ssdeep [54]) are a common and effective solution for this type of task and they have been successfully used in similar domains, e.g., to correlate samples that belong to the same malware families [35, 15]. However, as described in more detail in Section 3.4, computing the similarity between the objects extracted from 26,275 firmware images requires 10^{12} comparisons. Using the simpler fuzzy hash variant, we estimate that on a single dual-core computer this task would take approximately 850 days[2]. This simple estimation highlights one of the possible *computational challenges* associated with a large-scale firmware analysis. Even if we had a perfect database design and a highly optimized in-memory database, it would still be hard to compute, store, and query the fuzzy hash scores of all pairs of unpacked files. A distributed computational infrastructure can help reduce the total time since the task itself is parallelizable [57]. However, since the number of comparisons grows quadratically with the number of elements to compare, this problem quickly becomes impracticable for large image datasets. If, for example, one would like to build a fuzzy hash database for our whole dataset, which is just five times the size of the current sampled dataset, this effort would already take more than 150 CPU years instead of 850 CPU days. Our attempt to use the GPU-assisted fuzzy hashing provided by `sdhash` [62] only resulted in a limited speedup that was not sufficient to perform a full-scale comparison of all files in our dataset.

Challenge E: Results Confirmation

The first four challenges were mostly related to the collection of the dataset and the pre-processing of the firmware images. Once the code or the resources used by the embedded device have been successfully extracted and identified, researchers can focus their attention on the static analysis. Even though the details and goals of this step are beyond the scope of this paper, in Section 3.3 we present some examples of simple static analysis and we discuss the advantages of performing these techniques on a large scale.

However, one important research challenge remains regarding the way the results of static analysis can be confirmed. For example, we can consider a scenario where a researcher applies a new vulnerability detection technique to several thousand firmware images. Those images were designed to run on specific embedded devices, most of which are not available to the researcher and would be hard and costly to acquire. Lacking the proper hardware platform, there is still no way to manually or automatically test the *affected code* to confirm or deny the findings of the static analysis.

For example, in our experiments we identified a firmware image that included the `PHP 5.2.12` banner string. This allowed us to easily identify several vulnerabilities

[2] This is mainly because comparing fuzzy hashes is not a simple bit string comparison but actually involves a rather complex algorithm and high computational effort.

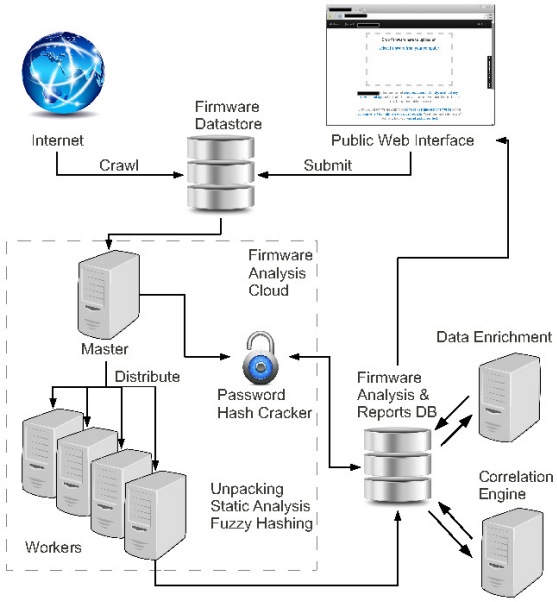

Figure 1: Architecture of the entire system.

associated with that version of the PHP interpreter. However, this is insufficient to determine if the PHP interpreter is vulnerable, since the vendor may have applied patches to correct known vulnerabilities without this being reflected in the version string. In addition, the vendor might have used an architecture and/or a set of compilation options which produced a non-vulnerable build of the component. Unfortunately, even if a proof of concept attack exists for that vulnerability, without the proper hardware it is impossible to test the firmware and confirm or deny the presence of the problem.

Confirming the results of the static analysis on firmware devices is a tedious task requiring manual intervention from an expert. Scaling this effort to thousands of firmware images is even harder. Therefore, we believe the development of new techniques is required to accurately deal with this problem at a large scale.

3 Setup

In this section we first present the design of our distributed static analysis and correlation system. Then we detail the techniques we used, and how we addressed the challenges described in Section 2.

3.1 Architecture

Figure 1 presents an overview of our architecture. The first component of our analysis platform is the *firmware data store*, which stores the unmodified firmware files that have been retrieved either by the *web crawler* or that have been submitted through the public *web interface*. When a new file is received by the firmware data store, it is automatically scheduled to be processed by the *analysis cloud*. The analysis cloud consists of a master node, and a number of worker and hash cracking nodes. The *master node* distributes unpacking jobs to the *worker nodes* (Figure 2), which unpack and analyze firmware images. *Hash cracking nodes* process password hashes that have been found during the analysis, and try to find the corresponding plaintext passwords. Apart from coordinating the worker nodes, the master node also runs the *correlation engine* and the *data enrichment system* modules. These modules improve the reports with results from the cross-firmware analysis.

The analysis cloud is where the actual analysis of the firmware takes place. Each firmware image is first submitted to the *master node*. Subsequently, *worker nodes* are responsible for unpacking and analyzing the firmware and for returning the results of the analysis back to the master node. At this point, the master node will submit this information to the *reports database*. If there were any uncracked password hashes in the analyzed firmware, it will additionally submit those hashes to one of the *hash cracking nodes* which will try to recover the plaintext passwords.

It is important to note that only the results of the analysis and the meta-data of the unpacked files are stored in the database. Even though we do not currently use the extracted files after the analysis, we still archive them for future work, or in case we want to review or enhance a specific set of analyzed firmware images.

The architecture contains two other components: the *correlation engine* and the *data enrichment system*. Both of them fetch the results of the firmware analysis from the reports database and perform additional tasks. The correlation engine identifies a number of “interesting” files and tries to correlate them with any other file present in the database. The enrichment system is responsible for enhancing the information about each firmware image by performing online scans and lookup queries (e.g., detecting vendor name, device name/code and device category).

In the remainder of this section we describe each step of the firmware analysis in more detail so that our experiments can be reproduced.

3.2 Firmware Acquisition and Storage

The first step of our experiments consisted in gathering a firmware collection for analysis. We achieved this goal by using mainly two methods: a web crawler that automatically downloads files from manufacturers’ websites and specialized mirror sites, and a website with a submis-

sion interface where users can submit firmware images for analysis.

We initialized the crawler with tens of support pages from well known manufacturers such as Xerox, Bosch, Philips, D-Link, Samsung, LG, Belkin, etc. Second, we used public FTP indexing engines [3] to search for files with keywords related to firmware images (e.g., `firmware`). The result of such searches yields either directory URLs, which are added to the crawler list of URLs to index and download, or file URLs, which are directly downloaded by the crawler. At the same time, the script strips filenames out of the URLs to create additional directory URLs.

Finally, we used Google Custom Search Engines (GCSE) [3] to create customized search engines. GCSE provides a flexible API to perform advanced search queries and returns results in a structured way. It also allows to programmatically create a very customized CSE on-the-fly using a combination of RESTful and XML APIs. For example, a CSE is created using `support.nikonusa.com` as the "Sites to Search" parameter. Then a firmware related query is used on the CSE such as `''firmware download''`. The CSE from the above example returns 2,210 results at the time of this publication. The result URLs along with associated meta-data are retrieved via the JSON API. Each URL was then used by the crawler or as part of other dynamic CSE, as previously described. This allowed us to mine additional firmware images and firmware repositories.

We chose not to filter data at collection time, but to download files greedily, deciding at a later stage if the collected files were firmware images or not. The reason for this decision is two-fold. First, accompanying files such as manuals and user guides can be useful for finding additional download locations or for extracting contained information (e.g., model, default passwords, update URLs). Second, as we mentioned previously, it is often difficult to distinguish firmware images from other files. For this reason, filtering a large dataset is better than taking a chance to miss firmware files during the downloading phase. In total, we crawled 284 sites and stopped downloading once the collection of files reached 1.8TB of storage. The actual storage required for this amount of data is at least 3-4 times larger, since we used mirrored backup storage, as well as space for keeping the unpacked files and files generated during the unpacking (e.g., logs and analysis results).

The public *web submission interface* provides a means for security researchers to submit firmware files for analysis. After the analysis is completed, the platform produces a report with information about the firmware contents as well as similarities to other firmware in our database. We have already received tens of firmware images through the submission interface. While this is currently a marginal source of firmware files, we expect that more firmware will be submitted as we advertise our service. This will also be a unique chance to have access to firmware images that are not generally available and, for example, need to be manually extracted from a device.

Files fetched by the web crawler and received from the web submission interface are added to the *firmware data store*. Files are simply stored on a file system and a database is used for meta-data (e.g., file checksum, size, download location).

3.3 Unpacking and Analysis

The next step towards the analysis of a firmware image is to unpack and extract the contained files or objects. The output of this phase largely depends on the type of firmware. In some examples, executable code and resources (such as graphics files or HTML code) can be linked into a binary blob that is designed to be directly copied into memory by a bootloader and then executed. Some other firmware images are distributed in a compressed and obfuscated file which contains a block-by-block copy of a flash image. Such an image may consist of several partitions containing a bootloader, a kernel and a file system.

Unpacking Frameworks

There are three main tools to unpack arbitrary firmware images: binwalk [41], FRAK [26] and Binary Analysis Toolkit (BAT) [66].

Binwalk is a well known firmware unpacking tool developed by Craig Heffner [41]. It uses pattern matching to locate and carve files from a binary blob. Additionally, it also extracts meta-data such as license strings.

FRAK is an unpacking toolkit first presented by Cui et al. [27]. Even though the authors mention that the tool would be made publicly available, we were not able to obtain a copy. We therefore had to evaluate its unpacking performance based on the device vendors and models that FRAK supports, according to [27]. We estimated that FRAK would have unpacked less than 1% of the files we analyzed, while our platform was able to unpack more than 81% of them. This said, both would be complementary as some of the file formats FRAK unpacks are unsupported by our tool at present.

The Binary Analysis Toolkit (BAT), formerly known as GPLtool, was originally designed by Tjaldur software to detect GPL violations [45, 66]. To this end, it recursively extracts files from a firmware blob and matches strings with a database of known strings from

Table 1: Comparison of Binwalk, BAT, FRAK and our framework. The last three columns show if the respective unpacker was able to extract the firmware. Note that this is a non statistically significant sample which is given for illustrating unpacking performance (manual analysis of each firmware is time consuming). As FRAK was not available for testing, its unpacking performance was estimated based on information from [26]. The additional performance of our framework stems from the many customizations we have incrementally developed over BAT (Figure 2).

Device	Vendor	OS	Binwalk	BAT	FRAK	Our framework
PC	Intel	BIOS	✗	✗	✗	✗
Camera	STL	Linux	✗	✓	✗	✓
Router	Bintec	-	✗	✗	✗	✗
ADSL Gateway	Zyxel	ZynOS	✓	✓	✗	✓
PLC	Siemens	-	✓	✓	✗	✓
DSLAM	-	-	✓	✓	✗	✓
PC	Intel	BIOS	✓	✓	✗	✓
ISDN Server	Planet	-	✓	✓	✗	✓
Voip	Asotel	Vxworks	✓	✓	✗	✓
Modem	-	-	✗	✗	✗	✓
Home Automation	Belkin	Linux	✗	✗	✗	✓
			55%	64%	0%	82%

GPL projects. Additionally, BAT supports file carving similar to binwalk.

Table 1 shows a simple comparison of the unpacking performance of each framework on a few samples of firmware images. We chose to use BAT because it is the most complete tool available for our purposes. It also has a significantly lower rate of false positive extractions compared to binwalk. In addition, binwalk did not support recursive unpacking at the time when we decided on an unpacking framework. Nevertheless, the interface between our framework and BAT has been designed to be generic so that integrating other unpacking toolkits (such as binwalk) is easy.

We developed a range of additional plugins for BAT. These include plugins which extract interesting strings (e.g., software versions or password hashes), add unpacking methods, gather statistics and collect interesting files such as private key files or `authorized_keys` files. In total we added 35 plugins to the existing framework.

Password Hash Cracking

Password hashes found during the analysis phase are passed to a hash cracking node. These nodes are dedicated physical hosts with a Nvidia Tesla GPU [56] that run a CUDA-enabled [59] version of *John The Ripper* [60]. John The Ripper is capable of brute forcing most encoded password hashes and detecting the type of hash and salt used. In addition to this, a dictionary can be provided to seed the password cracking. For each brute force attempt, we provide a dictionary built from common password lists and strings extracted from firmwares, manuals, *readme* files and other resources. This allows to find both passwords that are directly present in those files as well as passwords that are weak and based on keywords related to the product.

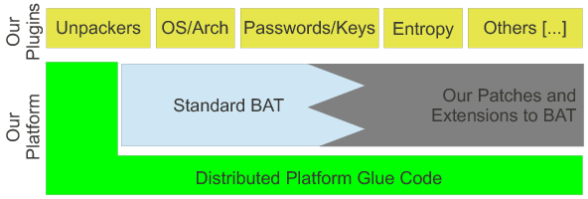

Figure 2: Architecture of a single worker node.

Parallelizing the Unpacking and Analysis

To accelerate the unpacking process, we distributed this task on several worker nodes. Our distributed environment is based on the *distributed-python-for-scripting* framework [65]. Data is synchronized between the repository and the nodes using *rsync (over ssh)* [67].

Our loosely coupled architecture allows us to run worker nodes virtually anywhere. For instance, we instantiated worker virtual machines on a local VMware server and several OpenStack servers, as well as on Amazon EC2 instances. At the time of this publication we were using 90 such virtual machines to analyze firmware files.

3.4 Correlation Engine

The unpacked firmware images and analysis results are stored into the *analysis & reports database*. This allows us to perform queries, to generate reports and statistics, and to easily integrate our results with other external components. The correlation engine is designed to find similarities between different firmware images. In particular, the comparison is made along four different dimensions: shared credentials, shared self-signed certificates, common keywords, and fuzzy hashes of the firmwares and objects within the firmwares.

Shared Credentials and Self-Signed Certificates

Shared credentials (such as hard coded *non-trivial* passwords) and shared self-signed certificates are effective in finding strong connections between different firmware images of the same vendor, or even firmwares of different vendors. For example, we were able to correlate two brands of CCTV systems based on a common *non-trivial* default password.

Therefore, finding a password of one vendor's product can directly impact the security of others. We also found a similar type of correlation for two other CCTV vendors that we linked through the same self-signed certificate, as explained in Section 5.2.

Keywords

Keywords correlation is based on specific strings extracted by our static analysis plugins. In some cases, for example in Section 5.1, the keyword "`backdoor`" revealed several other keywords. By using the extended set of keywords we clustered several vendors prone to the same backdoor functionality, possibly affecting $500,000$ devices. In other cases, files inside firmware images contain compilation and SDK paths. This turns out to be sufficient to cluster firmware images of different devices.

Fuzzy hashes

Fuzzy hash triage (comparison, correlation and clustering) is the most generic correlation technique used by our framework. The engine computes both the *ssdeep* and the *sdhash* of every single object extracted from the firmware image during the unpacking phase. This is a powerful technique that allows us to find files that are "similar" but for which a traditional hash (such as *MD5* or *SHA1*) would not match. Unfortunately, as we already mentioned in Section 2, a complete one-to-one comparison of fuzzy hashes is currently infeasible on a large scale. Therefore, we compute the fuzzy hashes of each file that was successfully extracted from a firmware image and store this result. When a file is found to be interesting we perform the fuzzy hash comparison between this file's hash and all stored hashes.

For example, a file (or all files unpacked from a firmware) may be flagged as interesting because it is affected by a known vulnerability, or because we found it to be vulnerable by static analysis. If another firmware contains a file that is similar to a file from a vulnerable firmware, then there might be a chance that the first firmware is also vulnerable. We present such an example in Section 5.3, where this approach was successful and allowed us to propagate known vulnerabilities of one device to other similar devices of *different* vendors.

Future work

In the literature, there are several approaches proposed to perform comparison, clustering, and triage on a large scale. Jang et al. propose large-scale triage techniques of PC malware in BitShred [52]. The authors concluded that at the rate of 8,000 unique malware samples per day, which required 31M comparisons, it is unfeasible on a single CPU to perform one-to-one comparisons to find malware families using hierarchical clustering. French and Casey [13] propose, before fuzzy hash comparison, to perform a "bins" partitioning approach based on the block and file sizes. This approach, for their particular dataset and bins partitioning strategy, allowed on average to reduce the search space for a given fuzzy hash down to 16.9%. Chakradeo et al. [20] propose MAST, an effective and well performing triage architecture for mobile market applications. It solves the manual and resource-intensive automated analysis at market-scale using Multiple Correspondence Analysis (MCA) statistical method.

As a future work, there are several possible improvements to our approach. For instance, instead of performing all comparisons on a single machine, we could adopt a distributed comparison and clustering infrastructure, such as the Hadoop implementation of MapReduce [32] used by BitShred. Second, on each comparison and clustering node we could use the "bins" partitioning approach from French and Casey [13].

3.5 Data Enrichment

The data enrichment phase is responsible for extending the knowledge base about firmware images, for example by performing automated queries and passive scans over the Internet. In the current prototype, the data enrichment relies on two simple techniques. First, it uses the `<title>` tag of web pages and `authentication realms` of web servers when these are detected inside a firmware. This information is then used to build targeted *search queries* (such as *"intitle:Router ABC-123 Admin Page"*) for both Shodan [5] and GCSE.

Second, we correlate SSL certificates extracted from firmware images to those collected by the ZMap project. ZMap was used in [37] to scan the whole IPv4 address space on the 443 port, collecting SSL certificates in a large database.

Correlating these two large-scale databases (i.e., ZMap's HTTPS survey and our firmware database) provides new insights. For example, we are able to quickly evaluate the severity of a particular vulnerability by identifying publicly reachable devices that are running a given firmware image. This gives a good estimate for the number of publicly accessible vulnerable devices.

For instance, our framework found 41 certificates having unprotected private keys. Those keys were extracted from firmware images in the unpacking and analysis phase. The data enrichment engine subsequently found the same self-signed certificate in over 35K devices reachable on the Internet. We detail this case study in Section 5.2.

3.6 Setup Development Effort

Our framework relies on many existing tools. In addition to this, we have put a considerable effort (over 20k lines of code according to `sloccount` [68]) to extend BAT, develop new unpackers, create the results analysis platform and run results interpretation.

4 Dataset and Results

In this section we describe our dataset and we present the results of the global analysis, including the discussion of the new vulnerabilities and the common bad practices we discovered in our experiments. In Section 5, we will then present a few concrete case studies, illustrating how such a large dataset can provide new insights into the security of embedded systems.

4.1 General Dataset Statistics

While we currently collect firmware images from multiple sources, most of the images in our dataset have been downloaded by crawling the Internet. As a consequence, our dataset is biased towards devices for which firmware updates can be found online, and towards known vendors that maintain well organized websites.

We also decided to exclude firmware images of smartphones from our study. In fact, popular smartphone firmware images are complete operating system distributions, most of them iOS, Android or Windows based – making them closer to general purpose systems than to embedded devices.

Our crawler collected 759,273 files, for a total of 1.8TB of data. After filtering out the files that were clearly unrelated (e.g., manuals, user guides, web pages, empty files) we obtained a dataset of 172,751 files. Our architecture is constantly running to fetch more samples and analyze them in a distributed fashion. At the time of this publication the system was able to process (unpack and analyze) 32,356 firmware images.

Firmware Identification The problem of properly identifying a firmware image (Challenge 2) still requires a considerable amount of manual effort. Doing so accurately and automatically at a large scale is a daunting task. Nevertheless, we are interested in having an estimate of the number of actual firmware images in our dataset.

For this purpose we manually analyzed a number of random samples from our dataset of 172,751 potential firmware images and computed a *confidence interval* [19] to estimate the global representativeness in the dataset. In particular, after manually analyzing 130 random files from the total of 172,751, we were able to mark only 44 as firmware images. This translates to a proportion of 34% ($\pm$ 8%) firmware images on our dataset – with a 95% confidence. The manual analysis process took approximately one person-week because the inspection of the extracted files for firmware code is quite tedious.

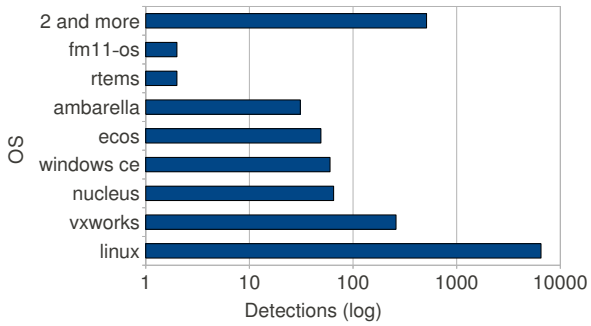

Figure 3: OS distribution among firmware images.

We can therefore expect our dataset to contain between 44,431 and 72,520 firmware images (by applying 34%−8%, and 34%+8% respectively, to the entire candidates set of 172,751). While the range is still relatively large, this estimation gives a 95% reliable measure of the useful data in our sample. We also developed a heuristic to automatically detect if a file is successfully unpacked or not. This heuristic takes multiple parameters, such as the number, type and size of files carved out from a firmware, into account. Such an empirical heuristic is not perfect, but it can guide our framework to mark a file as unpacked or not, and then take actions accordingly.

Files Analysis As described in Section 3.3, unpacking unknown files is an error-prone and time-consuming task. In fact, when the file format is not recognized, unpacking relies on a slow and imprecise carving approach. File carving is essentially an attempt to unpack at every offset of the file, iterating over several known signatures (e.g., archive magic headers).

As a result, out of the 32,356 files we processed so far, 26,275 were successfully unpacked. The process is nevertheless continuous and more firmware images are being unpacked over time.

4.2 Results Overview

In the rest of the section we present the results of the analysis performed by our plugins right after each firmware image was unpacked.

Files Formats The majority of initial files being unpacked were identified as *compressed files* or *raw data*. Once unpacked, most of those firmware images were

identified as targeting ARM (63%) devices, followed by MIPS (7%). As reported in Figure 3, Linux is the most frequently encountered embedded operating system in our dataset – being present in more than three quarters (86%) of all analyzed firmware images. The remaining images contain proprietary operating systems like VxWorks, Nucleus RTOS and Windows CE, which altogether represent around 7%. Among Linux based firmware images, we identified 112 distinct Linux kernel versions.

Password Hashes Statistics Files like `/etc/passwd` and `/etc/shadow` store hashed versions of account credentials. These are usual targets for attackers since they can be used to retrieve passwords which often allow to login remotely to a device at a later time. Hence, an analysis of these files can help understanding how well an embedded device is protected.

Our plugin responsible for collecting entries from `/etc/passwd` and `/etc/shadow` files retrieved 100 distinct password hashes, covering 681 distinct firmware images and belonging to 27 vendors. We were also able to recover the plaintext passwords for 58 of those hashes, which occur in 538 distinct firmware images. The most popular passwords were `<empty>`, `pass`, `logout`, and `helpme`. While these may look trivial, it is important to stress that they are actually used in a large number of embedded devices.

Certificates and Private RSA Keys Statistics Many vendors include self-signed certificates inside their firmware images [43, 42]. Due to bad practices in both *release management* and *software design*, some vendors also include the private keys (e.g., PEM, GPG), as confirmed by recent advisories [49, 51].

We developed two simple plugins for our system which collect SSL certificates and private keys. These plugins also collect their fingerprints and check for empty or trivial passphrases. So far, we have been able to extract 109 private RSA keys from 428 firmware images and 56 self-signed SSL certificates out of 344 firmware images. In total, we obtained 41 self-signed SSL certificates together with their corresponding private RSA keys. By looking up those certificates in the public ZMap datasets [36], we were able to automatically locate about 35,000 active online devices.

For all these devices, if the certificate and private key are not regenerated on the first boot after a firmware update, HTTPS encryption can be easily decrypted by an attacker by simply downloading a copy of the firmware image. In addition, if both a regenerated and a firmware-shipped self-signed certificate are used interchangeably, the user of the device may still be vulnerable to man-in-the-middle (MITM) attacks.

Packaging Outdated and Vulnerable Software Another interesting finding relates to bad *release management* by embedded firmware vendors. Firmware images often rely on many third-party software and libraries. Those keep updating and have security fixes every now and then. OWASP Top Ten [61] lists *"Using Components with Known Vulnerabilities"* at position nine and underlines that *"upgrading to these new versions is critical"*.

In one particular case, we identified a relatively recently released firmware image that contained a kernel (version 2.4.20) that was built and packaged ten years after its initial release. In another case, we discovered that some recently released firmware images contained nine years old BusyBox versions.

Building Images as *root* While prototyping, putting together a build environment as fast as possible is very important. Unfortunately, sometimes the easiest solution is just to setup and run the entire toolchains as superuser.

Our analysis plugins extracted several compilation banners such as `Linux version 2.6.31.8-mv78100 (root@ubuntu) (gcc version 4.2.0 20070413 (prerelease)) Mon Nov 7 16:51:58 JST 2011` or `BusyBox v1.7.0 (2007-10-15 19:49:46 IST)`.

24% of the 450 unique banners we collected containing the `user@host` combinations were associated to the `root` user. In addition to this, among the 267 unique hostnames extracted from those banners, *ten* resolved to public IP addresses and *one* of these even accepted incoming SSH connections.

All these findings reveal a number of unsafe practices ranging from *build management* (e.g., build process done as `root`) to *infrastructure management* (e.g., build hosts reachable over public networks), to *release management* (e.g., usernames and hostnames not removed from production release builds).

Web Servers Configuration We developed plugins to analyze the configuration files of web servers embedded in the firmware images such as `lighttpd.conf` or `boa.conf`. We then parsed the extracted files to retrieve specific configuration settings such as the running user, the documents root directory, and the file containing authentication secrets. We collected in total 847 distinct web server configuration files and the findings were discouraging. We found that in more than 81% of the cases the web servers were configured to run as a privileged user (i.e., having a setting such as `user=root`). This reveals unsafe practices of insecure design and configuration. Running the web server of an embedded device with unnecessarily high privileges can be extremely risky since the security of the entire device can be compromised by finding a vulnerability in one of the web components.

5 Case Studies

5.1 Backdoors in Plain Sight

Many backdoors in embedded systems have been reported recently, ranging from very simple cases [44] to others that were more difficult to discover [50, 64]. In one famous case [44], the backdoor was found to be activated by the string "`xmlset_roodkcableoj28840ybtide`" (i.e., `edit by 04882 joel backdoor` in reverse). This fully functional backdoor was affecting three vendors. Interestingly enough, this backdoor may have been detected earlier by a simple keyword matching on the open source release from the vendor[2].

Inspired by this case, we performed a string search in our dataset with various backdoor related keywords. Surprisingly, we found 1198 matches, in 326 firmware candidates.

Among those search results, several matched the firmware of a home automation device from a major vendor. According to download statistics from Google Play and Apple App Store, more than half a million users have downloaded an app for this device [9, 8].

We manually analyzed the firmware of this Linux-based embedded system and found that a daemon process listens on a network multicast address. This service allows execution of remote commands with `root` privileges without any authentication to anybody in the local network. An attacker can easily gain full control if he can send multicast packets to the device.

We then used this example as a *seed* for our *correlation engine*. With this approach we found exactly the same backdoor in two other classes of devices from two different vendors. One of them was affecting 109 firmware images of 44 camera models of a major CCTV solutions vendor, *Vendor C*. The other case is affecting three firmware images for home routers of a major networking equipment vendor, *Vendor D*.

We investigated the issue and found that the affected devices were relying on the same provider of a System on a Chip (SoC) for networking devices. It seems that this backdoor is intended for system debugging, and is part of a development kit. Unfortunately we were not able to locate the source of this binary. We plan to acquire some of those devices to verify the exploitability of the backdoor.

5.2 Private SSL Keys

In addition to the backdoors left in firmware images from *Vendor C*, we also found many firmware images containing public and *private RSA key* pairs. Those unprotected keys are used to provide SSL access to the CCTV camera's web interface. Surprisingly, this private key is the same across many firmware images of the same brand.

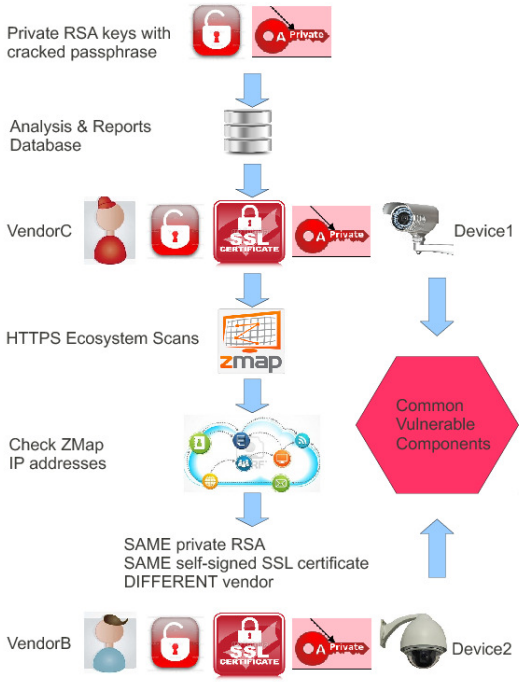

Figure 4: Correlation engine and shared self-signed certificates clustering.

Our platform automatically extracts the fingerprint of the public keys, private keys and SSL certificates. Those keys are then searched in ZMap's HTTPS survey database [36, 37]. *Vendor C*'s SSL certificate was found to be used by around 30K online IP addresses, most likely each corresponding to a single online device. We then fetched the web pages available at those addresses (without trying to authenticate). Surprisingly, we found CCTV cameras branded by another vendor – *Vendor B* – which appears to be an *integrator*. Upon inspection, cameras of *Vendor B* served *exactly the same* SSL certificate as cameras from *Vendor C* (including the SSL *Common Name*, and SSL *Organizational Unit* as well as many other fields of the SSL certificate). The only difference is that CCTV cameras of *Vendor B* returned branded authentication realms, error messages and logos. The *correlation engine* findings are summarized in Figure 4.

Unfortunately, the firmware images from *Vendor B* do not seem to be publicly available. We are planning to obtain a device to extract its firmware and to confirm our findings. We have reported these issues to the vendor. Nevertheless, it is very likely that devices from *Vendor B* are also vulnerable to the multicast packet backdoor given the clear relationship with *Vendor C* that that our platform discovered.

5.3 XSS in WiFi Enabled SD Cards?

SD cards are often more complex than one would imagine. Most SD cards actually contain a processor which runs firmware. This processor often manages functions such as the flash memory translation layer and wear leveling. Security issues have been previously shown on such SD cards [69].

Some SD cards have an embedded WiFi interface with a full fledged web server. This interface allows direct access to the files on the SD card without ejecting it from the device in which it is inserted. It also allows administration of the SD card configuration (e.g., WiFi access points).

We manually found a Cross Site Scripting (XSS) vulnerability in one of these web interfaces, which consists of a `perl` based web application. As this web application does not have platform specific binary bindings, we were able to load the files inside a similar Boa web server on a PC and confirm the vulnerability.

Once we found the exact `perl` files responsible for the XSS, we used our correlation engine based on fuzzy hashes. With this we automatically found another SD card firmware that is vulnerable to the same XSS. Even though the `perl` files were slightly different, they were clearly identified as similar by the fuzzy hash. This correlation would not have been detected by a normal checksum or by a regular hash function.

The process is visualized in Figure 5. The file (*) was found vulnerable. Subsequently, we identified correlated files based on fuzzy hashing. Some of them were related to the same firmware or a previous version of the firmware of the *same* vendor (in red). Also, fuzzy hash correlation identified a similar file in a firmware from a *different* vendor (in orange) that is vulnerable to the same weakness. It further identified some non-vulnerable or non-related files from other vendors (in green).

Those findings are reported as `CVE-2013-5637` and `CVE-2013-5638`. We were also able to confirm this vulnerability and extend the list of affected versions for one of these vendors.

Such manual vulnerability confirmation does not scale. Hence, in the future we plan to integrate static analysis tools for web applications [30, 11, 53, 38, 1] in our process.

6 Ethical Discussion

Large-scale scans to test for the presence of vulnerabilities often raise serious ethical concerns. Even simple Internet-wide network scans may trigger alerts from intrusion detection systems (IDS) and may be perceived as an attack by the scanned networks.

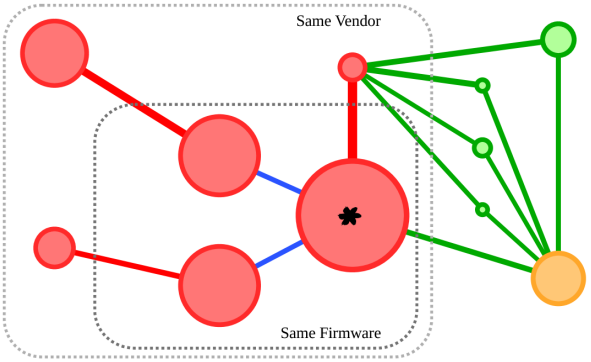

Figure 5: Fuzzy hash clustering and vulnerability propagation. A vulnerability was propagated from a *seed file (*)* to other two files from the same firmware and three files from the same vendor (in red) as well as one file from another vendor (in orange). Also four non-vulnerable files (in green) have a strong correlation with vulnerable files. Edge thickness displays the strength of correlation between files.

In our study we were particularly careful to work within legal and ethical boundaries. First, we obtain firmware images either through user submission or through legitimate distribution mechanisms. In this case, our web crawler was designed to obey the `robots.txt` directives. Second, when we found new vulnerabilities we worked together with vendors and CERTs to confirm the devices vulnerabilities and to perform responsible disclosure. Finally, the license of some firmware images may not allow redistribution. Therefore, the public web submission interface limits the ability to access firmware contents only to the users who uploaded the corresponding firmware image. Other users can only access anonymized reports. We are currently investigating ways to make the full dataset available for research purposes to well identified research institutions.

7 Related Work

Several studies have been proposed to asses the security of embedded devices by scanning the Internet. For instance, Cui et al. [28, 29] present a wide-scale Internet scan to first recognize devices that are known to be shipped with default password, and then to confirm that these devices are indeed still vulnerable by attempting to login into them. Heninger et al. [46] performed the largest ever network survey of TLS and SSH servers, showing that vulnerable keys are surprisingly widespread and that the vast majority appear to belong to headless or embedded devices. ZMap [37] is an efficient and fast network scanner, that allows to scan the complete Internet IPv4 address space in less than one hour. While the scans are not especially targeted to embedded devices, in our work we reuse the SSL certificates

scans performed by ZMap [36]. Similar scans were targeting specific vulnerabilities often present in embedded devices [40, 4]. Such wide-scale scans are mainly targeted at discovering online devices affected by already known vulnerabilities, but in some cases they can help to discover new flaws. However, many categories of flaws cannot be discovered by such scans. Some online services like Shodan [5] provide a global updated view on publicly available devices and web services. This easy-to-use research tool allows security researchers to identify systems worldwide that are potentially exposed or exploitable.

Unpacking firmware images is a known problem, and several tools for this purpose exist. Binwalk [41] is a firmware analysis toolbox that provides various methods and tools for extraction, inspection and reverse engineering of firmware images or other binary blobs. FRAK [26] is a framework to unpack, analyze, and repack firmware images of embedded devices. `FRAK` was never publicly released and reportedly supports only a few firmware formats (e.g., Cisco IP phones and IOS, HP laser printers). The Binary Analysis Toolkit (BAT) [45, 66] was originally designed to detect GPL license violations, mainly by comparing strings in a firmware image to strings present in open source software distributions. For this purpose `BAT` has to unpack firmware images. Unfortunately, as we show in Section 3, none of these tools are accurate and complete enough to be used *as is* in our framework.

There are many examples of security analysis of embedded systems [71]. Several network card firmware images have been analyzed and modified to insert a backdoor [33, 34] or to extend their functionality [16]. Davidson et al. [31] propose `FIE`, built on top of the `KLEE` symbolic execution engine, to incorporate new symbolic execution techniques. It can be used to verify security properties of some simple firmware images often found in practice. Zaddach et al. [70] describe Avatar, a dynamic analysis platform for firmware security testing. In Avatar, the instructions are executed in an emulator, while the IO accesses to the embedded system's peripherals are forwarded to the real device. This allows a security engineer to apply a wide range of advanced dynamic analysis techniques like tracing, tainting and symbolic execution.

A large set of firmware images of Xerox devices were reverse-engineered by Costin [24] leading to the discovery of hidden PostScript commands. Such commands allow an attacker to e.g., dump a device's memory, recover passwords, passively scan the network and more generically interact with devices' OS layers. Such attacks could be delivered to printers via web pages, applets, MS Word and other standard printed documents [23].

Bojinov et al. [18] conducted an assessment of the security of current embedded management interfaces. The study, conducted on real physical devices, found vulnerabilities in 21 devices from 16 different brands, including network switches, cameras, photo frames, and lights-out management modules. Along with these, a new class of vulnerabilities was discovered, namely *cross-channel scripting (XCS)* [17]. While XCS vulnerabilities are not particular to embedded devices, embedded devices are probably the most affected population. In a similar study, the authors manually analyzed ten Small Office/Home Office (SOHO) routers [48] and discovered at least two vulnerabilities per device.

Looking at insecure (remote) firmware updates, researchers reported the possibility to arbitrarily inject malware into the firmware of a printer [24, 27]. Chen [22] and Miller [58] presented techniques and implications of exploiting Apple firmware updates. In a similar direction, Basnight et al. [12] examined the vulnerability of PLCs to intentional firmware modifications. A general firmware analysis methodology is presented, and an experiment demonstrates how legitimate firmware can be updated on an Allen-Bradley ControlLogix L61 PLC. Zaddach et al. [72] explore the consequences of a backdoor injection into the firmware of a hard disk drive and uses it to exfiltrate data.

French and Casey [13] present fuzzy hashing techniques in applied malware analysis. Authors used `ssdeep` on *CERT Artifact Catalog* database containing 10.7*M* files. The study underlines the two fundamental challenges to operational usage of fuzzy hashing at scale: timeliness of results, and usefulness of results. To reduce the quadratic complexity of the comparisons, they propose assigning files into "bins" based on the block and file sizes. This approach, for their particular dataset and bins partitioning strategy, allowed for a given fuzzy hash to reduce the search space on average by 83.1%.

Finally, Bailey et al. [10] and Bayer et al. [14] propose efficient clustering approaches to identify and group malware samples at large scale. Authors perform dynamic analysis to obtain the execution traces of malware programs or obtain a description of malware behavior in terms of system state changes. These are then generalized into behavioral profiles which serve as input to an efficient clustering algorithm that allows authors to handle sample sets that are an order of magnitude larger than previous approaches. Unfortunately, this approach cannot be applied in our framework since dynamic analysis is unfeasible due to the heterogeneity of architectures used in firmware images.

8 Conclusion

In this paper we conducted a large-scale static analysis of embedded firmwares. We showed that a broader view on firmware is not only beneficial, but actually necessary

for discovering and analyzing vulnerabilities of embedded devices. Our study helps researchers and security analysts to put the security of particular devices in context, and allows them to see how known vulnerabilities that occur in one firmware reappear in the firmware of other manufacturers.

We plan to continue collecting new data and extend our analysis to all the firmware images we downloaded so far. Moreover, we want to extend our system with more sophisticated static analysis techniques that allow a more in-depth study of each firmware image. This approach shows a lot of potential and besides the few previously mentioned case studies it can lead to new interesting results such as the ones recently found by Costin et al. [25].

The summarized datasets are available at `http://firmware.re/usenixsec14`.

Acknowledgments

We thank the anonymous reviewers for their many suggestions for improving this paper. In particular we thank our shepherd, Cynthia Sturton, for her valuable time and inputs guiding this paper for publication. We also thank Pietro Michiardi and Daniele Venzano for providing access and support to their cloud infrastructure, and John Matherly of Shodan search engine for providing direct access to Shodan's data and resources.

The research leading to these results was partially funded by the European Union Seventh Framework Programme (contract Nr 257007 and project FP7-SEC-285477-CRISALIS).

Exit from Hell? Reducing the Impact of Amplification DDoS Attacks

Marc Kührer, Thomas Hupperich, Christian Rossow, Thorsten Holz
Horst Görtz Institute for IT-Security, Ruhr-University Bochum

Abstract

Amplification vulnerabilities in many UDP-based network protocols have been abused by miscreants to launch Distributed Denial-of-Service (DDoS) attacks that exceed hundreds of Gbps in traffic volume. However, up to now little is known about the nature of the amplification sources and about countermeasures one can take to remediate these vulnerable systems. Is there any hope in mitigating the amplification problem?

In this paper, we aim to answer this question and tackle the problem from four different angles. In a first step, we monitored and classified amplification sources, showing that amplifiers have a high diversity in terms of operating systems and architectures. Based on these results, we then collaborated with the security community in a large-scale campaign to reduce the number of vulnerable NTP servers by more than 92%. To assess possible next steps of attackers, we evaluate amplification vulnerabilities in the TCP handshake and show that attackers can abuse millions of hosts to achieve 20x amplification. Lastly, we analyze the root cause for amplification attacks: networks that allow IP address spoofing. We deploy a method to identify spoofing-enabled networks *from remote* and reveal up to 2,692 Autonomous Systems that lack egress filtering.

1 Introduction

Distributed Denial-of-Service (DDoS) attacks have been known since many years [8,9,24,34] and they still constitute an important problem today. For a long time, DDoS attacks were hard to tackle due to their *semantic* nature: it is difficult to distinguish an actual attack from a sudden rise in popularity for a given service due to a flash crowd ("Slashdot effect"). A large body of literature is available on this topic and many DDoS detection mechanisms and countermeasures have been proposed over the years (e.g., [14,15,43]). Furthermore, advances in *Cloud computing* and load balancing techniques helped to mitigate this problem [17,18], and nowadays simple types of DDoS attacks such as *SYN* and *UDP flooding* are well-understood.

However, the adversaries evolved and modern DDoS attacks typically employ so called *amplification attacks*, in which attackers abuse UDP-based network protocols to launch DDoS attacks that exceed hundreds of Gbps in traffic volume [21, 22]. This is achieved via *reflective* DDoS attacks [31] where an attacker does not directly send traffic to the victim, but sends spoofed network packets to a large number of systems that reflect the traffic to the victim (so called *reflectors*). Often, attackers choose reflectors that send back responses that are significantly larger than the requests, leading to an increased (*amplified*) attack volume. We call such reflectors *amplifiers*. Recently, many types of such amplification attacks were discovered [33]. However, little is known about the nature of the amplifiers and about countermeasures one can take to remediate vulnerable systems.

In this paper, we address this problem and study the root causes behind amplification DDoS attacks. We tackle the problem from four different angles and provide empirical measurement results based on Internet-scale scanning to quantify the problem.

In a first step, we want to understand the nature of amplifiers and determine which kinds of systems are vulnerable. Previous work on empirically understanding DDoS attacks typically focused on ways to estimate the size of the problem and understanding the infrastructure behind such attacks [1, 5, 26]. To increase the understanding of amplification attacks, we utilized protocol-specific fingerprinting to reveal as much information as possible from systems that can be abused on the Internet. More specifically, we enumerated the amplifier sources for seven network protocols and performed large-scale scans to collect information about vulnerable systems. This enables us to categorize the types of devices that can be abused in the wild. We found that there is a large diversity of vulnerable devices and analyzed their properties. For example, we found 40.8% of the vulnerable NTP hosts to run Cisco IOS, an OS that is deployed on Cisco network devices.

Based on these insights on amplifiers, a viable next step is to reduce the number of vulnerable systems on the Internet. Previous work on that topic mainly focused

on understanding botnet Command & Control servers that are used to orchestrate classical DDoS attacks [5]. However, modern amplification attacks use a completely different modus operandi. We contributed to a global security notification procedure where our scanning results were used to notify NOCs and CERTs of hundreds of large ISPs worldwide about NTP servers vulnerable to amplification attacks. Furthermore, we collaborated with security organizations in order to create advisories that describe the technical background and approaches to solve the problem. We analyzed the remediation success of these measures and found that the number of NTP servers vulnerable to `monlist` amplification dropped by 92% in a 13-week period between November 2013 and February 2014. We closely analyzed this effect and found that especially vulnerable NTP servers within ARIN have been mitigated, while other geographic regions lag behind.

Since it seems feasible to significantly reduce the number of amplifiers, a third angle of the problem is an analysis of potential attack vectors that adversaries could abuse in the future. We start with the basic insight that up to now UDP-based protocols are leveraged by attackers, since these protocols provide large amplification factors. We study a completely different kind of amplification attacks, namely TCP-based ones. Surprisingly, even TCP can be abused for amplification attacks, despite the fact that this protocol uses a 3-way handshake. This is due to the fact that certain TCP stacks retransmit `SYN/ACK` packets multiple times (some 20x or more) when they presume that the initial `SYN/ACK` segment was lost. Thus an amplification of 20x or more is possible. Empirical scan results suggest that there are hundreds of thousands of systems on the Internet that can be abused this way. We performed protocol-specific fingerprinting to learn more about the nature of such devices.

As a fourth angle of the problem, we analyzed the root cause behind amplification attacks: if a given network does not perform *egress filtering* (i.e., verifies that the source IP address in all outbound packets is within the range of allocated internal address blocks, see BCP 38 [13] for details), an attacker can spoof packets and thus initiate the first step of reflective DDoS attacks. Identifying such networks is a challenging problem [12] and existing solutions rely on a client deployed in the network under test [3, 36]. We utilize a novel remote test based on DNS proxies that enables us to identify thousands of Autonomous Systems that support IP spoofing.
To summarize, our contributions are as follows:

- We performed Internet-wide scans to identify and monitor all relevant potential amplifiers for seven network protocols vulnerable to amplification attacks. We fingerprint and categorize these systems, showing a high diversity in the amplifier landscape.
- We study the success of a global security notification campaign to alert administrators of vulnerable NTP servers and show the benefits and limitations of such large-scale initiatives.
- Aiming to assess further amplification DDoS techniques, we identify TCP as an alternative source for amplification—despite its three-way-handshake protocol. We reveal millions of systems that can be abused to amplify TCP traffic by a factor up to 20x.
- Finally, we aim to tackle the root cause for amplification DDoS attacks: networks that do not perform egress filtering and thus allow IP address spoofing. We deploy a *remote* scanning technique and find up to 2,692 ASes that permit spoofed IP traffic.

Paper Outline. The paper is organized as follows. In Section 2, we define the threat model and outline our scanning setup to perform Internet-wide scans. We then shed light onto the landscape of hosts that are vulnerable to UDP-based amplification DDoS attacks. In Section 3, we detail the effects of our NTP case study. Section 4 tackles the problem of TCP-based amplifiers, demonstrating that the TCP three-way-handshake can be abused for amplification attacks. In Section 5, we introduce a novel mechanism to identify networks that allow IP address spoofing. Section 6 reviews prior work and we conclude this paper in Section 7.

2 Amplification DDoS

We begin with an analysis of the threat landscape. To this end, we first review the general threat model before we analyze different aspects of amplification DDoS attacks. More specifically, we study the amplifier magnitude, measure what kinds of devices can be abused on the Internet, and determine the churn of amplifiers.

2.1 Threat Model

The scope of this work are amplification DDoS attacks. In such an attack, a miscreant abuses public systems (such as open recursive DNS resolvers) to reflect attack traffic to a DDoS victim [31]. In particular, she abuses hosts that not only reflect but also amplify the traffic. Typically, the attacker chooses connection-less protocols in which she can send relatively small requests that result in significantly larger responses. By spoofing the source of the traffic (i.e., impersonating the victim), she can enforce that the public systems—unwillingly—amplify and reflect traffic to the victim. Prior work has revealed that at least 14 UDP-based protocols are vulnerable to such abuse [33]. These protocols offer severe amplification rates—in the worst case, as with the `monlist` feature in NTP, they amplify traffic by a factor of up to 4,670.

2.2 Amplifier Magnitude

In this paper, we try to shed light onto the landscape of *amplifiers*, i.e., hosts that are vulnerable to amplification abuse. As a first step, we enumerate and observe these amplifiers in the IPv4 address space. That is, we performed Internet-wide scans for a subset of the vulnerable protocols: DNS, SNMP, SSDP, CharGen, QOTD, NTP, and NetBIOS. We chose to monitor these protocols, as prior work only approximated the amplifier landscape for them. The amplification vulnerabilities of these seven protocols can be abused by attackers to launch severe amplification attacks. In addition, all these seven protocols run server-side, thus hosts running such protocols are seemingly better connected and more stable in terms of IP address churn than hosts of end users.

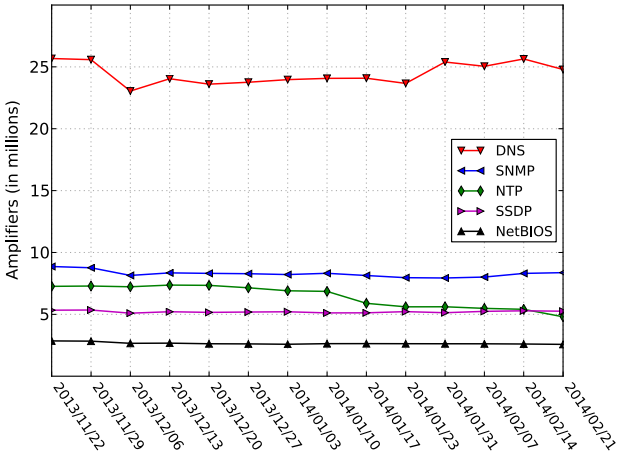

Figure 1: Trend of UDP-based amplifiers

Scanning Setup. We developed an efficient scanner to identify amplifiers for these protocols in Internet-wide scans. In order to respect good scanning practices as suggested by Durumeric et al. [11], we limit the number of requests that a particular network receives. For this reason, we compute the scan targets as a pseudo-random permutation of the entire IPv4 address space (except the IP address 0.0.0.0). That is, we use a linear feedback shift register (LFSR) to compute the order of the $2^{32}-1$ IPv4 addresses to be scanned. In order to avoid to become blacklisted, we refrained from aggressive scanning and distributed the scans over 48 hours. In addition, we set up a reverse DNS (rDNS) record for our scanner and configured a web server that presents project information and an explanation how to opt-out from our scans.

For each of the protocols, we send a request that can be used to amplify traffic. That is, we send NTP `version` requests, SSDP `SEARCH` requests, SNMP v2 `GetBulk` requests, DNS `A` lookups, and NetBIOS' default name lookup. We ran the scans on a weekly basis from Nov 22, 2013 to Feb 21, 2014 to observe potential changes in terms of amplifiers. We chose to use the weekends for our scans so that the load of both our scanning network and the scanned networks have less impact on business activities. In the case of CharGen and QOTD, we refrained from repeating the scans, as the number of amplifiers was too low to justify repeated full scans.

During the course of our scans, we received 90 emails from administrators asking about the scanning experiments. Adhering to these requests, we excluded 91 IP prefixes and 30 individual IP addresses (about 3.7 million IP addresses in total) after administrators asked us to do so. To allow comparisons between two scans, we ignored these IP addresses in all of our scans, i.e., even if they were not blacklisted at the beginning.

Table 1: Intersection of potential amplifiers based on the Internet-wide scan on Nov 22, 2013

	Intersection (in %)						
Protocol	*DNS*	*CharGen*	*NetBIOS*	*NTP*	*QOTD*	*SNMP*	*SSDP*
DNS	-	0.0	0.5	0.2	0.0	11.6	2.1
CharGen	1.7	-	2.4	20.0	4.0	9.4	1.3
NetBIOS	4.7	0.1	-	0.6	0.2	1.8	5.9
NTP	0.9	0.3	0.2	-	0.0	3.2	0.1
QOTD	14.0	11.8	18.5	8.4	-	4.2	8.5
SNMP	33.5	0.1	0.6	2.7	0.0	-	0.2
SSDP	9.9	0.0	3.1	0.2	0.1	0.4	-

Results. Figure 1 illustrates the number of identified amplifiers per protocol. By far the highest number of amplifiers was found for open recursive DNS resolvers, slightly fluctuating between 23 and 25.5 million systems. For most of the other protocols, the number of amplifiers is quite constant. An exception are NTP amplifiers, whose popularity constantly decreases, a phenomenon that we describe in detail in Section 3. None of the protocols (except for the two legacy protocols CharGen with 107,725 and QOTD with 36,609 vulnerable hosts) had fewer than 2.5 million amplifiers, showing a large landscape of hosts that can be abused.

Quite interestingly, some systems run multiple vulnerable services. Table 1 shows the intersection between the individual protocols relative to the overall number of amplifiers for the protocols specified in the first table column. The largest overlap is between DNS and SNMP: a third of the public SNMP hosts also run open recursive DNS resolvers. Note that the table is not symmetric, which, for example, reveals that less than 11.6% of the open DNS resolvers also run unprotected SNMP daemons. For most of the other protocols the intersection is negligible, though. This means that the number of amplifiers basically sums up. We measured almost 46 million amplifiers for all scanned UDP-based protocols.

Table 2: Results of the device fingerprinting for the amplifiers identified on Nov 22, 2013

	Hardware (in %)				Architecture (in %)					Operating System (in %)										
Protocol	*Router*	*Embedded*	*Others*	*Unknown*	*x86*	*MIPS*	*PowerPC*	*Others*	*Unknown*	*Unix*	*Linux*	*Ubuntu*	*FreeBSD*	*Windows*	*ZyNOS*	*Cisco IOS*	*Junos*	*NetOS*	*Others*	*Unknown*

2.3 Amplifier Classification

Observing the magnitude of the problem, we wondered what kinds of systems allow for such amplification vectors. In an attempt to answer this question, we use protocol-specific fingerprinting to reveal as much information as possible from these systems. That is, we generate device fingerprints by inspecting the replies from the amplifiers during our UDP scans. We dissect the responses of each host and protocol individually to classify systems in three categories: the underlying hardware (e.g., routers, desktop computers, or printers), the system architecture (such as x86, MIPS, or PowerPC), and the operating system.

Fingerprinting Setup. We manually compiled 1,873 regular expressions that allow a fine-granular generation of fingerprints. We further leverage Nmap service probes [27] to fingerprint the NetBIOS protocol. For NetBIOS, we also focus on the structure of the payload to obtain information about the OS. NTP `version` responses reveal the processor type, OS, and the version of the running NTP daemon. To generate fingerprints for the SNMP protocol, we analyze the object identifier values (OID) in the responses. For SSDP, the responses contain text fragments resembling HTTP headers that provide system information in the `Server` header field. Additionally, SSDP headers include Unique Service Name (USN) and Search Target (ST) fields, providing more general information about a device.

We improve the coverage of our UDP fingerprints by scanning the amplifiers for common TCP-based protocols. We use FTP, HTTP, HTTPS, SSH, and Telnet to leverage information in protocol banners and text fragments. We synchronize the TCP and UDP scans, hence once a full Internet-wide UDP scan is finished, we initiate a follow-up TCP scan for hosts that are found to be an amplifier for at least one UDP protocol.

Results. Table 2 depicts the fingerprint results obtained for the amplifiers found on Nov 22, 2013. For reasons of brevity, we summarize fingerprint details with less than 2% share to *Others*. Note that the category "router" also includes gateways, switches, and modems as many of these devices provide similar features.

The best results for the OS classification are achieved for NTP. We find that 40.8% of the vulnerable NTP hosts run Cisco IOS, an OS that is deployed on Cisco devices such as business routers and switches. We further identify 1,267,008 amplifiers (17.4%) running Linux on MIPS and 357,076 devices (4.9%) running Linux on PowerPC. These two combinations are common for consumer devices such as routers and modems. The majority of NTP amplifiers thus run on networking equipment.

Similarly, two thirds of the SNMP amplifiers are routers. With a share of 17.8%, the ZyNOS system stands out—apparently running unprotected SNMP services per default. But we also observe a wide distribution of other SNMP devices. This includes 58,000 office printers (0.7%), 51,037 firewall appliances (0.6%), and 40,061 network cameras (0.5%). Routers are even more prominent among SSDP hosts with a share of about 94.3%. This shows that at least three of the analyzed protocols are overly prominent on routers.

On the contrary, the vast majority of NetBIOS amplifiers run Windows on x86, a typical setup of desktop computers. Since the Conficker outbreak in 2008, it is known that millions of Windows systems on the Internet are reachable via the NetBIOS [32] protocol.

Unfortunately, DNS provides only limited fingerprint information and we thus had to solely rely on the TCP fingerprints to classify DNS servers. However, most DNS servers did not run TCP services, resulting in a high number of uncategorized hosts. Even if TCP services were accessible, the provided information was often too generic (e.g., banners as "Apache", "SSH-2.0-OpenSSH", or "FTP Server"). However, we could identify 5.4% of the hosts (1,388,348) as MIPS-based routers with ZyNOS, which is common for broadband routers distributed by manufacturer ZyXEL.

A high diversity of amplifiers is attested when looking at smaller clusters. For example, we find 695 vulnerable devices to be running *Miele Logic*, a payment system for Miele devices such as washing machines. Similarly, we identify 9,224 amplifiers running server man-

Table 3: Amplifier churn rate per protocol

	Initial Scan	Week 1		Week 13	
Protocol	(#)	(#)	(%)	(#)	(%)
DNS	25,681,450	12,190,302	47.5	8,263,508	32.2
NetBios	2,853,213	1,455,351	51.0	979,266	34.3
NTP	7,269,015	6,859,043	94.4	4,222,060	58.1
SNMP	8,866,748	4,939,118	55.7	3,411,563	38.5
SSDP	5,336,107	3,088,148	57.9	2,067,830	38.8

agement systems (like iLO, iDRAC, or IPMI). We further find 51,351 Digital Video Recorders, 7,739 Power Distribution Units, and 20,927 Network Attached Storage devices (NAS) to be vulnerable to amplification.

Ambiguous Fingerprints. We had to resolve a few conflicts when combining the fingerprints from multiple protocols. For NTP amplifiers, we find valid TCP fingerprints for 1,919,932 hosts, while conflicts emerge for 9,945 IP addresses (0.5%). For SNMP, we leverage TCP data for 2,042,541 amplifiers while obtaining 31,346 conflicts (1.5%). We presume that these conflicts were caused by responses from "border" devices such as routers that host some services themselves (e.g., SNMP and SSH), while requests for FTP or HTTP were forwarded to the devices connected to the router, resulting in multiple fingerprints for a single IP address. To resolve these conflicts, we assign a lower priority to TCP fingerprints when classifying the amplifiers. In addition, we refrained from aggregating the individual UDP fingerprints to one large set, as the overlap between the UDP protocols is low anyway (cf. Table 1).

2.4 Amplifier Churn

An important aspect from the attacker's point of view is how fast the set of amplifiers changes. An up-to-date list of reliable amplifiers is key to achieving a high impact during an attack. For this reason, we measure the *churn rate* of the amplifiers per protocol, which shows how fast a list of amplifiers becomes outdated. That is, we enumerate the amplifiers based on their IP addresses on Nov 22, 2013 and check if these hosts are still vulnerable for amplification attacks in the subsequent weeks.

Table 3 lists the numbers of amplifiers for the five UDP protocols that we monitored on long term. Figure 2 illustrates the ratio of amplifiers that are still reachable at the same IP address over time. For most protocols (DNS, NetBIOS, SNMP, and SSDP) the churn of amplifiers is quite high: only about 50% of the initial hosts are still reachable after one week. After the second week, we again observe a minor decrease, resulting in a total of 40 - 50% of available amplifiers for each protocol. For the following weeks we find the number of amplifiers to reach an almost steady level.

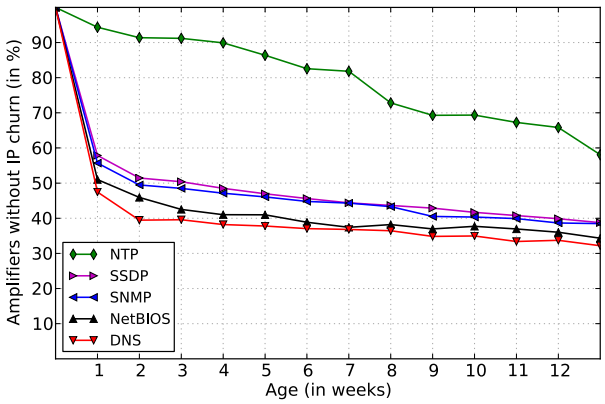

Figure 2: IP churn of potential amplifiers

To understand the nature of the significant drop after the first week and obtain knowledge about the vulnerable systems still reachable after 13 weeks, we leverage our fingerprinting techniques. We find the amplifiers that became outdated within the first week to be mostly connected via consumer routers (e.g., 78.8% for SNMP). We assume that these routers are connected via DSL with low IP address lease times, causing the rapid breakdown rate after one week [37]. To confirm this assumption, we aggregated reverse DNS records for a random sample of 100,000 unreachable amplifiers and checked for common indicators of dial-up connections (i.e., the appearance of tokens such as "dialup", "dyn", or "pool"—we further manually verified the Top 5 providers not providing indicators in the rDNS data). We indeed found at least 82.8% of the IP addresses to be linked to connections with dynamic IP address assignment. This means that an attacker needs to frequently re-scan for amplifiers or otherwise risks to decrease the impact of her attacks.

The amplifiers that are still reachable after 13 weeks presumably have longer lease times or static Internet connectivity. For example, we can see a clear distinction between countries in which SSDP hosts disappeared after a week (e.g., China, Argentina, Russia) and countries in which most hosts are still reachable after 13 weeks (e.g., Korea, United States, Canada). While only 3.4% of the Chinese amplifiers were still reachable after 13 weeks, still more than 69% of the Canadian amplifiers were available. This shows that the geolocation of Internet links (and thus the risk to face IP address churn) highly influences the availability of amplifiers.

Interestingly, the NTP protocol draws a completely different picture. Given a fixed list of vulnerable hosts, the ratio of available NTP amplifiers decreases at a negligible rate. After four weeks, an attacker can still abuse approximately 90% of the initial NTP amplifiers. After 13 weeks, still 58.1% of the initially-scanned hosts are

reachable. Of the 41.9% decrease after 13 weeks, many systems presumable disappeared because of our NTP amplifier notification campaign (cf. Section 3)—and not because of IP churn. The actual churn is thus even lower and significantly differs from churn in the other protocols. In contrast to the vulnerable amplifiers of the other protocols, more than 40% of the NTP amplifiers are running Cisco IOS that is commonly distributed on business routers and switches with static IP addresses. We further find 53.7% of the vulnerable hosts to be located within the United States (31.3%), South Korea (13.0%), and Japan (9.4%) for which the typical IP lease times for broadband are above average.

3 Case Study: NTP Amplification

After inspecting the amplification attacks in general, this section focuses on NTP, which we consider by far the worst among all known vulnerable protocols. NTP is a promising amplification vector for an attacker for three reasons. First, NTP server implementations allow for amplification factors of up to 4,670 [33]. Attackers can abuse the `monlist` feature in popular `ntpd` versions, which requests a list of up to 600 NTP server clients in about 44kB UDP payload. Second, as we have seen in Section 2.4, NTP servers have minimal IP address churn. Lastly, NTP offers even further amplification vectors. For example, the NTP `version` request reveals a verbose system fingerprint (OS, architecture, server info) of the NTP server, allowing about 24-fold amplification.

Attackers have already practically demonstrated the impact of NTP attacks. For example, in February 2014, CloudFlare observed a 400 Gbps attack against a French hosting provider [22]—the largest DDoS attack observed so far. If the attacker had even more resources (in particular bandwidth) to send spoofed `monlist` requests, the impact of such an attack could have been even higher.

Luckily, NTP servers can be configured such that the `monlist` requests are disabled for unauthorized users, and more recent `ntpd` versions protect this feature with a proper session handshake. These changes typically do not bring disadvantages for the administrators, while they eliminate the amplification vector. Even disabling functionality like `monlist` does not break time synchronization. But although secure configurations are well-documented, most administrators are not aware of the amplification vulnerabilities and operate NTP servers in (sometimes bad) default configurations. From a security-perspective this raises several urging questions: once we found amplification vulnerabilities, how can we reduce the number of amplifiers? Can we notify administrators? How effective would such a notification procedure be?

3.1 NTP Amplifier Notifications

In a large-scale campaign, we have launched a global notification procedure to alert NTP administrators about the amplification problems. We thankfully cooperated with many parties striving towards the same goal: reducing the number of NTP amplifiers.

Datasets. We define two datasets of NTP amplifiers. NTP_{ver} contains all NTP servers that reply to `version` requests, i.e., systems that are "less" vulnerable to amplification abuse. This is the same dataset that we fingerprinted in Section 2. As a subset of this, NTP_{mon} contains the NTP servers that also support the `monlist` requests, i.e., systems that allow for more "severe" amplification.

Campaign. We collaborated with security organizations in order to create technical advisories that describe how to solve the amplification problems in NTP. This resulted in public advisories of CERT-CC [42] and MITRE [25]. Due to the high number of vulnerable Cisco devices for NTP amplification (cf. Table 2), we also contacted Cisco which resulted in a public advisory of Cisco's PSIRT [7]. The advisories describe how to disable the `monlist` feature in typical NTP server implementations (such as `ntpd`). The same configuration change also disables `version` responses. Thus, in principle, the advisories help to reduce the number of servers in both datasets, NTP_{ver} and NTP_{mon}.

In addition, we distributed lists of IP addresses of the systems in NTP_{mon} among trusted institutions. For example, we shared our data with direct contacts in NOCs and CERTs of hundreds of large ISPs worldwide. Furthermore, we cooperated with data clearing houses (e.g., TrustedIntroducer [41] and ShadowServer [35]) that informed their subscribers. Lastly, we informed the NTP Pool Project [28] about misconfigured hosts in the public pool of NTP servers and synchronized our notifications with the OpenNTPProject [30] to start the announcements simultaneously.

We did not actively notify systems that are only in NTP_{ver} for two reasons. First, we saw an urgent need to close the amplifiers in NTP_{mon}, as the `monlist` amplification is in the order of magnitudes higher than of other NTP features. Second, we can then compare the efficiency of advisories (which affect both datasets) with the effects of active and personalized notifications (which affect only NTP_{mon}).

3.2 Analyzing the Remediation Success

We ran weekly scans for NTP amplifiers to observe the developments over time. Figure 3 shows the number of NTP amplifiers per week and marks important events.

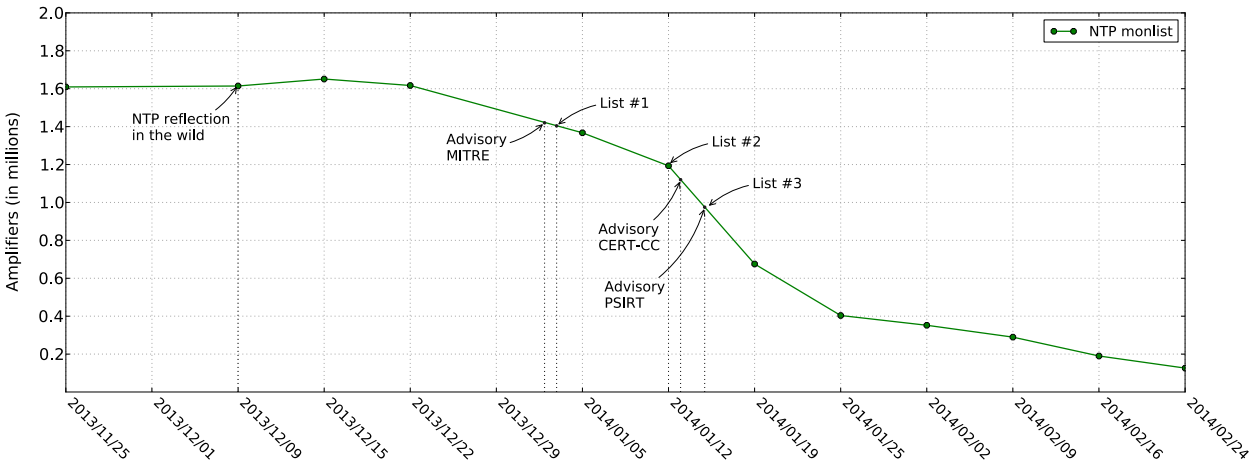

Figure 3: Trend of NTP_{mon} amplifiers

At their peaks on Dec 15, 2013, we tracked 7,364,792 servers in NTP_{ver} and 1,651,199 servers in NTP_{mon}, respectively. The number of amplifiers in NTP_{mon} is steady at first, also after Symantec has released a blog article about the attacks late December 2013 [39]. However, the number of amplifiers starts to drop (15.4%) right after we released the CVE and shared a first (incomplete) list of IP addresses. A second major drop (43.4%) happened during the week we distributed twice an updated (and complete) list of potential amplifiers and two other advisories were released. After publishing further weekly notifications (omitted from the graph for better readability) we have observed a steady decrease of amplifiers.

At the end of our measurements on Feb 24, 2014, the number of amplifiers reached a local minimum at 4,802,212 (NTP_{ver}) and 126,080 (NTP_{mon}). Compared to the peak numbers, this constitutes significant drops in both datasets. The number of amplifiers in NTP_{ver} decreased by 33.9%, a success likely stemming from the advisories and recent publicity on NTP attacks in general. However, looking at the development of *severe* amplifiers shows how successful global notification efforts can be: the number of amplifiers (NTP_{mon}) dropped by 92.4% with an ongoing decrease.

To verify whether the number of amplifiers for NTP_{mon} still decreases continuously, we performed another Internet-wide scan on Jun 20, 2014 and find 87,463 hosts still vulnerable to `monlist` amplification, i.e., a decrease of almost 40,000 hosts since Feb 24, 2014.

Fingerprinting. We compared the fingerprints of the NTP_{mon} datasets at the start and end of our measurements. We clearly observe decreasing numbers for all architectures, OSes, and hardware types. Interestingly, the ratio of MIPS-based amplifiers dropped from 47.2% to 19.1%, while the ratio of x86-based systems increased from 40.2% to 58.0%. Similarly, 23.0% of the devices of a popular router manufacturer remain vulnerable—a value standing out from the average decrease. On absolute scale, though, the numbers drop across all fingerprints, indicating that the clean-up was not driven only by a single device type or manufacturer.

Table 4: Decrease of NTP_{mon} amplifiers per country

	Amplifiers (in #)			Remaining
Country	Nov 22, 2013	Feb 24, 2014	Decrease	(in %)
US	1,073,666	28,415	1,045,251	2.6
KR	88,289	16,183	72,106	18.3
RU	58,519	11,476	47,043	19.6
DE	50,627	4,793	45,834	9.5
CA	36,070	1,881	34,189	5.2
CN	32,995	4,172	28,823	12.6
JP	29,915	2,777	27,138	9.3
GB	24,408	2,741	21,667	11.2
UA	19,270	2,716	16,554	14.1
BR	13,900	2,719	11,181	19.6
TW	13,362	6,397	6,965	47.9
NL	13,122	3,934	9,188	30.0
FR	12,992	4,557	8,435	35.1
CZ	11,825	1,226	10,599	10.4
PL	10,891	1,960	8,931	18.0

Geographic Distribution. We also investigated the geographical distribution of the amplifiers. For this, we used the MaxMind GeoIP database [23] to assign a country to the IP address of an amplifier. We then compared how the numbers of amplifiers evolve in single countries. Table 4 lists the remaining amplifiers of the 15 countries, which had the most amplifiers in Nov 2013. The clean-up was—on relative scale—most successful in the US, where the number of amplifiers decreased to only 2.6%. In other countries like Taiwan the number decreased only to 47.9%. These differences may be caused by the number and quality of direct contacts we had in the US compared to Taiwan: we admittedly had more contacts in the

Table 5: Decrease of NTP_{mon} amplifiers per RIR

	Amplifiers (in #)			Remaining
RIR	Nov 22, 2014	Feb 24, 2014	Decrease	(in %)
ARIN	1,112,422	30,766	1,081,656	2.8
RIPE	283,991	53,324	230,667	18.8
APNIC	202,719	38,122	164,597	18.8
LACNIC	21,721	5,075	16,646	23.4
AFRINIC	7,495	920	6,575	12.3

US and Europe compared to the rest of the world. But it also shows that the current network of CERTs is not perfectly connected to share our information equally in all countries. For example, also European countries like France (35.1%) and Austria (47.1%) lag behind the average decrease. However, on an absolute scale, the situation is different. While the number of NTP amplifiers was clearly reduced in the US, still 28,415 systems remain vulnerable to `monlist` amplification.

Table 5 shows the absolute numbers of NTP servers per Regional Internet Registry (RIR), which (very roughly) indicates the continent of the amplifiers. It shows that we face a global problem, but also proves that all regions in the world have acknowledged the problems.

Per-Provider Statistics. A closer look at the Autonomous Systems (AS) distribution sheds light onto how amplifiers have been closed. Of the 96 ASes that had at least 1,000 amplifiers, about half have shut down more than 95% of the amplifiers. This shows that many providers either enforce most amplifiers in their networks to be shut down or successfully filter NTP traffic at the network level. More specifically, we identified 73 ASes (0.44% of all ASes we observed during our monitoring period) that had more than 100 NTP servers in one week, and did not have a single vulnerable server left open in the subsequent weeks. This strongly suggests that these providers perform network-level filters, as it is unlikely that so many individual servers were all cleaned up within a few days. Nine ASes left open more than half of the amplifiers, i.e., these providers do very little to mitigate the threat. We are currently establishing individual contacts with the least-active ASes and hope to understand the reasons for the remaining amplifier landscape in their networks.

Result Verification. We verified if the drop in NTP amplifiers is not caused by networks blocking our scanner [10]. This can already be seen in the amplifier trend graph (Figure 1), in which the number of amplifiers for other protocols remains almost constant. To be sure, we scanned for NTP amplifiers from a secondary host in a different `/16` network. The primary scanner indeed missed 8.6% of the amplifiers that the secondary scanner found. We manually investigated this and found 904 networks (`/20`) that have at least five amplifiers that the primary scanner missed—indicating that some networks do blacklist our scanner. While our primary scanner has thus missed amplifiers, these systems make up an almost-negligible part of the 92.2% decrease of amplifiers.

3.3 Lessons Learned

Summarizing, the campaign to reduce the number of NTP `monlist` amplifiers was quite effective and showed remediation successes for almost 95% of the vulnerable hosts just after 6 months. As such, it would be interesting to see recipes to repeat this success in similar campaigns for other security-critical issues, such as amplification vulnerabilities in other protocols or even unrelated, but security-critical problems like the `heartbleed` vulnerability in OpenSSL. Figure 3 clearly shows that the counteractions (advisories and IP address lists) correlate with the decrease in numbers of amplifiers.

Unfortunately, it is impossible to proof causality, in particular, to see which IP address distribution channels or which advisories were most effective. However, in our conversations with providers we had the impression that it helps to repeatedly point out the problem. Further, it may not be sufficiently effective to have public advisories that nobody reads. Instead, we found that communication was key to motivate CERTs and providers to act accordingly. Once we reached out to CERTs and providers, it typically was no problem to close the vulnerable hosts.

On the negative side, though, we experienced that the Internet community is not well-prepared for such campaigns. Although we were quite well-connected with nationally and internationally operating CERTs and providers, it is hard to reach out to all providers individually. If providers and CERTs were better connected to non-profit data clearing houses (like `shadowserver.org`), vulnerability notifications could be sent out more efficiently.

4 TCP-based Amplification Attacks

In the previous section, we have shown that we can have an influence on the amplifier landscape. As such, we introduce next steps attackers may take once we "fix" all the protocols that have been documented to be vulnerable for amplification attacks [33]. Given the connection-less nature of UDP, it comes as no real surprise that UDP-based protocols may allow for amplification attacks.

In this section, we analyze to what extent TCP allows for amplification attacks similar to the UDP-based attacks. TCP is a connection-oriented protocol, in which early on (i.e., during the handshake) the IP addresses of both communication parties are implicitly verified via

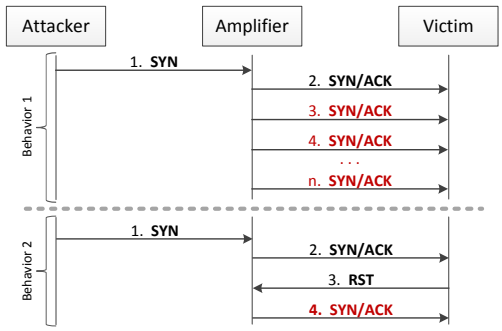

Figure 4: Amplification abuse in the TCP handshake

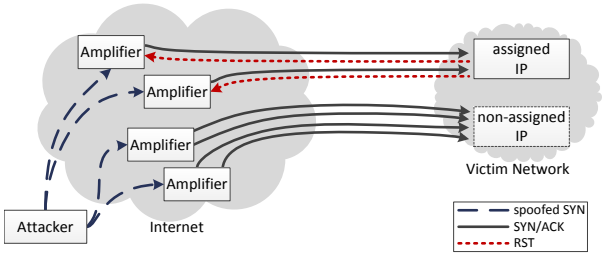

Figure 5: Attacker's choice of targets

initially-random TCP sequence numbers. We evaluate how TCP can be abused for amplification regardless of the TCP three-way-handshake.

From the viewpoint of the attackers, abusing TCP brings multiple benefits. First, providers cannot easily block or filter TCP traffic related to well-known protocols (such as HTTP), as compared to protocols that are less critical (such as CharGen, QOTD, or SSDP). In addition, it is hard to distinguish attacks from normal traffic in a stream of TCP control segments, while providers can deploy payload-based filters for attack traffic from many UDP-based protocols. Lastly, there are millions of potential TCP amplifiers out there and "fixing" them seems like an infeasible operation.

4.1 TCP Amplification Background

TCP initiates a connection with a three-way-handshake, which works as follows: a client willing to start a TCP connection sends a `SYN` segment to a server and this packet contains a random sequence number seq_A. If the server is willing to accept the client, it responds with a `SYN/ACK` segment, in which the acknowledgment number is set to $seq_A + 1$ and a random sequence number seq_B is added as well. In the third step, the client completes the connection setup by sending a final `ACK` to the server where the sequence number is set to $seq_A + 1$ and the acknowledgement number is set to $seq_B + 1$.

At first sight, TCP thus does not allow amplification: all segments are of the same size and no data bytes are exchanged before the handshake is finished. Assuming that the server draws TCP sequence numbers at random, there is no practical way to complete the handshake with IP-spoofed traffic. If the client address is spoofed, theoretically only one single `SYN/ACK` is sent to a potential victim. While this allows to reflect traffic, it does not amplify the traffic and therefore does not attack a victim with more bytes than sent by an attacker.

In practice, though, TCP connections encounter packet loss. TCP stacks thus deploy segment retransmissions, i.e., they retransmit segments that have not been acknowledged by the other party. We noticed that retransmissions also occur *during the handshake*. Many popular TCP stacks resend `SYN/ACK` segments until: (i) an `ACK` is received (and the connection is successfully established), (ii) a threshold is met (and the connection times out), or (iii) the connection is closed by the client (e.g., via a `RST` segment). In face of amplification attacks, this is problematic, as the client's IP address is not validated until the handshake is complete.

Figure 4 illustrates two typical behaviors of the TCP handshake. The first behavior illustrates a server repeatedly sending `SYN/ACK` segments, resulting in a TCP amplification. The second behavior points out a way for amplification even though the client (i.e., the victim) sends a `RST` segment to tear down the (not-yet-existing) TCP connection. In principle, this instructs servers (i.e, amplifiers) to stop sending any further `SYN/ACK` segments. We measured if hosts obey to this behavior.

4.2 Measuring TCP Amplification

As a first step to estimate the scope of this problem, we measure how the TCP stacks implement retransmissions during the TCP handshake. We perform an Internet-wide `SYN` scan and record the replies for further analysis. Our scanner does not complete the handshakes (i.e., we do not send `ACK` segments). With this, we aim to mimic the behavior of a system under an amplification attack that did not initiate the TCP connection in question. If TCP segments arrive that do not belong to any (half-)open connection (such as the reflected `SYN/ACK` segments in our scenario), TCP stacks either i) ignore these segments, or ii) respond with a `RST` segment, asking the other side to abort the TCP connection.

A victim, however, might not able to respond with `RST` packets, e.g., when it is already suffering from overload. Similarly, an attacker does not necessarily need to steer her attack against assigned IP addresses as shown in Figure 5. That is, the attacker can target an unassigned IP address so that there is no host that responds with `RST` segments. As a result, the capacity of the victim's net-

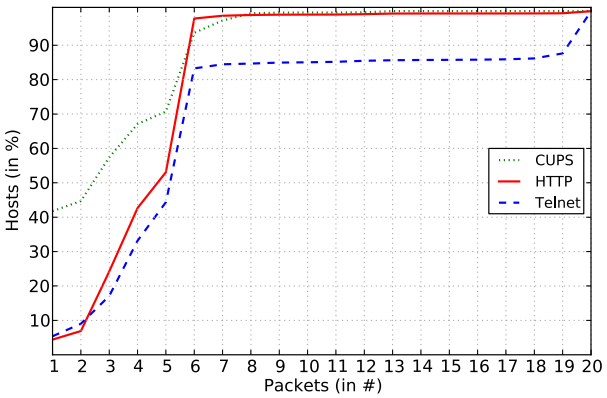

Figure 6: HTTP, Telnet, and CUPS without RST

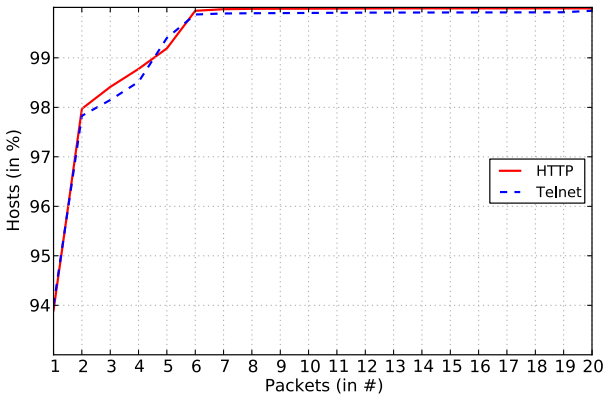

Figure 7: HTTP and Telnet with RST

work is overloaded by SYN/ACK segments. Addressing arbitrary IP addresses in the target network thus allows an attacker to control that no RST responses will be sent, leading to higher impact of an amplification attack.

TCP Scanning. We run two separated TCP scans to mimic both behaviors. In the first scan, we only send SYN segments and do not send anything back when receiving SYN/ACK segments. In the second scan, we "acknowledge" each incoming SYN/ACK segment with a RST segment. We performed the first scan for two popular protocols (i.e., HTTP and Telnet) and one printer-oriented protocol (CUPS). We chose these protocols, as according to Internet Census 2012, HTTP and Telnet yield a high number of reachable hosts [40]. In addition, to evaluate the TCP behavior of printers, we chose to scan CUPS.

In total, 66,785,451 HTTP hosts, 23,519,493 Telnet hosts, and 1,845,346 CUPS hosts replied to our requests. Figure 6 shows the results of the first scans as a CDF. The graph outlines that 6% of all HTTP hosts reply with a single SYN/ACK response and 24% of the hosts send at most three packets. A rise can be observed in-between 3 and 4 packets, meaning that 42% of the hosts reply to our SYN requests with 4 packets or less. We find the highest rise for 5 to 6 packets as 53.1% of all hosts send at most five SYN/ACK segments, but already 97.8% send six segments (or less). That is, 46.9% of the reachable HTTP hosts allow an amplification factor of 6 or higher.

Similar trends can be observed for the Telnet protocol. We find 55.6% of all Telnet hosts to enable an amplification attack with factor 6 or higher. In contrast to HTTP, about 12.2% of the Telnet hosts (more than 2.8 million systems) amplify requests even by factor 20. CUPS hosts, on the contrary, show less severe amplification rates. About 41.8% of the CUPS hosts replied with only a single packet and, in general, the number of segments sent by CUPS hosts is lower.

Figure 7 shows the results of our second scan (with RST). Indeed, sending RST tremendously changes the behavior of TCP stacks. In contrast to our first scan only 0.03% of Telnet hosts allow amplification by factor 20 which is a negligible number of 7,247 hosts. Almost 94% of all Telnet hosts send only one SYN/ACK packet in response; the same number applies for HTTP. A minor fraction of hosts keep resending SYN/ACK segments. We count 506,476 devices for HTTP and 114,157 devices for Telnet that send six SYN/ACK segments. Still, for the attack victim, replying with RST segments significantly reduces the impact for TCP amplification attacks and thus constitutes a potential proactive countermeasure.

4.3 Categorizing TCP Amplifiers

In this subsection, we aim to categorize the most prevalent behaviors that we have identified in the previous sections. Figures 6 and 7 have revealed significant groups of hosts that reply with the same number of TCP segments. Table 6 summarizes how many hosts belong to each of these groups. What kinds of systems are vulnerable to amplification attacks? To answer this question, we fingerprint the selected groups by re-using our TCP-based scans to obtain information via FTP, HTTP, HTTPS, SSH, and Telnet.

First, we classify the HTTP hosts that sent exactly six segments. Of the systems for which we obtained a fingerprint, about 88% (in total 3,228,000 hosts) run a Linux or Unix OS. Manual inspection has revealed that many of them are routers or embedded devices often running an FTP server (e.g., for a NAS). Other devices were vendor-specific, such as the ZynOS operating system. We also found numerous MikroTik devices and a smaller group of TP-LINK routers and D-Link devices. In contrast, there are only 0.2% Windows amplifiers in this group of hosts, hence this group of TCP amplifiers mainly consists of routers and various kinds of embedded devices.

Table 6: Hosts vulnerable to TCP amplification

	Number of response segments			
Scan	3	4	6	20
Without RST:				
CUPS	12.7%	9.7%	22.9%	0.0005%
	234,478	179,069	422,622	9
HTTP	17.3%	18.5%	44.7%	0.6%
	11,558,250	12,322,327	29,834,824	395,361
Telnet	8.1%	16.1%	38.9%	12.2%
	1,899,095	3,780,499	9,147,151	2,872,878
With RST:				
HTTP	0.44%	0.36%	0.76%	0.0005%
	294,535	243,028	506,476	349
Telnet	0.32%	0.37%	0.47%	0.03%
	76,774	88,504	114,157	7,247

In auxiliary tests, we have measured that Windows hosts (Windows 7, Vista, and XP) send four or five `SYN/ACK` segments in response—depending on the WINSOCK implementation. Although this amplification is not negligible, it is significantly lower than for other devices.

Second, we determine what kind of Telnet hosts sent six packets. Again, Unix and Linux are predominant as about 115 times more hosts in this group run Unix or Linux compared to the number of devices running Windows. Many of these hosts (49%) are routers, while other occurring devices are media servers, network cameras, digital video recorders, or VoIP phones.

Third, we analyze the Telnet hosts that sent 20 `SYN/ACK` segments. We found that 84.3% of all fingerprintable hosts in this group are routers or embedded devices. These embedded hosts—often based on MIPS or ARM architecture—include devices such as Raspberry Pis and printers. We found 86.1% of the devices to utilize the embedded web server *Allegro RomPager* and 37.5% to be manufactured by TP-LINK. In the remaining hosts, we also identified networking devices running ZynOS, ClearOS, or Cisco IOS. Typical desktop computers are negligible in this group: Windows is installed on 0.3% and MacOS on 0.0005% of these systems.

Lastly, we investigate the Telnet hosts that sent more than 20 `SYN/ACK` segments (21,981 hosts with an average of 971 response segments). Most of these hosts (87.9%) were found to be business and consumer routing devices of which 34% were running the embedded web server *GoAhead-Webs*. We find 50.4% of these devices to be a specific ATM Integrated Access device manufactured by RAD. Another 13.2% of the devices utilized the web server *Allegro RomPager* that we find to be associated to devices of manufacturers such as TP-LINK and ZyXEL. More information can be found in a further paper [20].

We conclude that amplification factors of 20 and more are largely caused by embedded devices and routers. We have contacted the vendors and wait for their feedback regarding these vulnerabilities.

5 Spoofer Identification

IP address spoofing is the root cause for amplification attacks, as it enables attackers to specify arbitrary targets that are flooded with reflected traffic. The Internet community addressed this issue as early as in May 2000 and suggested that—whenever possible—spoofed traffic should be blocked at the network edge [13]. However, as the attacks in practice have shown, spoofing still seems to be possible—yet it is unclear to what extent.

Up to now, the most powerful resource for tracking networks that allow spoofing is the Spoofer Project [36]. The project offers a client software that one can use to test if the own network filters IP-spoofed packets. Yet, such measurements require volunteers who download, compile/install, and run a client software. Aggregating user measurements in a study in July 2013, Beverly et al. show that about 610 of the 2582 tested ASes allow IP spoofing (at least partially, i.e., in some of their announced IP prefixes) [4]. On relative scale, however, less than 5% of the total number of ASes were tested. In other words, for more than 95% of the ASes it remains unclear if they support IP spoofing.

5.1 Remote Spoofer Test

Ideally, one would have a methodology to track networks that allow IP spoofing without the need for individuals running manual or tool-based tests from within the network. Such *remote tests* would boost the measurement coverage, so that we can alert administrators about potential misconfigurations that permit IP spoofing in their networks. We deploy such a large-scale experiment that enables us to identify thousands of ASes that support IP spoofing—from remote. Our DNS-based technique was first mentioned by Mauch on the NANOG mailing list in August 2013 [16]. It relies on public DNS proxies (or DNS stub resolvers—we will refer to "proxy" in the following) that have a broken networking implementation.

Figure 8 describes the core idea of the technique. The party that wants to identify spoofers (i.e., us) controls an Internet-scale scanner S and a name server that is authoritative for a domain suffix d_{suf}. In our case the domain d_{suf} is `scan.syssec.rub.de`. Note that we do not have control over devices on the right hand side, i.e., the DNS resolver and the optional DNS proxy, respectively. In step (1), the scanner S sends a DNS `A` lookup for domain d to an open resolver P. The domain d uses d_{suf} as domain suffix, but is specifically crafted for each scanning target. That is, S encodes a hex-formatted IP address of the scanning target P in the domain. This allows us to tell from the DNS response to which IP address we have sent the corresponding DNS request. In addition, to avoid caching

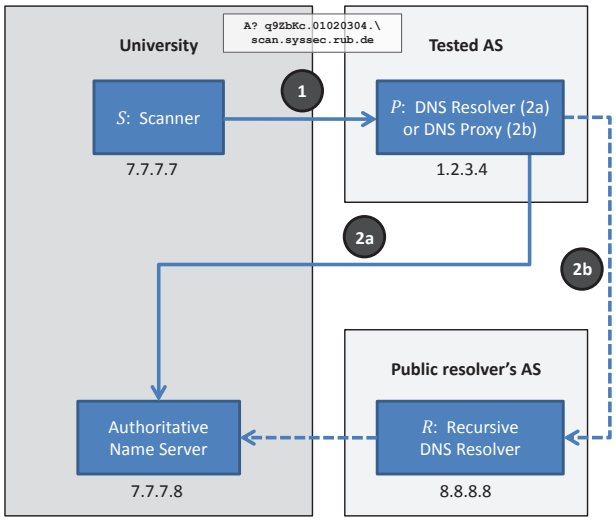

Figure 8: Setup to scan for spoofing-enabled networks. *R* is optional if *P* is an iterative resolver (step 2a) and is only used if *P* is a DNS proxy (step 2b)

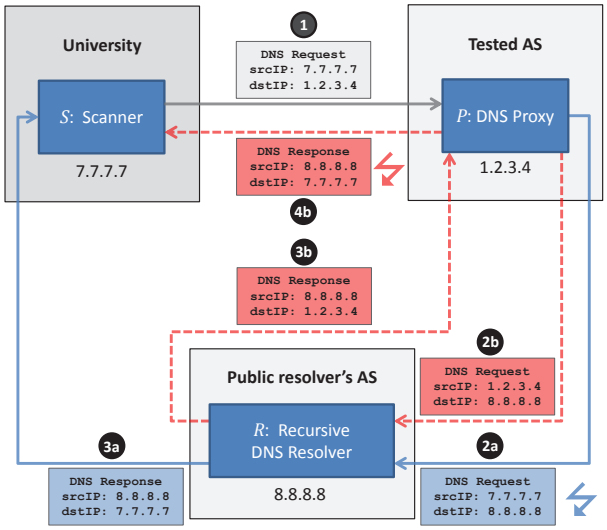

Figure 9: Network overview illustrating the two possible paths for DNS requests and responses when receiving responses for which the replying IP address did not match the IP address that was encoded in the requested domain

effects, we encode a random value in *d* that changes per request. In our case, *d* for target IP address 1.2.3.4 looks like `q9ZbKc.01020304.scan.syssec.rub.de`, whereas "q9ZbKc" is the random domain prefix and "01020304" the hex-formatted IP address.

When sending the request to *P*, one has to keep in mind that *P* may have different roles. If the scanned target *P* is a public recursive DNS resolver, *P* iteratively resolves the domain name by contacting the authoritative name servers down the domain tree as summarized in step (2a). For the purposes of our experiments such recursive resolvers are not important because they do not forward requests or responses. As we will show later, though, our technique to identify spoofing-enabled networks is based on the assumption that systems forward requests or responses. Quite often, *P* is not a resolver but a DNS proxy that forwards the DNS communication from a client (i.e., our scanner) to an iterative resolver *R*, as illustrated in step (2b).

We now leverage the fact that some DNS proxies do not correctly change the IP addresses when forwarding the request. In principle, to forward the DNS lookup to the resolver, the proxy *P* needs to change both the source and destination IP address of the request: it switches the source from *S* to its own address and the destination from its own address to *R*. Similarly, to forward the DNS response to the client, *P* changes the source from *R* to *P* and the destination from *P* to *S*. However, we encountered DNS proxies that do not change the addresses correctly. That is, we received DNS responses for which the replying IP address did not match the IP address that was encoded in the requested domain *d*. Instead, when *S* receives the response, the source IP address is set to *R*.

There are a few potential explanations for this observation. One is that *P* is a multi-homed system, i.e., has multiple interfaces with IP addresses in different networks. In many cases, though, proxies were using well-known resolvers (such as Google DNS) or resolvers in different ASes, excluding this possibility. Another explanation is that these devices have broken networking implementations, which cause the packets to have "wrong" IP header information when being forwarded. This could, e.g., be caused by broken Network Address Translation (NAT) implementations or faulty DNS proxy software.

Figure 9 illustrates the corresponding network situation when we receive a DNS response for which the source IP address of the UDP packet does not match the IP address that we encoded in the domain name of the DNS request. When sending a DNS request to the proxy (step 1), either *P* does not change the source address when forwarding the request to resolver *R* as outlined in step (2a) (i.e., the proxy effectively impersonates the sender *S*) so that *R* directly responds to *S* (step 3a). Alternatively, the proxy forwards the request to the resolver *R* (step 2b), obtains a DNS response (step 3b), and does not change the source address when forwarding the response to the sender *S* (step 4b), thus impersonates the resolver *R*. Either way, if *R* and *S* are not within *P*'s AS, then the proxy *P* is located in a network that permits the transmission of spoofed IP addresses. Both behaviors cause typical DNS clients to fail the resolution, as the DNS response comes from an unexpected IP address.

Table 7: Number of misconfigured DNS resolvers P and the corresponding Autonomous Systems

Filter	$\#P$	$\#AS_P$	Top 3 Countries
Top 4 Resolver	42,691	301	BR (52%), IT (11%), HU (10%)
Top 10 Resolver	45,072	352	BR (53%), IT (10%), HU (9%)
Distinct AS	170,451	2,692	CN (55%), BR (17%), RU (5%)
Distinct AS / $\#\text{resp}_R > 1$	161,988	2,063	CN (55%), BR (18%), RU (5%)
Distinct AS / $\#\text{resp}_R \geq 10$	137,075	870	CN (53%), BR (20%), RU (6%)

Clients will not even receive the replies if their network is protected by a stateful firewall, which drop UDP packets unrelated to any UDP stream known to the firewall. Unfortunately, we could not examine in detail which part of the forwarding was broken, as we did not control any of the recursive resolvers that the spoofing proxies used.

5.2 Finding Spoofing-Enabled Networks

While performing our Internet-wide scans, we observed a mismatch of source IP address and encoded target address for more than 2.2% of all responsive DNS servers, resulting in a total of 581,777 DNS proxies which redirect incoming requests to 225,888 distinct recursive DNS resolvers. To explore these misbehaving DNS proxies and the corresponding ASes in more detail, we enumerate the number of ASes permitting IP address spoofing using the following filtering methods:

(i) Our most conservative estimation is based only on responses from four commonly-used open resolvers operated by Google (i.e., 8.8.8.8 and 8.8.4.4) and OpenDNS (208.67.222.222 and 208.67.220.220). These servers ("Top 4") are a subset of the servers in the second approach.

(ii) Less conservative, we take into account DNS responses of the most popular ten resolvers ranked by the number of proxies using them ("Top 10").

(iii) Lastly, we focus on proxies for which $AS(S) \neq AS(P) \neq AS(R)$ applies. In other words, the proxy is not located in the same AS as both the sender S and the resolver R, and thus is spoofing the identity of one of these identities.

Table 7 illustrates the results obtained for each filtering method. In total, 7.7% of the potentially-spoofing DNS proxies forward the DNS requests to the Top 10 well-known resolvers (filter (ii)), resulting in 352 distinct ASes the proxies are located in. When limiting our focus to the Top 4 resolvers (filter (i)), we still identify 301 different ASes that permit spoofed traffic. Furthermore, we find 29.3% of all proxies to be located in different ASes than the sender S and the resolvers R (filter (iii)), resulting in 2,692 ASes permitting the proxies to either spoof the IP address of S or R.

Of the 225,888 individual resolvers R we find 50.7% utilized by multiple DNS proxies. To exclude potentially multi-homed systems with multiple interfaces in distinct ASes, we restrict the set of resolvers to those which responded to requests from multiple proxies and find 2,063 ASes that allow spoofed traffic. When further filtering the set to resolvers that replied to at least ten different proxies, we still identify 870 ASes permitting spoofing. Using our remote test, we can thus identify more spoofing-enabled ASes than the current state-of-the-art manual analyses performed by the Spoofer Project [36].

5.3 Fingerprinting IP-Spoofing Devices

Lastly, we want to understand what type of devices follow the weird practice of spoofing IP addresses while forwarding DNS requests/responses. For this, we use our TCP-based fingerprints to classify the 42,691 devices that used Google DNS or OpenDNS as iterative resolver. Of these devices, 6,120 devices replied to our TCP requests and 5,674 resolvers provided information suitable for fingerprinting. In total, we find 3,033 devices running the Dropbear SSH daemon, particularly employed on embedded devices. We also identify 1,437 MikroTik routers to be forwarding requests specifically to the Google DNS servers. Further 540 devices of the manufacturer Airlive perform similar behavior.

We achieve similar results when fingerprinting the hosts of the other filtering methods (see previous subsection). We again find Dropbear, MikroTik, and Airlive to appear frequently. We assume that these devices have either bad NAT rules or erroneous DNS proxy implementations. However, requests for more specific information from the vendors remained unanswered until now.

5.4 Remote Test Limitations

Our results show that DNS-based spoofing tests are a powerful resource to identify spoofing-enabled networks. One inherent limitation of this approach is, though, that such tests do only reveal the fact *that* (and not *if*) a network allows IP spoofing. We leave it up to future work to test if the tests can be expanded accordingly. For example, we could scan for DNS proxies that can be fingerprinted as systems that typically spoof IP addresses. In addition, collaborating with the recursive resolvers (such as OpenDNS or Google DNS) may reveal further insights about the spoofing systems. Lastly, given the large number of hosts running other protocols than DNS, it may be possible to use further protocols for similar remote spoofing tests.

6 Related Work

Our work was inspired by the analysis of amplification attacks by Rossow [33]. He identified 14 UDP-based network protocols that are vulnerable to amplification attacks and gave a thorough overview of countermeasures. We continue this line of research and classify the amplifiers. We show in an Internet-wide NTP amplifier notification initiative that the threats can be mitigated by cooperation within the security community. We furthermore investigate to what extent TCP-based amplification attacks are possible. Lastly, we provide an overview of spoofing-enabled networks. Our work is thus a thorough and novel extension of Rossow's initial analysis.

We group further related works by their topic:

TCP Amplification. To the best of our knowledge, we are the first to evaluate the amplification potential of the TCP three-way handshake. Prior work on TCP amplification has addressed guessable TCP sequence numbers, which in principle allow to establish TCP connections with spoofed packets [2, 31]. In addition, Paxson et al. looked at amplification in Transactional TCP (T/TCP)—which has very low popularity though [31]. Lastly, well-known stateful TCP attacks like the FTP bounce attack also allow for amplification [6]. Many of these attacks have been largely fixed with secure TCP stack implementations or by hardening certain protocols (e.g., FTP). The amplification vulnerabilities that we discovered in the TCP three-way handshake may again require improvements to TCP stacks.

Internet-Wide Scanning. Durumeric et al. presented ZMap, a publicly-available tool optimized for Internet-wide scans [11]. In fact, we leverage most of their proposed techniques and implemented their guidelines also for our custom scanner. Zhang et al. used Internet-wide scans to correlate the mismanagement and the maliciousness of networks [44]. They find networks that host open recursive DNS resolvers highly correlate to other malicious activities (such as spamming) initiated from these networks. Our work is orthogonal, as we follow a proactive approach to cooperate with the providers in order to get the vulnerabilities fixed. Two non-academic projects deployed by Mauch, the OpenNTPProject [30] and Open Resolver Project [29], also address the problems of amplification sources from a practical point of view. We have collaborated with Mauch to inform administrators of NTP servers vulnerable to the `monlist` amplification and are grateful for his support.

DDoS Attack Types. An alternative way to launch powerful DDoS attacks are networks of remotely-controllable bots. Büscher and Holz analyze DirtJumper, a botnet family with the specific task to perform DDoS attacks by abusing the Internet connection of infected desktop computers [5]. The DirtJumper botnet attacks at the application-level layer and does not aim to exhaust bandwidth, though. Kang et al. propose the Crossfire attack, in which bots direct low-intensity flows to a large number of publicly accessible servers [19]. These flows are concentrated on carefully chosen links such that they flood these links and disconnect target servers from the Internet. Studer and Perrig describe the Coremelt attack, in which bots send legitimate traffic to each other to flood and disable a network link between them [38]. All these attacks rely on bots, while our threat model only assumes that an attacker has any spoofing-enabled Internet uplink. Although the amplification DDoS attacks primarily try to congest bandwidth of a single victim, they can possibly be combined with the aforementioned techniques.

7 Conclusion

We have confirmed that amplification attacks remain a major Internet security issue—not only for UDP-based protocols. We identified TCP as an alternative source for amplification—despite its three-way-handshake protocol. We find millions of systems with TCP stacks that can be abused to amplify TCP traffic by a factor of 20x or higher. Our work revealed a tremendous number of potential amplification sources for both UDP and TCP-based protocols and classified these systems. During a first-ever large-scale notification campaign, we have observed a significant decrease in the number of amplifiers for NTP, giving hope for future attempts in fixing protocols that have similarly-severe amplification vulnerabilities. Finally, our remote spoofing test has identified more than 2,000 networks that do not use proper egress filtering—indicating that it is still a long way to go until we will have a spoofing-free Internet.

Acknowledgment

We would like to thank the anonymous reviewers and Jared Mauch for their constructive and valuable comments. This work was supported by the German Federal Ministry of Education and Research (BMBF Grants 16BY1110 (MoBE) and 16BY1201D (iAID)).

Abstract

Tor's growing popularity and user diversity has resulted in network performance problems that are not well understood. A large body of work has attempted to solve these problems without a complete understanding of where congestion occurs in Tor. In this paper, we first study congestion in Tor at individual relays as well as along the entire end-to-end Tor path and find that congestion occurs almost exclusively in egress kernel socket buffers. We then analyze Tor's socket interactions and discover two major issues affecting congestion: Tor writes sockets sequentially, and Tor writes as much as possible to each socket. We thus design, implement, and test KIST: a new socket management algorithm that uses real-time kernel information to *dynamically compute the amount to write* to each socket while considering *all writable circuits* when scheduling new cells. We find that, in the medians, KIST reduces circuit congestion by over 30 percent, reduces network latency by 18 percent, and increases network throughput by nearly 10 percent. We analyze the security of KIST and find an acceptable performance and security trade-off, as it does not significantly affect the outcome of well-known latency and throughput attacks. While our focus is Tor, our techniques and observations should help analyze and improve overlay and application performance, both for security applications and in general.

1 Introduction

Tor [21] is the most popular overlay network for communicating anonymously online. Tor serves millions of users daily by transferring their traffic through a source-routed *circuit* of three volunteer relays, and encrypts the traffic in such a way that no one relay learns both its source and intended destination. Tor is also used to resist online censorship, and its support for hidden services, network bridges, and protocol obfuscation has helped attract a large and diverse set of users.

While Tor's growing popularity, variety of use cases, and diversity of users have provided a larger anonymity set, they have also led to performance issues [23]. For example, it has been shown that roughly half of Tor's traffic can be attributed to BitTorrent [18, 43], while the more recent use of Tor by a botnet [29] has further increased concern about Tor's ability to utilize volunteer resources to handle a growing user base [20, 36, 37, 45].

Numerous proposals have been made to battle Tor's performance problems, some of which modify the mechanisms used for path selection [13, 59, 60], client throttling [14, 38, 45], circuit scheduling [57], and flow/congestion control [15]. While some of this work has or will be incorporated into the Tor software, none of it has provided a comprehensive understanding of *where* the most significant source of congestion occurs in a complete Tor deployment. This lack of understanding has led to the design of uninformed algorithms and speculative solutions. In this paper, we seek a more thorough understanding of congestion in Tor and its effect on Tor's security. We explore an answer to the fundamental question—"*Where* is Tor slow?"—and design informed solutions that not only decrease congestion, but also improve Tor's ability to manage it as Tor continues to grow.

Congestion in Tor: We use a multifaceted approach to exploring congestion. First, we develop a shared library and Tor software patch for measuring congestion *local to relays* running in the public Tor network, and use them to measure congestion from three live relays under our control. Second, we develop software patches for Tor and the open-source Shadow simulator [7], and use them to measure congestion along the *full end-to-end path* in the largest known, at-scale, private Shadow-Tor deployment. Our Shadow patches ensure that our congestion measurements are accurate and realistic; we show how they significantly improve Shadow's TCP implementation, network topology, and Tor models.[1]

[1] We have contributed our patches to the Shadow project [7] and they have been integrated as of Shadow release `1.9.0`.

To the best of our knowledge, we are the first to consider such a comprehensive range of congestion information that spans from individual application instances to full network sessions for the entire distributed system. Our analysis indicates that congestion occurs almost exclusively inside of the kernel egress socket buffers, dwarfing the Tor and the kernel ingress buffer times. This finding is consistent among all three public Tor relays we measured, and among relays in every circuit position in our private Shadow-Tor deployment. This result is significant, as Tor does not currently prevent, detect, or otherwise manage kernel congestion.

Mismanaged Socket Output: Using this new understanding of *where* congestion occurs, we analyze Tor's socket output mechanisms and find two significant and fundamental design issues: Tor *sequentially* writes to sockets while ignoring the state of all sockets other than the one that is currently being written; and Tor writes *as much as possible* to each socket.

By writing to sockets sequentially, Tor's circuit scheduler considers only a small subset of the circuits with writable data. We show how this leads to improper utilization of circuit priority mechanisms, which causes Tor to send lower priority data from one socket *before* higher priority data from another. This finding confirms evidence from previous work indicating the ineffectiveness of circuit priority algorithms [35].

By writing as much as possible to each socket, Tor is often delivering to the kernel more data than it is capable of sending due to either physical bandwidth limitations or throttling by the TCP congestion control protocol. Not only does writing too much increase data queuing delays in the kernel, it also further reduces the effectiveness of Tor's circuit priority mechanisms because Tor relinquishes control over the priority of data after it is delivered to the kernel.[2] This kernel overload is exacerbated by the fact that a Tor relay may have thousands of sockets open at any time in order to facilitate data transfer between other relays, a problem that may significantly worsen if Tor adopts recent proposals [16, 26] that suggest increasing the number of sockets between relays.

KIST: Kernel-Informed Socket Transport: To solve the socket management problems outlined above, we design KIST: a Kernel-Informed Socket Transport algorithm. KIST has two features that work together to significantly improve Tor's control over network congestion. First, KIST changes Tor's circuit level scheduler so that it chooses from *all* circuits with writable data rather than just those belonging to a single TCP socket. Second, to complement this global scheduling approach, KIST also dynamically manages the amount of data written to each socket based on real-time kernel and TCP state information. In this way, KIST attempts to minimize the amount of data that exists in the kernel that cannot be sent, and to maximize the amount of time that Tor has control over data priority.

We perform in-depth experiments in our at-scale private Shadow-Tor network, and we show how KIST can be used to relocate congestion from the kernel into Tor, where it can be properly managed. We also show how KIST allows Tor to correctly utilize its circuit priority scheduler, reducing download latency by over 660 milliseconds, or 23.5 percent, for interactive traffic streams typically generated by web browsing behaviors.

We analyze the security of KIST, showing how it affects well-known latency and throughput attacks. In particular, we show the extent to which the latency improvements reduce the number of round-trip time measurements needed to conduct a successful latency attack [31]. We also show how KIST does not significantly affect an adversary's ability to collect accurate measurements required for the throughput correlation attack [44] when compared to vanilla Tor.

Outline of Major Contributions: We outline our major contributions as follows:

- in Section 3 we discuss improvements to the open-source Shadow simulator that significantly enhance its accuracy, including experiments with the largest known private Tor network of 3,600 relays and 13,800 clients running real Tor software;
- in Section 4 we discuss a library we developed to measure congestion in Tor, and results from the first known end-to-end Tor circuit congestion analysis;
- in Section 5 we show how Tor's current management of sockets results in ineffective circuit priority, detail the KIST design and prototype, and show how it improves Tor's ability to manage congestion through a comprehensive and full-network evaluation; and
- in Section 6 we analyze Tor's security with KIST by showing how our performance improvements affect well-known latency and throughput attacks.

2 Background and Related Work

Tor [21] is a volunteer-operated anonymity service used by an estimated hundreds of thousands of daily users [28]. Tor assumes an adversary who can monitor a portion of the underlying Internet and/or operate Tor relays. People primarily use Tor to prevent an adversary from discovering the endpoints of their communications, or disrupting access to information.

Tor Traffic Handling: Tor provides anonymity by forming source-routed paths called *circuits* that consist of (usually) three relays on an overlay network. Clients transfer TCP-based application traffic within these circuits; encrypted application-layer headers and payloads

[2] To the best of our knowledge, the Linux kernel uses a variant of the first-come first-serve queuing discipline among sockets.

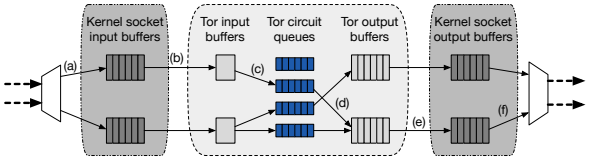

Figure 1: Internals of cell processing within in a Tor relay. Dashed lines denote TCP connections. Transitions between buffers—both within the kernel (side boxes) and within Tor (center box)—are shown with solid arrows.

make it more difficult for an adversary to discern an intercepted communication's endpoints or learn its plaintext.

A given circuit may carry several Tor *streams*, which are logical connections between clients and destinations. For example, a HTTP request to usenix.org may result in several Tor streams (i.e., to fetch embedded objects); these streams may all be transported over a single circuit. Circuits are themselves multiplexed over TLS connections between relays whenever their paths share an edge; that is, all concurrent circuits between relays u and v will be transferred over the same TLS connection between the two relays, irrespective of the circuits' endpoints.

The unit of transfer in Tor is a 512-byte *cell*. Figure 1 depicts the internals of cell processing within a Tor relay. In this example, the relay maintains two TLS connections with other relays. Incoming packets from the two TCP streams are first demultiplexed and placed into kernel socket input buffers by the underlying OS (Figure 1a)[3]. The OS processes the packets, usually in FIFO order, delivering them to Tor where they are reassembled into TLS-encrypted cells using dedicated Tor input buffers (Figure 1b). Upon receipt of an entire TLS datagram, the TLS layer is removed, the cell is onion-crypted,[4] and then transferred and enqueued in the appropriate Tor circuit queue (Figure 1c). Each relay maintains a queue for each circuit that it is currently serving. Cells from the same Tor input buffer may be enqueued in different circuit queues, since a single TCP connection between two relays may carry multiple circuits.

Tor uses a priority-based circuit scheduling approach that attempts to prioritize interactive web clients over bulk downloaders [57]. The circuit scheduler selects a cell from a circuit queue to process based on this prioritization, onion-crypts the cell, and stores it in a Tor output buffer (Figure 1d). Once the Tor output buffer contains sufficient data to form a TLS packet, the data is written to the kernel for transport (Figure 1f).

Improving Tor Performance: There is a large body of work that attempts to improve Tor's network performance, e.g., by refining Tor's relay selection strategy [11,55,56] or providing incentives to users to operate Tor relays [36,37,45]. These approaches are orthogonal and can be applied in concert with our work, which focuses on improving Tor's congestion management.

Most closely related to this paper are approaches that modify Tor's circuit scheduling, flow control, or transport mechanisms. Reardon and Goldberg suggest replacing Tor's TCP-based transport mechanism with UDP-based DTLS [54], while Mathewson explores using SCTP [40]. Murdoch [47] explains that the UDP approach is promising, but there are challenges that have thus far prevented the approach from being deployed: there is limited kernel support for SCTP; and the lack of hop-by-hop reliability from UDP-based transports causes increased load at Tor's exit relays. Our work allows Tor to best utilize the existing TCP transport in the short term while work toward a long term UDP deployment strategy continues.

Tang and Goldberg propose the use of the exponential weighted moving average (EWMA) to characterize circuits' recent levels of activity, with bursty circuits given greater priority than busy circuits [57] (to favor interactive web users over bulk downloaders). Unfortunately, although Tor has adopted EWMA, the network has not significantly benefitted from its use [35]. In our study of *where* Tor is slow, we show that EWMA is made ineffective by Tor's current management of sockets, and can be made effective through our proposed modifications.

AlSabah et al. propose an ATM-like congestion and flow control system for Tor called N23 [15]. Their approach causes pushback effects to previous nodes, reducing congestion in the entire circuit. Our KIST strategy is complementary to N23, focusing instead on local techniques to remove kernel-level congestion at Tor relays.

Torchestra [26] uses separate TCP connections to carry interactive and bulk traffic, isolating the effects of congestion between the two traffic classes. Conceptually, Torchestra moves circuit-selection logic to the kernel, where the OS schedules packets for the two connections. Relatedly, AlSabah and Goldberg introduce PCTCP [16], a transport mechanism for Tor in which each circuit is assigned its own IPsec tunnel. In this paper, we argue that overloading the kernel with additional sockets reduces the effectiveness of circuit priority mechanisms since the kernel has no information regarding the priority of data. In contrast, we aim to move congestion management to Tor, where priority scheduling can be most effective.

Nowlan et al. [50] propose the use of uTCP and uTLS [49] to tackle the "head-of-line" blocking problem in Tor. Here, they bypass TCP's in-order delivery mechanism to peek at traffic that has arrived but is not ready to be delivered by the TCP stack (e.g., because an earlier packet was dropped). Since Tor multiplexes multiple cir-

[3]For simplicity, we consider only relays that run Linux since such relays represent 75% of all Tor relays and contribute 91% of the bandwidth of the live Tor network [58].

[4]Encrypted or decrypted, depending on circuit direction.

cuits over a single TCP connection, their technique offers significant latency improvements when connections are lossy, since already-arrived traffic can be immediately processed. Our technique can be viewed as a form of application-layer head-of-line countermeasure since we move scheduling decisions from the TCP stack to within Tor. In contrast to Nowlan et al.'s approach, we do not require any kernel-level modifications or changes to Tor's transport mechanism.

3 Enhanced Network Experimentation

To increase confidence in our experiments, we introduce three significant enhancements to the Shadow Tor simulator [35] and its existing models [33]: a more realistic simulated kernel and TCP network stack, an updated Internet topology model, and the largest known deployed private Tor network. The enhancements in this section represent a large and determined engineering effort; we will show how Tor experimental accuracy has significantly benefited as a result of these improvements. We remark that our improvements to Shadow will have an immediate impact beyond this work to the various research groups around the world that use the simulator.

Shadow TCP Enhancements: After reviewing Shadow [7], we first discovered that it was missing many important TCP features, causing it to be less accurate than desired. We enhanced Shadow by adding the following: retransmission timers [52], fast retransmit/recovery [12], selective acknowledgments [42], and forward acknowledgments [41]. Second, we discovered that Shadow was using a very primitive version of the basic additive-increase multiplicative-decrease (AIMD) congestion control algorithm. We implemented a much more complete version of the CUBIC algorithm [27], the default congestion control algorithm used in the Linux kernel since version 2.6.19. CUBIC is an important algorithm for properly adjusting the congestion window. We will show how our implementation of these algorithms greatly enhance Shadow's accuracy, which is paramount to the remainder of this paper. See Appendix A.1 [34] for more details about our modifications.

We verify the accuracy of Shadow's new TCP implementation to ensure that it is adequately handling packet loss and properly growing the congestion window by comparing its behavior to ns [51], a popular network simulator, because of the ease at which ns is able to model packet loss rates. In our first experiment, both Shadow and ns have two nodes connected by a 10 MiB/s link with a 10 ms round trip time. One node then downloads a 100 MiB file 10 times for each tested packet loss rate. Figure 2a shows that the average download time in Shadow matches well with ns over varying packet loss rates. Although not presented here, we similarly validated Shadow with our changes against a real network link using the bandwidth and packet loss rate that was achieved over our switch; the results did not significantly deviate from those presented in Figure 2a.

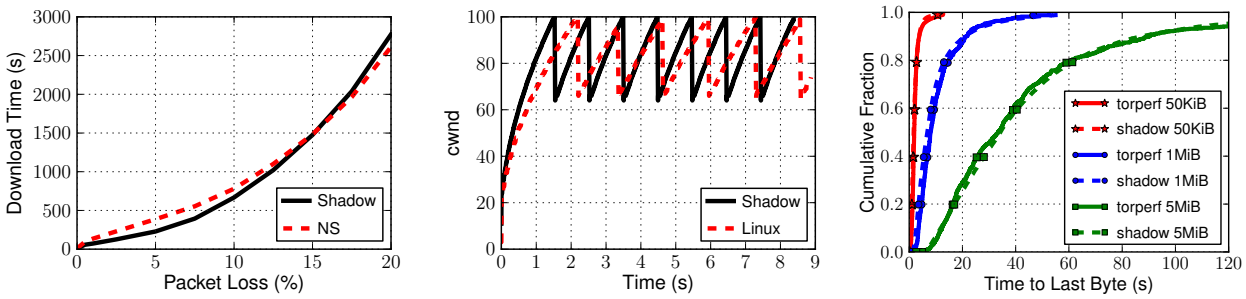
For our second experiment, we check that the growth of the congestion window using CUBIC is accurate. We first transfer a 100 MiB file over a 100 Mbit/s link between two physical Ubuntu 12.04 machines running the 3.2.0 Linux kernel. We record the `cwnd` (congestion window) and `ssthresh` (slow start threshold) values from the `getsockopt` function call using the `TCP_INFO` option. We then run an identical experiment in Shadow, setting the slow start threshold to what we observed from Linux and ensuring that packet loss happens at roughly the same rate. Figure 2b shows the value of `cwnd` in both Shadow and Linux over time, and we see almost identical growth patterns. The slight variation in the saw-tooth pattern is due to unpredictable variation in the physical link that was not reproduced by Shadow. As a result, Shadow's `cwnd` grew slightly faster than Linux's because Shadow was able to send one extra packet. We believe this is an artifact of our particular physical configuration and do not believe it significantly affects simulation accuracy in general: more importantly, the overall saw-tooth pattern matches well.

The two experiments discussed above give us high confidence that our TCP implementation is accurate, both in responding to packet loss and in operation of the CUBIC congestion control algorithm.

Shadow Topology Enhancements: To ensure that we are causing the most realistic performance and congestion effects possible during simulation, we enhance Shadow using techniques from recent research in modeling Tor topologies [39, 59], traceroute data from CAIDA [2], and client/server data from the Tor Metrics Portal [8] and Alexa [1]. This data-driven Internet map is more realistic than the one Shadow provides, and includes 699,029 vertices and 1,338,590 edges. For space reasons, we provide more details in Appendix A.2 [34].

Tor Model: Using Shadow with the improvements discussed above, we build a Tor model that reflects the real Tor network as it existed in July 2013, using the then-latest stable Tor version `0.2.3.25`. (We use this model for all experiments in this paper.) Using data from the Tor Metrics Portal [8], we configure a complete, private Tor network following Tor modeling best practices [33], and attach every node to the closest network location in our topology map. The resulting Tor network configuration includes 10 directory authorities, 3,600 relays, 13,800 clients, and 4,000 file servers—the largest known working private experimental Tor network, and the first to run at scale to the best of our knowledge.

The 13,800 clients in our model provide background traffic and load on the network. 10,800 of our clients



(a) Download Time, Shadow vs. ns (b) Congestion Window, Shadow vs. Linux (c) Download Time, Shadow-Tor vs. Tor

Figure 2: Figure 2a compares Shadow to ns download times. Figure 2b compares congestion window over time when Shadow and Linux have the same link properties. Figure 2c compares Shadow-Tor to live Tor measurements collected from Tor Metrics [8].

download 320 KiB files (the median size of a web page according to the most recent web statistics published by a Google engineer [53]) and then wait for a time chosen uniformly at random from the range [1, 60 000] milliseconds after each completed download. 1,200 of our clients repeatedly download 5 MiB files with no pauses between completing a download and starting the next. The ratio of these client behaviors was chosen according to the latest known measurements of client traffic on Tor [18, 43]. Shadow also contains 1,800 TorPerf [9] clients that download a file over a fresh circuit and pause for 60 seconds after each successful download. (TorPerf is a tool for measuring Tor performance.) 600 of the TorPerf clients download 50 KiB files, 600 download 1 MiB files, and 600 download 5 MiB files. Our simulations run for one virtual hour during each experiment.

Figure 2c shows a comparison of publicly available TorPerf measurements collected on the live Tor network [8] to those collected in our private Shadow-Tor network. As shown in Figure 2c, our full size Shadow-Tor network is extremely accurate in terms of time to complete downloads for all file sizes. These results give us confidence that our at-scale Shadow-Tor network is strongly representative of the deployed Tor network.

4 Congestion Analysis

In this section, we explore *where* congestion happens in Tor through a large scale congestion analysis. We take a multifaceted approach by measuring congestion as it occurs in both the live, public Tor network, and in an experimental, private Tor network running in Shadow. By analyzing relays in the public Tor network, we get the most realistic and accurate view of what is happening at our measured relays. We supplement the data from a relatively small public relay sample with measurements from a much larger set of private relays, collecting a larger and more complete view of Tor congestion.

To understand congestion, we are interested in measuring the time that data spends inside of Tor as well as inside of kernel sockets in both the incoming and outgoing directions. We will discuss our findings in both environments after describing the techniques that we used to collect the time spent in these locations.

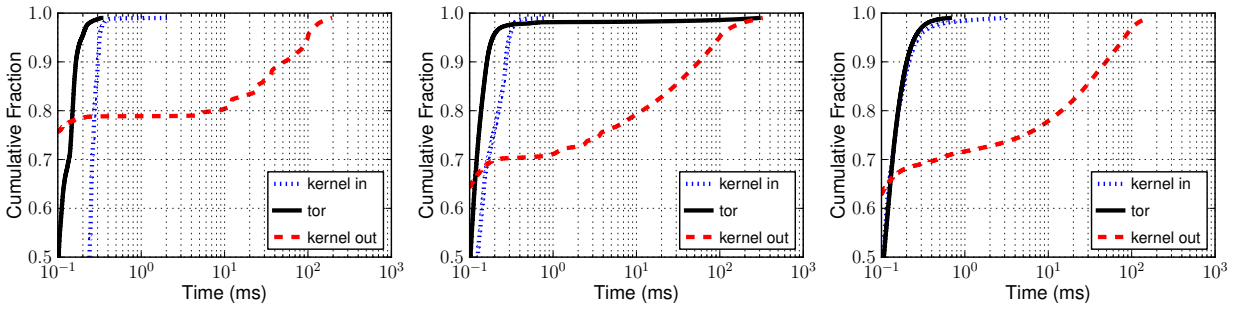
4.1 Congestion in the Live Tor Network

Relays running in the operational network provide the most accurate source of congestion data, as these relays are serving real clients and transferring real traffic. As mentioned above, we are interested in measuring queuing times inside of the Tor application as well as inside of the kernel, and so we developed techniques for both in the local context of a public Tor relay.

Tor Congestion: Measuring Tor queuing times requires some straightforward modifications to the Tor software. As soon as a relay reads the entire cell, it internally creates a cell structure that holds the cell's circuit ID, command, and payload. We add a new unique cell ID value. Whenever a cell enters Tor and the cell structure is created, we log a message containing the current time and the cell's unique ID. The cell is then switched to the outgoing circuit. After it's sent to the kernel we log another message containing the time and ID. The difference between these times represents Tor application congestion.

Kernel Congestion: Measuring kernel queuing times is much more complicated since Tor does not have direct access to the kernel internals. In order to log the times when a piece of data enters and leaves the kernel in both the incoming and outgoing directions, we developed a new, modular, application-agnostic, multithreaded library, called `libkqtime`.[5] `libkqtime` uses `libpcap` [6] to determine when data crosses the host/network boundary, and *function interposition* on

[5] `libkqtime` was written in 770 LOC, and is available for download as open source software [5].



(a) curiosity1 (b) curiosity2 (c) curiosity3

Figure 3: The distribution of congestion inside Tor and the kernel on our 3 relays running in the public Tor network, as measured between 2014-01-20 and 2014-01-28. Most congestion occurred in the outbound kernel queues on all three relays.

the `write()`, `send()`, `read()`, and `recv()` functions to determine when it crosses the application/kernel boundary. The library copies a 16 byte tag as data enters the kernel from either end, and then searches for the tag as data leaves the kernel on the opposite end. This process works in both directions, and the timestamps collected by the library allow us to measure both inbound and outbound kernel congestion. Appendix B [34] gives a more detailed description of `libkqtime`.

Results: To collect congestion information in Tor, we first ran three live relays (curiosity1, curiosity2, and curiosity3) using an unmodified copy of Tor release `0.2.3.25` for several months to allow them to stabilize. We configured them as non-exit nodes and used a network appliance to rate limit curiosity1 at 1 Mbit/s, curiosity2 at 10 Mbit/s, and curiosity3 at 50 Mbit/s. Only curiosity2 had the guard flag (could be chosen as entry relay for a circuit) during our data collection. On 2014-01-20, we swapped the Tor binary with a version linked to `libkqtime` and modified as discussed in Section 4.1. We collected Tor and kernel congestion for 190 hours (just under 8 days) ending on 2014-01-28, and then replaced the vanilla Tor binary.

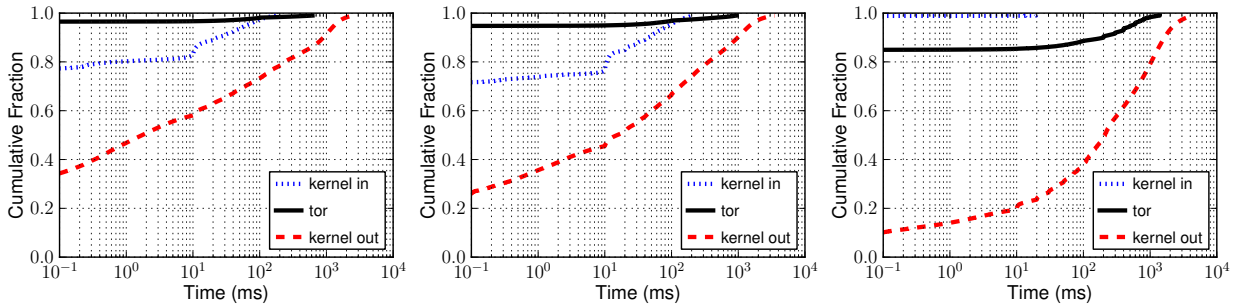
The distributions of congestion as measured on each relay during the collection period are shown in Figure 3 with logarithmic x-axes. Our measurements indicate that most congestion, when present, occurs in the *kernel outbound queues*, while kernel inbound and Tor congestion are both less than 1 millisecond for over 95 percent of our measurements. This finding is consistent across all three relays we measured. Kernel outbound congestion increases from curiosity1 to curiosity2, and again slightly from curiosity2 to curiosity3, indicating that congestion is a function of relay capacity or load. We leave it to future work to analyze the strength of this correlation, as that is outside the scope of this paper.

Ethical Considerations: We took careful protections to ensure that our live data collection did not breach users' anonymity. In particular, *we captured only buffered data timing information*; no network addresses were ever recorded. We discussed our experimental methodology with Tor Project maintainers, who raised no objections. Finally, we contacted the IRB of our relay host institution. The IRB decided that no review was warranted since our measurements did not, in their opinion, constitute human subjects research.

4.2 Congestion in a Shadow-Tor Network

While congestion data from real live relays is the most accurate, it only gives us a limited view of congestion local to our relays. The congestion measured at our relays may or may not be representative of congestion at other relays in the network. Therefore, we use our private Shadow-Tor network to supplement our congestion data and enhance our analysis. Using Shadow provides many advantages over live Tor: it's technically simpler; we are able to measure congestion *at all relays* in our private network; we can track the congestion of every cell *across the entire circuit* because we do not have privacy concerns with Shadow; and we can analyze how congestion changes with varying network configurations.

Tor and Kernel Congestion: The process for collecting congestion in Shadow is simpler than in live Tor, since we have direct access to Shadow's virtual kernel. In our modified Tor, each cell again contains a unique ID as in Section 4.1. However, when running in Shadow, we also add a 16 byte magic token and include both the unique ID and the magic token when sending cells out to the network. The unique ID is forwarded with the cell as it travels through the circuit. Since Shadow prevents Tor from encrypting cell contents for efficiency reasons, the Shadow kernel can search outgoing packets for the unencrypted magic token immediately before they leave the virtual network interface. When found, it logs the unique cell ID with a timestamp. It performs an analogous procedure for incoming packets immediately after they arrive on the virtual network interface. These



(a) Relays in Entry Position (b) Relays in Middle Position (c) Relays in Exit Position

Figure 4: Relay congestion by circuit position in our Shadow-Tor network, measured on on circuits using end-to-end cells from 1,200 clients selected uniformly at random. Most congestion occurred in the outbound kernel queues, independent of relay position.

Shadow timestamps are combined with the timestamps logged when a cell enters and leaves Tor to compute both Tor and kernel congestion.

Results: We use our model of Tor as described in Section 3, with the addition of the cell tracking information discussed above. Since tracking every cell would consume an extremely large amount of disk space, we sample congestion as follows: we select 10 percent of the non-TorPerf clients (1,200 total) in our network chosen uniformly, and track 1 of every 100 cells traveling over circuits they initiate. The tracking timestamps from these cells are then used to attribute congestion to the relays through which the cells are traveling.

It is important to understand that our method does not sample *relay* congestion uniformly: the congestion measurements will be biased towards relays that are chosen more often by clients, according to Tor's bandwidth-weighted path selection algorithm. This means that our results will represent the congestion that a typical *client* will experience when using Tor. We believe that these results are more meaningful than those we could obtain by uniformly sampling congestion at each relay independently (as we did in Section 4.1), because ultimately we are interested in improving clients' experience.

The distributions of congestion measured in Shadow for each circuit position are shown in Figure 4. We again find that congestion occurs most significantly in the kernel outbound queues, regardless of a relay's circuit position. Our Shadow experiments indicate higher congestion than in live Tor, which we attribute to our client-oriented sampling method described above.

5 Kernel-Informed Socket Transport

Our large scale congestion analysis from Section 4 revealed that the most significant delay in Tor occurs in outbound kernel queues. In this section, we first explore how this problem adversely affects Tor's traffic management by disrupting existing scheduling mechanisms to the extent that they become ineffective. We then describe the KIST algorithm and experimental results.

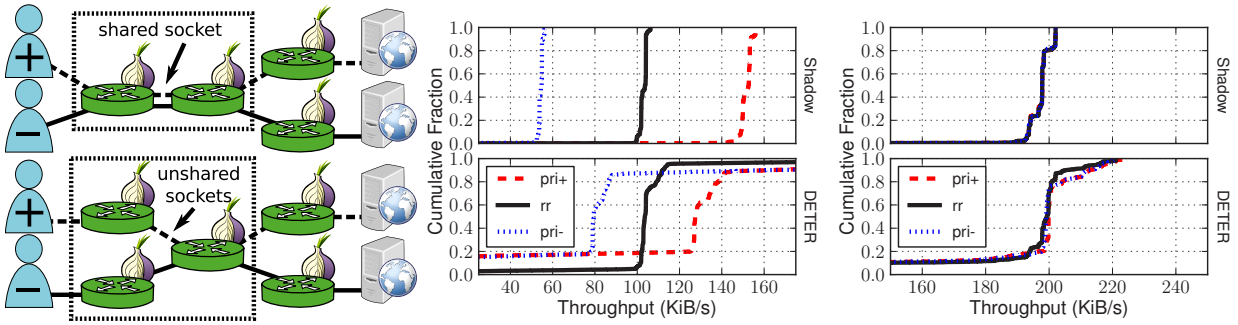
5.1 Mismanaged Socket Output

As described in Section 2, each Tor relay creates and maintains a single TCP connection to every relay to which it is connected. All communication between two relays occurs through this single TCP connection channel. In particular, this channel multiplexes all circuits that are established between its relay endpoints. TCP provides Tor a reliable and in-order data transport.

Sequential Socket Writes: Tor uses the asynchronous event library `libevent` [4] to assist with sending and receiving data to and from the kernel (i.e. network). Each TCP connection is represented as a socket in the kernel, and is identified by a unique socket descriptor. Tor registers each socket descriptor with libevent, which itself manages kernel polling and triggers an asynchronous notification to Tor via a callback function of the readability and writability of that socket. When Tor receives this notification, it chooses to read or write as appropriate.

An important aspect of these libevent notifications is that they happen for *one socket at a time*, regardless of the number of socket descriptors that Tor has registered. Tor attempts to send or receive data from that one socket without considering the state of any of the other sockets. This is particularly troublesome when writing, as Tor will only be able to choose from the non-empty circuits belonging to the currently triggered socket and no other. Therefore, Tor's circuit scheduler may schedule a circuit with worse priority than it would have if it could choose from all sockets that are able to be triggered at that time. Since the kernel schedules with a first-come first-serve (FCFS) discipline, Tor may actually be sending data out of priority order simply due to the order in which the socket notifications are delivered by libevent.

Bloated Socket Buffers: Linux uses TCP autotuning to dynamically and monotonically increase each



(a) Socket Sharing Scenarios (b) Throughput with Shared Socket (c) Throughput with Unshared Sockets

Figure 5: Socket sharing affects circuit priority scheduling.

socket buffer's capacity using the socket connection's bandwidth-delay product calculation [61]. TCP auto-tuning increases the amount of data the kernel will accept from the application in order to ensure that the socket is able to fully utilize the network link. TCP auto-tuning is an extremely useful technique to maximize throughput for applications with few sockets or without priority requirements. However, it may cause problems for more complex applications like Tor.

When libevent notifies Tor that a socket is writable, Tor writes as much data as possible to that socket (i.e., until the kernel returns `EWOULDBLOCK`). Although this improves utilization when only a few auto-tuned sockets are in use, consider a Tor relay that writes to thousands of auto-tuned sockets (a common situation since Tor maintains a socket for every relay with which it communicates). These sockets will *each* attempt to accept enough data to fully utilize the link. If Tor fills all of these sockets to capacity, the kernel will clearly be unable to immediately send it all to the network. Therefore, with many active sockets in general and for asymmetric connections in particular, the potential for kernel queuing delays are dramatic. As we have shown in Section 4, writing as much as possible to the kernel as Tor currently does results in large kernel queuing delays.

Tor can no longer adjust data priority once it is sent to the kernel, even if that data is still queued in the kernel when Tor receives data of higher importance later. To demonstrate how this may result in poor scheduling decisions, consider a relay with two circuits: one contains sustained, high throughput traffic of worse priority (typical of many bulk data transfers), while the other contains bursty, low throughput traffic of better priority (typical of many interactive data transfer sessions). In the absence of data on the low throughput circuit, the high throughput circuit will fill the entire kernel socket buffer whether or not the kernel is able to immediately send that data. Then, when a better priority cell arrives, Tor will immediately schedule and write it to the kernel. However, since the kernel sends data to the network in the same order in which it was received from the application (FCFS), that better priority cell data must wait until all of the previously received high throughput data is flushed to the network. This problem theoretically worsens as the number of sockets increase, suggesting that recent research proposing that Tor use multiple sockets between each pair of relays [16, 26] may be misguided.

Effects on Circuit Priority: To study the effects on circuit priority, we customized Tor as follows. First, we added the ability for each client to send a special cell after building a circuit that communicates one of two priority classes to the circuit's relays: a better priority class; or a worse priority class. Second, we customized the built-in EWMA circuit scheduler that prioritizes bursty traffic over bulk traffic [57] to include a priority factor $\mathscr{F}$: the circuit scheduler counts $\mathscr{F}$ cells for every cell scheduled on a worse priority circuit. Therefore, the EWMA of the worse priority class will effectively increase $\mathscr{F}$ times faster than normal, giving a scheduling advantage to better priority traffic.

We experiment with two separate private Tor networks: one using Shadow [35], a discrete event network simulator that runs Tor in virtual processes; and the other using DETER [3], a custom experimentation testbed that runs Tor on bare-metal hardware. We consider two clients downloading from two file servers through Tor in the scenarios shown in Figure 5a:

- *shared socket:* the clients share entry and middle relays, but use different exit relays – the clients' circuits each belong to the same socket connecting the middle to the entry; and
- *unshared sockets:* the clients share only the middle relay – the clients' circuits each belong to independent sockets connecting the middle to each entry.

We assigned one client's traffic to the better priority class (denoted with "+") and the other client's traffic to the worse priority class (denoted with "-"). We configured all nodes with a 10 Mbit symmetric access link, and approximated a middle relay bottleneck by setting its socket buffer size to 32 KiB. Our configuration allows us

to focus on the socket contention that will occur at the middle relay, and the four cases that result when considering whether or not the two circuits share incoming or outgoing TCP connections at the middle relay. Clients downloaded data through the circuits continuously for 10 minutes in Shadow and 60 minutes on DETER.[6]

The results collected during each of the scenarios are shown in Figure 5. Plotted is the cumulative distribution of the throughput achieved by the better ("pri+") and worse ("pri-") priority clients using the priority scheduler, as well as the combined cumulative distribution for both clients using Tor's default round-robin scheduler ("rr"). As shown in Figure 5b, performance differentiation occurs correctly with the priority scheduler on a shared socket. However, as shown in Figure 5c, the priority scheduler is unable to differentiate throughput when the circuits do not share a socket.

Discussion: As outlined above, the reason for no differentiation in the case of the unshared socket is that both circuits are treated independently by the scheduler due to the sequential libevent notifications and the fact that Tor currently schedules circuits belonging to one socket at a time while ignoring the others. We used TorPS [10], a Tor path selection simulator, to determine how often we would expect unshared sockets to occur in practice. We used TorPS to build 10 million paths following Tor's path selection algorithm, and computed the probability of two circuit paths belonging to each scenario. We found that any two paths may be classified as unshared (they share at least one relay but never share an outgoing socket) at least 99.775 percent of the time, clearly indicating that adjusting Tor's socket management may have a dramatic effect on data priority inside of Tor.

Note that the socket mismanagement problem is not solved simply by parallelizing the libevent notification system and priority scheduling processes (which would require complex code), or by utilizing classful queuing disciplines in the kernel (which would require root privileges); while these may improve control over traffic priority to some extent, they would still result in bloated buffers containing data that cannot be sent due to closed TCP congestion windows.

5.2 The KIST Algorithm

In order to overcome the inefficiencies resulting from Tor's socket management, KIST chooses between *all circuits* that have queued data *irrespective* of the socket to which the circuit belongs, and *dynamically adjusts the amount written* to each socket based on real-time kernel information. We now detail each of these approaches.

[6]The small-scale experiments described here are meant to isolate Tor's internal queuing behavior for analysis purposes, and do not fully represent the live Tor network, its background traffic, or its load.

Algorithm 1 The KIST `NotifySocketWritable()` callback, invoked by libevent for each writable socket.

Require: $sdesc, conn, \mathscr{T} \leftarrow GlobalWriteTimeout$

1: $L_p \leftarrow getPendingConnectionList()$
2: **if** L_p **is** $Null$ **then**
3: $\quad L_p \leftarrow newList()$
4: $\quad setPendingConnectionList(L_p)$
5: $\quad createCallback(\mathscr{T}, \texttt{NotifyGlobalWrite()})$
6: **end if**
7: **if** $L_p.contains(conn)$ **is** $False$ **then**
8: $\quad L_p.add(conn)$
9: **end if**
10: $disableNotify(sdesc)$

Global Circuit Scheduling: Recall that libevent delivers write notification events for a single socket at a time. Our approach with KIST is relatively straightforward: rather than handle the kernel write task immediately when libevent notifies Tor that a socket is writable, we simply collect a set of sockets that are writable over a time interval specified by an adjustable `GlobalWriteTimeout` parameter. This allows us to increase the number of candidate circuits we consider when scheduling and writing cells to the kernel: we may select among all circuits which contain cells that are waiting to be written to one of the sockets in our writable set.

The socket collection approach is outlined in Algorithm 1. The socket descriptor `sdesc` and a connection state object `conn` are supplied by libevent. Note that we disable notification events for the socket (as shown in line 10) in order to prevent duplicate notification events during the socket collection interval.

After the `GlobalWriteTimeout` time interval, KIST begins writing cells to the sockets according to the circuit scheduling policy. There are two major phases to this process, which is outlined in Algorithm 2. In lines 4 and 8, we distinguish sockets that contain raw bytes ready to be written directly to the kernel (previously scheduled cells with TLS headers attached) from those with additional cells ready to be converted to raw bytes. KIST first writes the already scheduled raw bytes (lines 4-7), and then schedules and writes additional cells after converting them to raw bytes and adding TLS headers (lines 13-15). Note that the connections should be enumerated (on line 3 of Algorithm 2) in an order that respects the order in which cells were converted to raw bytes by the circuit scheduler in the previous round.

The global scheduling approach does not by itself solve the bloated socket buffer problem. KIST also dynamically computes socket write limits on line 2 of Algorithm 2 using real-time TCP, socket, and bandwidth information, which it then uses when deciding how much to write to the kernel.

Algorithm 2 The KIST `NotifyGlobalWrite()` callback, invoked after the `GlobalWriteTimeout` period.

1: $L_{eligible} \leftarrow newList()$
2: $K \leftarrow collectKernelInfo(getConnectionList())$
3: **for all** *conn* **in** $getPendingConnectionList()$ **do**
4: **if** $hasBytesForKernel(conn)$ **is** $True$ **then**
5: $enableNotify(conn)$
6: $nBytes \leftarrow writeBytesToKernel(K, conn)$
7: **end if**
8: **if** $hasCells(conn)$ **is** $True$ **and** $getLimit(K, conn) > 0$ **then**
9: $L_{eligible}.add(conn)$
10: **end if**
11: **end for**
12: **while** $L_{eligible}.isEmpty()$ **is** $False$ **do**
13: $conn \leftarrow scheduleCell(L_{eligible})$ {cell to bytes}
14: $enableNotify(conn)$
15: $nBytes \leftarrow writeBytesToKernel(K, conn)$
16: **if** $nBytes$ **is** 0 **or** $getLimit(K, conn)$ **is** 0 **then**
17: $L_{eligible}.remove(conn)$
18: **end if**
19: **end while**

Managing Socket Output: KIST attempts to move the queuing delays from the kernel outbound queue to Tor's circuit queue by keeping kernel output buffers as small as possible, i.e., by only writing to the kernel as much as the kernel will actually send. By delaying the circuit scheduling decision until the last possible instant before kernel starvation occurs, Tor will ultimately improve its control over the priority of outgoing data. This approach attempts to give Tor approximately the same control over outbound data that it would have if it had direct access to the network interface. When combined with global circuit scheduling, Tor's influence over outgoing data priority should improve.

To compute write limits, KIST first makes three system calls for each connection: `getsockopt` on level `SOL_SOCKET` for option `SO_SNDBUF` to get *sndbufcap*, the capacity of the send buffer; `ioctl` with command `SIOCOUTQ` to get *sndbuflen*, the current length of the send buffer; and `getsockopt` on level `SOL_TCP` for option `TCP_INFO` to get *tcpi*, a variety of TCP state information. The TCP information used by KIST includes the connection's maximum segment size *mss*, the congestion window *cwnd*, and the number of *unacked* packets for which the kernel is waiting for an acknowledgment from the TCP peer. KIST then computes a write limit for each connection c as follows:

$$\begin{aligned} socket\_space_c &= sndbufcap_c - sndbuflen_c \\ tcp\_space_c &= (cwnd_c - unacked_c) \cdot mss_c \\ limit_c &= \min(socket\_space_c, tcp\_space_c) \end{aligned} \quad (1)$$

The key insight in Equation 1 is that TCP will not allow the kernel to send more packets than dictated by the congestion window, and that the unacknowledged packets prevent the congestion window from sliding open. By respecting this write limit for each connection, KIST ensures that the data sent to the kernel is immediately sendable and reduces kernel queuing delays.

If all connections are sending data in parallel, it is still possible to overwhelm the kernel with more data than it can physically send to the network. Therefore, KIST also computes a global write limit at the beginning of each `GlobalWriteTimeout` period:

$$\begin{aligned} sndbuflen\_prev &= sndbuflen \\ sndbuflen &= \textstyle\sum_{c_i} \left(sndbuflen_{c_i}\right) \\ bytes\_sent &= sndbuflen - sndbuflen\_prev \\ limit &= \max(limit, bytes\_sent) \end{aligned} \quad (2)$$

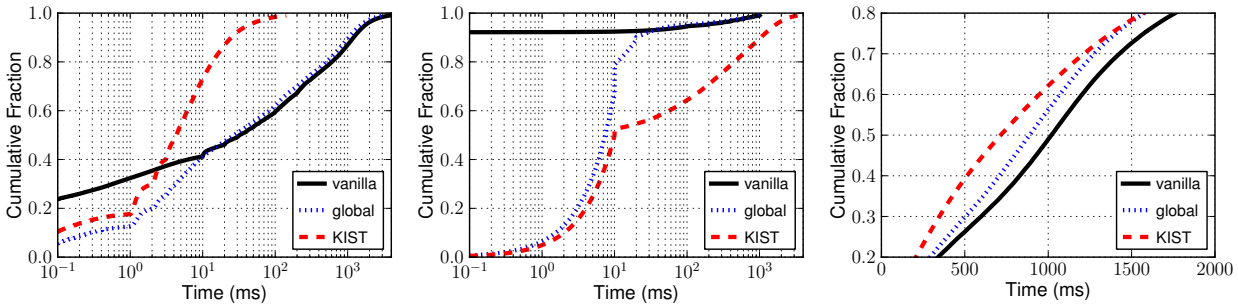
Note that Equation 2 is an attempt to measure the actual upstream bandwidth speed of the machine. In practice, this could be done in a testing phase during which writes are not limited, configured manually, or estimated using other techniques such as packet trains [32].

The connection and global limits are computed at the beginning of a scheduling round, i.e., on line 2 of Algorithm 2; they are enforced whenever bytes are written to the kernel, i.e., on lines 6 and 15 of Algorithm 2. Note that they will be bounded above by Tor's independently configured connection and global application rate limits.

5.3 Experiments and Results

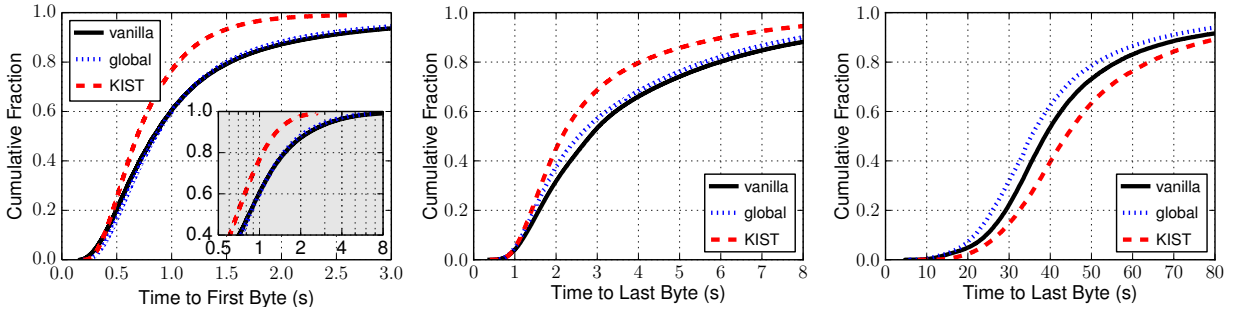
We use Shadow and its models as discussed in Section 3 to measure KIST's effect on network performance, congestion, and throughput. We also evaluate its CPU overhead. See Appendix C [34] for an analysis under a more heavily loaded Shadow-Tor network. Note that we found that KIST performs as well or better under heavier load than under normal load as presented in this section, indicating that it can gracefully scale as Tor grows.

Prototype: We implemented a KIST protoype as a patch to Tor version `0.2.3.25`, and included the elements discussed in Section 4 necessary for measuring congestion during our experiments. We tested vanilla Tor using the default `CircuitPriorityHalflife` of 30, the global scheduling part of KIST (without enforcing the write limits), and the complete KIST algorithm. We configured the global scheduler to use a 10 millisecond `GlobalWriteTimeout` in both the global and KIST experiments. Note that our KIST implementation ignores the connection enumeration order on line 3 of Algorithm 2, an optimization that may further improve Tor's control over priority in cases where the global limit is reached before the algorithm reaches line 12.



(a) Kernel Out Congestion (b) Tor Congestion (c) Circuit Congestion

Figure 6: Congestion for vanilla Tor, KIST, and the global scheduling part of KIST (without enforcing write limits). Figures 6a and 6b show the distribution of cell congestion local to each relay (with logarithmic x-axes), while Figure 6c shows the distribution of the end-to-end circuit congestion for all measured cells.



(a) All Clients (b) 320 KiB "web" clients (c) 5 MiB "bulk" clients

Figure 7: Client performance for vanilla Tor, KIST, and the global scheduling part of KIST (without enforcing write limits). Figure 7a shows the distribution of the time until the client receives the first byte of the data payload, for all clients, while the inset graph shows the same distribution with a logarithmic x-axis. Figures 7b and 7c show the distribution of time to complete a 320 KiB and 5 MiB file by the "web" and "bulk" clients, respectively.

Congestion: Recall that the goal of KIST is to move congestion from the kernel outbound queue to Tor where it can better be managed. Figure 6 shows KIST's effectiveness in this regard. In particular, Figure 6a shows that KIST reduces kernel outbound congestion over vanilla Tor by one to two order of magnitude for over 40 percent of the sampled cells. Further, it shows that the queue time is less than 200 milliseconds for 99 percent of the cells measured, compared to over 4000 milliseconds for both vanilla Tor and global scheduling alone.

Figure 6b shows how global scheduling and KIST increase the congestion inside of Tor. Both global scheduling and KIST result in sharp Tor queue time increases up to 10 milliseconds, after which the existing 10 millisecond `GlobalWriteTimeout` timer event will fire and Tor will flush more data to the kernel. With global scheduling, most of the data queued in Tor quickly gets transferred to the kernel following this timeout, whereas data is queued inside of Tor much longer when using KIST. This result is an explicit feature of KIST, as it means Tor will have more control over data priority when scheduling circuits.

While we have shown above how KIST is able to move congestion from the kernel into Tor, Figure 6c shows the aggregate effect on cell congestion during its complete existence through the entire end-to-end circuit. KIST reduces aggregate circuit congestion from 1010.1 milliseconds to 704.5 milliseconds in the median, a 30.3 percent improvement, while global scheduling reduces congestion by 13 percent to 878.8 milliseconds.

The results in Figure 6 show that KIST indeed achieves its congestion management goals while highlighting the importance of limiting kernel write amounts in addition to globally scheduling circuits.

Performance: We show in Figure 7 how KIST affects client performance. Figure 7a shows how network latency is generally affected by showing the time until the first byte of every download by all clients. Global scheduling alone is roughly indistinguishable from vanilla Tor, while KIST reduces latency to the first byte for over 80 percent of the downloads—in the median, KIST reduces network latency by 18.1 percent from 0.838 seconds to 0.686 seconds. The inset graph has a logarithmic x-axis and shows that KIST is particularly

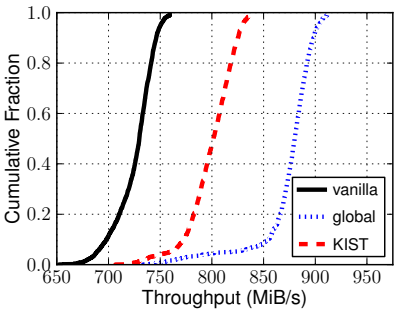


Figure 8: Aggregate relay write throughput for vanilla Tor, KIST, and the global scheduling part of KIST (without enforcing write limits). Both of our enhancements increase network throughput over vanilla Tor.

beneficial in the upper parts of the distribution: in the 99th percentile, latency is reduced from more than 7 seconds to less than 2.7 seconds.

Figures 7b and 7c show the distribution of time to complete each 320 KiB download for the "web" clients and each 5 MiB file for the "bulk" clients, respectively. In our experiments, the 320 KiB download times decreased by over 1 second for over 40 percent of the downloads, while the download times for 5 MiB files increased by less than 8 seconds for all downloads. These changes in download times are a result of Tor correctly utilizing its circuit priority scheduler, which prioritizes traffic with the lowest exponentially-weighted moving average throughput. As the "web" clients pause between downloads, their traffic is often prioritized ahead of "bulk" traffic. Our results indicate that not only does KIST decrease Tor network latency, it also increases Tor's ability to appropriately manage its traffic.

Throughput: We show in Figure 8 KIST's effect on relay throughput. Shown is the distribution of aggregate bytes written per second by all relays in the network. We found that throughput improves when using KIST due to a combination of the reduction in network latency and our client model: web clients completed their downloads faster in the lower latency network and therefore also downloaded more files. By lowering circuit congestion, KIST improves utilization of existing bandwidth resources over vanilla Tor by 71.6 MiB/s, or 9.8%, in the median. While the best network utilization is achieved with global scheduling without write limits (a 150.1 MiB/s, or 20.5%, improvement over vanilla Tor in the median), we have shown above that it is less effective than KIST at reducing kernel congestion and allowing Tor to correctly prioritize traffic.

Overhead: The main overhead in KIST involves the collection of socket and TCP information from the kernel using three separate calls to `getsockopt` (socket capacity, socket length, and TCP info). These three system calls are made for every connection after every `GlobalWriteTimeout` interval. To understand the overhead involved with these calls, we instrumented curiosity3 from Section 4 to collect timing information while performing the syscalls required by KIST. Our test ran on the live relay running an Intel Xeon x3450 CPU at 2.67GHz for 3 days and 14 hours, and collected a timing sample every second for a total of 309,739 samples. We found that the three system calls took 0.9140 microseconds per connection in the median, with a mean of 0.9204 and a standard deviation of 3.1×10^{-5}.

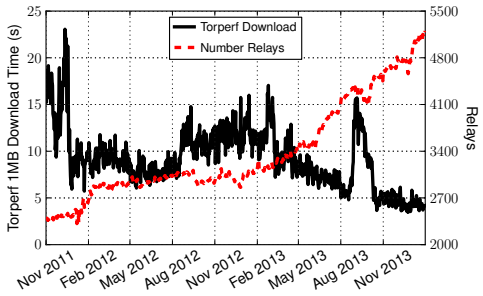

Figure 9: Network size correlates with performance.

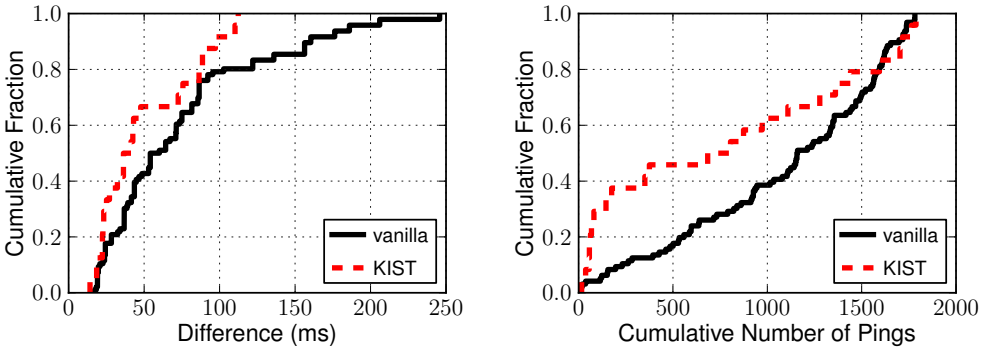
The number of connections a relay may have is bounded above roughly by the number of relays in the network, which is currently around 5,000. Therefore, we expect the overhead to be less than 5 milliseconds and reasonable for current relays. If this overhead becomes problematic as Tor grows, the gathering of kernel information can be outsourced to a helper thread and continuously updated over time. Further, we have determined through discussions with Linux kernel developers that the *netlink socket diag* interface could be used to collect information for several sockets at once—an optimization that may provide significant reductions in overhead.

6 Security Analysis

Performance and Security: Performance and ease of use affect adoption rates of any network technology. They have played a central role in the size and diversity of the Tor userbase. This can then affect the size of the network itself as users are more willing to run parts of the network or contribute financially to its upkeep, e.g., via torservers.net. Growth from performance improvements affect the security of Tor by increasing the uncertainty for many types of adversaries concerning who is communicating with whom [17, 20, 22, 37]. Performance factors in anonymous communication systems like Tor are thus pertinent to security in a much more direct way than they typically would be for, say, a faster signature algorithm's impact on the security of an authentication system.

Though real and more significant, direct effects of performance on Tor's security from network and userbase growth are also hard to show, given both the variety of



(a) Latency Estimate Difference

(b) Cumulative Pings until Best Estimate

Figure 10: Latency leaks are more pronounced (10a) and are faster (10b) with KIST.

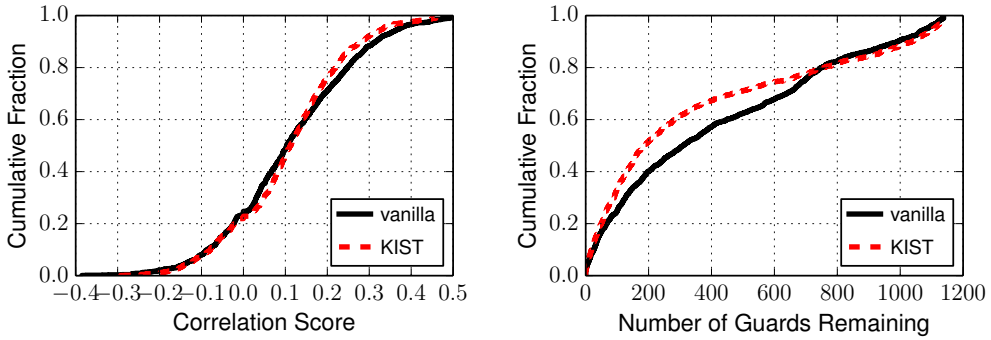
causal factors and the difficulty of gathering useful data while preserving privacy. Whatever the causal explanation, a correlation ($-.62$) between Tor performance improvement over time (measured by the median download time of a 1 MB file) and network size is shown in Figure 9. (Numbers are from the Tor Metrics Portal [8].) Similar results hold when number of relays is replaced with bandwidth metrics. Which is more relevant depends on the adversary's most significant constraints: adversary size and distribution across the underlying network are important considerations [39].

More measurable effects can occur if a performance change creates a new opportunity for attack or makes an existing attack more effective or easier to mount. Performance change may also eliminate or diminish previous possible or actual attacks. Growth effects are potentially the greatest security effects of our performance changes, but we now focus on these more directly observable aspects. They include attacks on Tor based on resource contention or interference [19, 24, 25, 31, 44, 46, 48] or simply available resource observation [44], or observing other performance properties, such as latency [31]. Many papers have also explored improvements to Tor performance via scheduling, throttling, congestion management, etc. (see Section 2). Manipulating performance enhancement mechanisms can turn them into potential vectors of attack themselves [38]. Geddes *et al.* [25] analyzed anonymity impact of several performance enhancement mechanisms for Tor.

Latency Leak: The basic idea of a latency leak attack as first set out in [30] is to measure RTT (roundtrip time) between a compromised exit and the client of some target connection repeatedly and then to pick the shortest result as an indication of latency. Next compare this to the known, measured latency through all the hops in the circuit except client to entry relay. (Other attacks such as throughput measurement, discussed below, are assumed to have already identified the relays in the circuit.) Next, use that to determine the latency between the client of the target connection and its entry relay, which is in a known network location. This can significantly reduce the range of possible network locations for the client. When measuring latency using our improved models and simulator, we discovered that this attack is generally able to determine latency well with vanilla Tor. While KIST improves the overall accuracy, the improvement is small when a good estimate was also found with vanilla Tor.

Figure 10a shows the results of an experiment run on our model from Section 3 with random circuit and client choices, indicating the difference between the correct latency and the estimate after a few hundred pings once per second. Roughly 20% of circuits for both vanilla Tor and KIST are within 25ms of the correct latency. After this they diverge, but both have a median latency estimate of about 50ms or less. It is only for the worst 10-20% of estimates, which are presumably not useful anyway, that KIST is substantially better. While the eventual accuracy of the attack is comparable for both, the attacker under KIST is significantly faster on average. Figure 10b shows the cumulative number of pings (seconds) until a best estimate is achieved. After 200 pings, nearly 40% of KIST circuits have achieved their best estimate while less than 10% have for vanilla Tor. And the median number of pings needed for KIST is about 700 vs. 1200 for vanilla Tor.

The accuracy of the latency attack indicated above is a significant threat to network location, which from a technical perspective is what Tor is primarily designed to protect. It could be diminished by padding latency. Specifically any connection at the edges of the Tor network, at either source or destination end, could be dynamically padded by the entry or exit relay respectively to ideally make latency of all edge connections through that relay uniform—more realistically to significantly decrease the network location information leaked by latency. Relays can do their own RTT measurements for any edge



(a) Throughput Correlation, Probe to Target Client (b) Guards Remaining in Candidate Guard Set

Figure 11: While the aggregate throughput correlations of the probe to the true guard over the set of all probes (11a) are not significantly affected by KIST, it is slightly easier for the adversary to eliminate candidate guards of a target client (for all clients) (11b) when using KIST.

connection and pad accordingly. There are many issues around this suggestion, which we leave to future work.

Throughput Leak: The throughput attack introduced by Mittal *et al.* [44] identifies the entry relay of a target connection by setting up one-hop probe circuits from attack clients through all prospective entry relays and back to the client in order to measure throughput at those relays. These throughputs are compared to the throughput observed by the exit relay of the target circuit. The attack is directed against circuits used for bulk downloading since these will attempt a sustained maximum throughput, and will result in congestion effects on bottleneck relays that allow the adversary to reduce uncertainty about possible entry relays. Mittal *et al.* also looked at attacks on lower bandwidth interactive traffic and found some success, although with much less accuracy than for bulk traffic.

We analyze the extent to which KIST affects the throughput attack. While measuring throughput at entry relays, we also adopt the simplification of Geddes *et al.* [25] of restricting observations to entry relays that are not used as middle or exit relays for other bulk downloading circuits. This allows us the efficiency of making measurements for several simulated attacks simultaneously while minimizing interference between their probes.

Figure 11a shows the cumulative distribution of scores for correlation of probe throughput at the correct entry relay with throughput at the observed exit relay under vanilla Tor and under KIST scheduling (on the network and user model given in Section 3). Throughput was measured every 100 ms. We found that the throughput correlations are not significantly affected by KIST.

To explain the correlation scores, recall from Section 5.2 how KIST reduces both circuit congestion and network latency by allowing Tor to properly prioritize circuits independent of the TCP connections to which they belong. This leads to two competing potential effects on the throughput attack: (1) a less congested network will increase the sensitivity of the probes to variations in throughput, thereby allowing stronger correlations between the throughput achieved by the probe client and that achieved by the target client; and (2) a circuit's throughput is most correlated with that of its bottleneck relay, and KIST's improved scheduling should also reduce the bottleneck effects of congestion in the network and allow weaker throughput correlations. Further, the improved priority scheduling (moving from round-robin over TCP connections to properly utilizing EWMA over circuits) will cause the throughput of each client to become slightly "burstier" over the short term as the priority causes the scheduler to oscillate between the circuits. We suspect that the similar correlation scores are the result of combining these effects.

To further understand KIST's affect on the throughput attack, we measure how the correlation of every client's throughput to the *true* guard's throughput compares to the correlation of the client's throughput to that of every other *candidate* guard in the network. For every client, we start with a candidate guard set of all guards, and remove those guards with a lower correlation score with the client than the true guard's score. Figure 11b shows the distribution, over all clients, of the extent to which we were able to reduce the size of the candidate guard set using this heuristic. Although KIST reduced the uncertainty about the true guard used by the target client, we do not expect the small improvement to significantly affect the ability to conduct a successful throughput attack in practice.

7 Conclusion

In this paper, we outlined the results of an in-depth congestion study using both public and private Tor net-

works. We identified that most congestion occurs in outbound kernel buffers, analyzed Tor socket management, and designed a new socket transport mechanism called KIST. Through evaluation in a full-scale private Shadow-Tor network, we conclude that KIST is capable of moving congestion into Tor where it can be better managed by application priority scheduling mechanisms. More specifically, we found that by considering all sockets and respecting TCP state information when writing data to the kernel, KIST reduces both congestion and latency while increasing utilization. Finally, we performed a detailed evaluation of KIST against well-known latency and throughput attacks. While KIST increases the speed at which true network latency can be calculated, it does not significantly affect the accuracy of the probes required to correlate throughput.

Future work should extend our simulation-based evaluation and consider how KIST performs for relays in the live Tor network. We note that our analysis is based exclusively on Linux relays, as 91% of Tor's bandwidth is provided by relays running a Linux-based distribution [58]. Although we expect KIST to improve performance similarly across platforms because it primarily works by managing socket buffer levels, future work should consider how KIST is affected by the interoperation of relays running on a diverse set of OSes. Finally, our KIST prototype would benefit from optimizations, particularly by running the process of gathering kernel state information in a separate thread and/or using the *netlink socket diag* interface.

Acknowledgments

We thank our shepherd, Rachel Greenstadt, and the anonymous reviewers for providing feedback that helped improve this work. We thank Roger Dingledine for discussions about measuring congestion in Tor, and Patrick McHardy for suggesting the use of the netlink socket diag interface. Abstract

Website fingerprinting attacks allow a local, passive eavesdropper to identify a user's web activity by leveraging packet sequence information. These attacks break the privacy expected by users of privacy technologies, including low-latency anonymity networks such as Tor. In this paper, we show a new attack that achieves significantly higher accuracy than previous attacks in the same field, further highlighting website fingerprinting as a genuine threat to web privacy. We test our attack under a large open-world experimental setting, where the client can visit pages that the attacker is not aware of. We found that our new attack is much more accurate than previous attempts, especially for an attacker monitoring a set of sites with low base incidence rate. We can correctly determine which of 100 monitored web pages a client is visiting (out of a significantly larger universe) at an 85% true positive rate with a false positive rate of 0.6%, compared to the best of 83% true positive rate with a false positive rate of 6% in previous work.

To defend against such attacks, we need provably effective defenses. We show how simulatable, deterministic defenses can be provably private, and we show that bandwidth overhead optimality can be achieved for these defenses by using a supersequence over anonymity sets of packet sequences. We design a new defense by approximating this optimal strategy and demonstrate that this new defense is able to defeat any attack at a lower cost on bandwidth than the previous best.

1 Introduction

Privacy technologies are becoming more popular: Tor, a low-latency anonymity network, currently has 500,000 daily users and the number has been growing [21]. However, users of Tor are vulnerable to *website fingerprinting* attacks [4, 17, 23]. Users of other privacy technologies such as SSH tunneling, VPNs and IPsec are also vulnerable to website fingerprinting [10].

When a client browses the web, she reveals her destination and packet content to intermediate routers, which are controlled by ISPs who may be susceptible to malicious attackers, eavesdroppers, and legal pressure. To protect her web-browsing privacy, the client would need to encrypt her communication traffic and obscure her destinations with a proxy such as Tor. Website fingerprinting refers to the set of techniques that seek to re-identify these clients' destination web pages by passively observing their communication traffic. The traffic will contain packet lengths, order, and timing information that could uniquely identify the page, and website fingerprinting attacks use machine classification to extract and use this information (see Section 2).

A number of attacks have been proposed that would compromise a client's expected privacy, and defenses have been proposed to counter these attacks (see Section 3). Most previous defenses have been shown to fail against more advanced attacks [4, 6, 15]; this is because they were evaluated only against specific attacks, with no notion of provable effectiveness (against all possible attacks). In this paper, we will show an attack that further highlights the fact that clients need a provably effective defense, for which an upper bound on the accuracy of any possible attack can be given. We will then show how such a defense can be constructed. Only with a provably effective defense can we be certain that clients are protected against website fingerprinting.

The contributions of our paper are as follows:

1. We propose a significantly improved attack that achieves a higher accuracy with a training and testing time that is orders of magnitude lower than the previous best. Our attack is a k-Nearest Neighbour classifier applied on a large feature set with weight adjustment. Our attack is designed to find flaws in defenses and achieve high success rates even with those defenses, and we demonstrate that

several known defenses have almost no impact on our attack. We describe this attack in Section 4.

2. Using this attack, we tackle a large open-world problem, in which the attacker must determine which of 100 monitored pages the client is visiting, but the client can visit a large number of pages that the attacker cannot train on. We demonstrate that the attack is still truly effective in this realistic scenario in Section 5, and that it outperforms the previous best attack by Wang and Goldberg [23] (which we call OSAD) on the same data set.

3. We show that simulatable, deterministic defenses can be turned into provably private defenses in our model. In our model, we consider a defense to be successful only if it produces packet sequences that are identical (in time, order, and packet lengths) to packet sequences from different web pages. This strong notion of indistinguishability of packet sequences yields our provably private defenses. We found that the bandwidth-optimal simulatable, deterministic defense is to transmit packets using supersequences over anonymity sets. We construct a principled defense using an approximation of the smallest common supersequence problem and clustering techniques in Section 6 and evaluate it in Section 7.

We follow up with a discussion on realistic applicability and reproducibility of our results in Section 8 and conclude in Section 9.

2 Basics

2.1 Website Fingerprinting on Tor

Website fingerprinting (WF) refers to the process of attempting to identify a web-browsing client's behaviour—specifically, which web pages she is visiting—by observing her traffic traces. We assume that the client is using a proxy to hide her true destination, as well as encryption to hide her packet contents, as without these basic defenses she reveals her destination to a trivial eavesdropper. Users of Tor have these defenses.

More recent attacks can successfully perform website fingerprinting with an attacker that only has local observation capacity; i.e. the attacker merely observes the traffic traces of the client without any interference. The attacker is located on the client's network, such as the client's ISP, or he has gained control of some router near the client. Attacks requiring more capabilities have been proposed, such as attacks which leverage active traffic-shaping strategies [8], remote ping detection [9] and, sometimes, involve tampering with the client's device [12]. Our attack achieves high accuracy with only a local, passive attacker.

In general, the attacker's strategy is as follows. The attacker collects packet traces from several web pages that he is interested in monitoring. Then, the attacker observes packet traces generated by the client during her web browsing, and compares these traces with the ones he collected by performing supervised classification. We note two assumptions that all previous works on WF have made of the attacker:

1. Well-defined packet traces. It is assumed that the attacker knows where the packet trace of a single page load starts and ends. If the client takes much longer to load the next page after the current one is loaded, this assumption can be justified.

2. No other activity. We assume the client is not performing any other activity that could be confused for page-loading behaviour, such as downloading a file.

These assumptions are used by all previous works on WF as they simplify the problem, though it should be noted that these assumptions are advantageous for the attacker. We discuss how the attacker can carry out a successful attack without these assumptions in Section 8.

Website fingerprinting is harder on Tor than simple SSH or VPN tunneling [10]. This is because Tor uses cell padding, such that data is sent in fixed-size (512-byte) cells. In addition, Tor has background noise (circuit construction, SENDME packets, etc.) which interferes with website fingerprinting [23]. As Tor has a large user base and an extensive architecture upon which defenses can be applied, recent works and our work are interested in attacking and defending Tor, especially as Tor developers remain unconvinced that website fingerprinting poses a real threat [19].

2.2 Classification

Given a packet sequence, the attacker learns the client's destination web page with a classification algorithm (classifier). The attacker first gathers packet sequences of known pages that he is interested in monitoring (the training set). This is known as supervised training as the true labels of these packet sequences are known to the attacker. We can test the effectiveness of such a classifier by applying it to a data set of packet sequences that the attacker did not train on (the testing set), and measuring the accuracy of the classifier's predictions.

Central to the classifier is a notion of distance between packet sequences. A larger distance indicates that the two packet sequences are less likely to be from the same

page. Previous authors have used varying formulae for distance, ranging from comparing the occurrence counts of unique packet lengths to variations of Levenshtein distance. The distance used reflects how features are used to distinguish web pages. These features are, explicitly or implicitly, extracted from packet sequences to compare them with each other.

Our attack is based on the important observation that a class representing a web page is multi-modal. Several factors cause a web page to vary: network conditions, random advertisements and content, updating data over time, and unpredictable order of resources. Client configuration may also affect page loading.[1] An attacker can deal with multi-modal data sets by gathering enough data to have representative elements from each mode. For example, an attacker can gather two modes of a page, one for low-bandwidth connections, and another for high-bandwidth connections.[2] We use a classifier designed for multi-modal classes, for which different modes of the class do not need to have any relationship with each other.

3 Related Work

This section surveys the related work on website fingerprinting (WF). We classify attacks into those which depend on revealed resource lengths (HTTP 1.0), revealed packet lengths (HTTP 1.1, VPNs, SSH tunneling, etc.), and hidden packet lengths (Tor). We also survey the previous work on defenses in this section.

3.1 Resource length attacks

In HTTP 1.0, web page resources (images, scripts, etc.) are each requested with a separate TCP connection. This implies that an attacker who is able to distinguish between different connections can identify the total length of each resource. The earliest attacks were performed in this scenario: Cheng et al. in 1998 [5], Sun et al. in 2002 [20], and Hintz in 2003 [11]. These works showed that observing resource lengths can help identify a page. HTTP 1.1 uses persistent connections, and therefore more recent browsers and privacy technologies are not susceptible to resource length attacks.

3.2 Unique packet length attacks

Liberatore and Levine in 2006 [14] showed how unique packet lengths are a powerful WF feature with two attacks: one using the Jaccard coefficient and another using the Naïve Bayes classifier. Under the first attack, the classifier mapped each packet sequence to its set of unique packet lengths (discarding ordering and frequency). Then, it used the Jaccard coefficient as a measurement of the distance between two packet sequences. The Naïve Bayes classifier used packet lengths and their occurrence frequencies as well, but also discarded ordering and timing. The Naïve Bayes assumption is that the occurrence probabilities of different packet lengths are independent of each other. Later, Herrmann et al. [10] proposed a number of improvements to this attack by incorporating techniques from text mining.

Bissias et al. in 2006 [2] published an attack based on cross-correlation with interpacket timings, but it is less accurate than the Naïve Bayes attacks. Lu et al. in 2010 [15] published an attack that heavily focuses on capturing packet burst patterns with packet ordering, discarding packet frequencies and packet timing.

3.3 Hidden packet length attacks

Herrmann et al. were not able to successfully perform WF on Tor [17], where unique packet lengths are hidden by fixed-size Tor cells. In 2009, Panchenko et al. [17] showed an attack that succeeded against web-browsing clients that use Tor. As unique packet lengths are hidden on Tor, Panchenko et al. used other features, which are processed by a Support Vector Machine (SVM). These features attempted to capture burst patterns, main document size, ratios of incoming and outgoing packets, and total packet counts, which helped identify a page. Dyer et al. in 2012 [6] used a similar but smaller set of features for a variable n-gram classifier, but their classifier did not perform better in any of the scenarios they considered.

Cai et al. in 2011 improved the accuracy of WF on Tor. Using the edit distance to compare packet sequences, they modified the kernel of the SVM and showed an attack with significantly increased accuracy on Tor [4]. Wang and Goldberg in 2013 further improved the accuracy of Cai et al.'s scheme on Tor by modifying the edit distance algorithm [23], creating OSAD. These modifications were based on observations on how web pages are loaded. As it is the current state of the art under the same attack scenario, we will compare our attack to OSAD.

3.4 Defenses

Defenses are applied on the client's connection in order to protect her against website fingerprinting attacks. We present a new classification of defenses in this section. First, defenses can be "simulatable" or "non-simulatable". A simulatable defense can be written as a defense function D that takes in a packet sequence and

[1] On the Tor Browser changing the browser configuration is discouraged as it makes browser fingerprinting easy.

[2] Data collection on Tor will naturally result in such a situation because of random circuit selection.

outputs another packet sequence. The function does not look at the true contents of the packets, but only their length, direction and time. An advantage of simulatable defenses is the implementation cost, as non-simulatable defenses would need to be implemented on the browser and would have access to client data, which may be difficult for some clients to accept. The implementation of a simulatable defense requires no more access to information than a website fingerprinting attacker would typically have.

Secondly, defenses can be "deterministic" or "random"—for deterministic defenses the function D always returns the same packet sequence for each input packet sequence p.[3] Our goal is to design a provably private defense that has an upper bound on the accuracy of any attack. Random defenses (noise) have the disadvantage that choosing a good covering is not guaranteed. An attacker that can link together different page loads can partially remove the noise. Furthermore, implementations of random defenses must be careful so that noise cannot be easily distinguished from real packets.

Non-simulatable, random: This includes Tor's request order randomization defense. Responding to Panchenko's attack, Tor developers decided to enable pipelining on Tor and randomize pipeline size and request orders [18]. The randomization was further increased after OSAD [19]. We test our attack against the more randomized version that is built into Tor Browser Bundle 3.5.

Non-simulatable, deterministic: This includes portions of HTTPOS [16]. The HTTPOS defense is built into the client's browser, allowing the client to hide unique packet lengths by sending an HTTP range request strategically.

Simulatable, random: This includes traffic morphing [24], which allows a client to load a web page using a packet size distribution from a *different* page, and Panchenko's background noise [17], where a decoy page is loaded simultaneously with the real page to hide the real packet sequence.

Simulatable, deterministic: This includes packet padding, which is done on Tor, and BuFLO, presented and analyzed by Dyer et al. [6]. BuFLO sends data at a constant rate in both directions until data transfer ends. In this work, we will show that defenses in this category can be made to be provably private,[4] and we will show such a defense with a much lower overhead than BuFLO.

[3] Using a random procedure to learn D does not make D itself random.

[4] BuFLO is not provably private on its own.

4 Attack

In this section, we describe our new attack, which is designed to break website fingerprinting defenses. Our attack is based on the well-known k-Nearest Neighbours (k-NN) classifier, which we briefly overview in Section 4.1. The attack finds flaws in defenses by relying on a large feature set, which we describe in Section 4.2. We then train the attack to focus on features which the defense fails to cover and which therefore remain useful for classification. We describe the weight adjustment process in Section 4.3.

4.1 k-NN classifier

k-NN is a simple supervised machine learning algorithm. Suppose the training set is S_{train} and the testing set is S_{test}. The classifier is given a set of training points (packet sequences) $S_{train} = \{P_1, P_2, \ldots\}$. The training points are labeled with classes (the page the packet sequence was loaded from); let the class of P_i be denoted $C(P_i)$. Given a testing point $P_{test} \in S_{test}$, the classifier guesses $C(P_{test})$ by computing the distance $D(P_{test}, P_{train})$ for each $P_{train} \in S_{train}$. The algorithm then classifies P_{test} based on the classes of the k closest training points.

Despite its simplicity, the k-NN classifier has a number of advantages over other classifiers. Training involves learning a distance between pairs of points; the classifier could use a known (e.g. Euclidean) distance, though selecting the distance function carefully can greatly improve the classification accuracy. Testing time is very short, with a single distance computation to each training point. Multi-modal sets can be classified accurately, as the classifier would only need to refer to a single mode of each training set.

The k-NN classifier needs a distance function d for pairs of packet sequences. The distance is non-trivial for packet sequences. We want the distance to be accurate on simple encrypted data without extra padding, but also accurate when defenses are applied that remove features from our available feature set. We therefore start with a large feature set $F = \{f_1, f_2, \ldots\}$. Each feature is a function f which takes in a packet sequence P and computes $f(P)$, a non-negative number. Conceptually, each feature is designed such that members of the same class are more likely to have similar features than members of different classes. We give our feature set in Section 4.2. The distance between P and P' is computed as:

$$d(P,P') = \sum_{1 \le i \le |F|} w_i |f_i(P) - f_i(P')|$$

The weights $W = \{w_1, w_2, \ldots, w_{|F|}\}$ are learned as in Section 4.3, where we describe how the weights for uninformative features (such as one that a defense success-

fully covers) are reduced. As weight learning proceeds, the k-NN distance comes to focus on features that are useful for classification.

We tried a number of other distances, including the edit distance used by Cai et al. [4] and OSAD, which they used to compute the kernel of SVMs. The results for using their distances on the k-NN classifier are similar to those using the SVM. As we shall see in Section 5, using our proposed distance allows a significant improvement in accuracy over these distances, with or without extra defenses.

4.2 Feature set

Our feature set is intended to be diverse. The construction of the feature set is based on prior knowledge of how website fingerprinting attacks work and how defenses fail.

Our feature set includes the following:

- General features. This includes total transmission size, total transmission time, and numbers of incoming and outgoing packets.

- Unique packet lengths. For each packet length between 1 and 1500, and each direction, we include a feature which is defined as 1 if it occurs in the data set and 0 if it does not. This is similar to the algorithms used by Liberatore and Levine [14] and Herrmann et al. [10], where the presence of unique packet lengths is an important feature. These features are not useful when packet padding is applied, as on Tor.

- Packet ordering. For each outgoing packet, we add, in order, a feature that indicates the total number of packets before it in the sequence. We also add a feature that indicates the total number of incoming packets between this outgoing packet and the previous one. This captures the burst patterns that helped Cai et al. achieve their high accuracy rates.

- Concentration of outgoing packets. We count the number of outgoing packets in non-overlapping spans of 30 packets, and add that as a feature. This indicates where the outgoing packets are concentrated without the fineness (and volatility) of the packet ordering features above.

- Bursts. We define a burst of outgoing packets as a sequence of outgoing packets, in which there are no two adjacent incoming packets. We find the maximum and mean burst length, as well as the number of bursts, and add them as features.

- Initial packets. We also add the lengths of the first 20 packets (with direction) in the sequence as features.

Some feature sets, such as packet ordering, have variable numbers of features. We define a maximum number of features for the set, and if the packet sequence does not have this many features, we pad with a special character (X) until it reaches the maximum number. Recall that our distance is the weighted sum of absolute differences between features; let us denote the difference as $d_{f_i}(P,P')$. For each feature f_i, if at least one of the two values is X, then we define $d_{f_i}(P,P')$ to be 0, such that the difference is ignored and does not contribute to the total distance. Otherwise, we compute the difference as usual.

We treat all features equally. However, we note that as the general features are amongst the strongest indicators of whether or not two packet sequences belong to the same mode of a page, we could use them with a search algorithm to significantly reduce training and testing time (i.e. reject pages with significantly different values in the general feature without computing the whole distance).

The total number of features is close to 4,000 (3,000 of which are just for the unique packet lengths). If a defense covers some features and leaves others open (e.g. traffic morphing retains total transmission size and burst features), our algorithm should be successful in adjusting weights to focus on useful features.

We design our attack by drawing from previous successful attacks, while allowing automatic defense-breaking. In particular, we note that there exists a choice of weights for which our attack uses a similar distance metric as the attacks proposed by Cai et al. [4] and Wang and Goldberg [23], as well as the Jaccard coefficient by Liberatore and Levine [14]. However, we will find better choices of weights in the next subsection. We drew the inspiration for some features from the work by Panchenko et al. [17], in particular, those concerning the start of the page (which may indicate the size of the HTML document). We note that unlike Panchenko et al. [17], we do not add the entire packet sequence as features.

4.3 Weight initialization and adjustment

In this subsection, we describe how we learn $w_1, w_2, \ldots, w_{|F|}$, the weights that determine our distance computation. The values of these weights determine the quality of our classifier. We learn the weights using an iterative, local weight-learning process as follows. The weight-learning process is carried out for R rounds (we will see how the choice of R affects the accuracy later). For each round, we focus on a point $P_{train} \in S_{train}$ (in or-

der), performing two steps: the weight recommendation step and the weight adjustment step.

Weight recommendation. The objective of the weight recommendation step is to find the weights that we want to reduce. During the weight recommendation step, the distances between P_{train} and all other $P' \in S_{train}$ are computed. We then take the closest k_{reco} points (for a parameter k_{reco}) within the same class $S_{good} = \{P_1, P_2, \ldots\}$ and the closest k_{reco} points within all other classes $S_{bad} = \{P'_1, P'_2, \ldots\}$; we will focus only on those points.

We denote $d(P,S)$, where S is a set of packet sequences, as the sum of the distances between P and each sequence in S.

Let us denote

$$d_{maxgood_i} = \max(\{d_{f_i}(P_{train}, P) | P \in S_{good}\})$$

For each feature, we compute the number of relevant bad distances, n_{bad_i}, as

$$n_{bad_i} = |\{P' \in S_{bad} | d_{f_i}(P_{train}, P') \leq d_{maxgood_i}\}|$$

This indicates how bad feature f_i is in helping to distinguish S_{bad} from S_{good}. A large value of n_{bad_i} means that feature f_i is not useful at distinguishing members of P_{train}'s class from members of other classes, and so the weight of f_i should be decreased; for example, features perfectly covered by a defence (such as unique packet lengths in Tor) will always have $n_{bad_i} = k_{reco}$, its maximum possible value. Conversely, small values of n_{bad_i} indicate helpful features whose weights should be increased.

Weight adjustment. We adjust the weights to keep $d(P_{train}, S_{bad})$ the same while reducing $d(P_{train}, S_{good})$. Then, for each i such that $n_{bad_i} \neq \min(\{n_{bad_1}, n_{bad_2}, \ldots, n_{bad_{|F|}}\})$, we reduce the weight by $\Delta w_i = w_i \cdot 0.01$. We then increase all weights w_i with $n_{bad_i} = \min(\{n_{bad_1}, n_{bad_2}, \ldots, n_{bad_{|F|}}\})$ equally such that $d(P_{train}, S_{bad})$ remains the same.

We achieved our best results with two more changes to the way weights are reduced, as follows:

- We further multiply $\Delta w_i = w_i \cdot 0.01$ by n_{bad_i}/k_{reco}. Therefore, a weight with greater n_{bad_i} (a less informative weight) will be reduced more.

- We also decrease Δw_i if P_{train} is already well classified. N_{bad} is defined as:

  $$N_{bad} = |\{P' \in S_{bad} | d(P_{train}, P') \leq d_{maxgood}\}|$$

  Specifically, we multiply Δw_i by $0.2 + N_{bad}/k_{reco}$. N_{bad} can be considered an overall measure of how poorly the current point is classified, such that points which are already well-classified in each iteration have less of an impact on the weights. The addition of 0.2 indicates that even perfectly classified points still have some small impact on the weights (so that the weight adjustment will not nullify their perfect classification).

Both of these above changes improved our classification accuracy. We achieved our best results with $k_{reco} = 5$.

We initialized the weight vector W randomly by choosing a random value for each w_i uniformly between 0.5 and 1.5. Adding randomness gave us a chance of finding better solutions than a deterministic algorithm as we could avoid local maxima that bind our classifier away from the global maximum.

Note that we are not claiming these particular choices of parameters and constants yield an optimal attack, and further work may yet uncover improved attacks against defenses without provable privacy guarantees.

5 Attack evaluation

Our attack is specifically designed to find gaps in defenses, and in this section we will demonstrate its efficacy with experimentation on real web traffic. We will first begin by showing the effectiveness of our scheme against Tor with its default packet padding and order randomization defense in Section 5.1. This setting is a good standard basis of comparison as WF is a threat to the privacy guarantees provided by Tor, and several of the latest state-of-the-art attacks are designed for and evaluated on Tor. We will see that our attack performs better than the best known attacks. The parameters of our attack can be modified to decrease the false positive rate at the cost of decreasing the true positive rate, and we examine the tradeoff in Section 5.2. Then, we show that our attack is also more powerful than known attacks on various known and published defenses in Section 5.3, with a number of defenses shown to be nearly completely ineffective against our scheme.

5.1 Attack on Tor

We validate our attack in two experimental settings to demonstrate the effectiveness of our attack on Tor.

First, we perform experiments in an open-world experimental setting. Even though the number of pages in the world wide web is far too large for us to train on, we can achieve realistic results by limiting the objective of the attacker. Here, the attacker wants to decide whether or not a packet sequence comes from a monitored page; additionally, for monitored pages, the attacker aims to identify the page. We denote the non-monitored page set

that the attacker uses for training as C_0, and the effects of varying its size will be tested in evaluation. This open-world experimental setting gives us realistic results for plausible attackers.

We use a list of 90 instances each of 100 sensitive pages as well as 1 instance each of 5,000 non-monitored pages. We note that this problem is more difficult for the attacker than any that has been evaluated in the field, as other authors have evaluated their schemes on either strictly closed-world settings or very small open-world problems (a few monitored pages). It is a realistic goal for the attacker to monitor a large set of pages in the open-world setting.

Our list of 100 monitored pages was compiled from a list of blocked web pages from China, the UK, and Saudi Arabia. These include pages ranging from adult content, torrent trackers, and social media to sensitive religious and political topics. We selected our list of 5,000 non-monitored pages from Alexa's top 10,000 [1], in order, excluding pages that are in the list of monitored pages by domain name. The inherent differences between the above data sets used for training and testing assist classification, just as they would for a realistic attacker. Page loading was done with regular circuit resetting, no caches and time gaps between multiple loads of the same page (as suggested by Wang and Goldberg [23]), such that the attacker will not use the same circuits as the target client, or collect its data at the same time. We used iMacros 8.6.0 on Tor Browser 3.5.1 to collect our data.

Training the k-Nearest Neighbour classifier is required to learn the correct weights. We learn the weights by splitting part of the training set for weight adjustment and evaluation as above. We perform weight adjustment for $R = 6000$ rounds on 100 pages and 60 instances each, which means that every instance is cycled over once. Then, accuracy is computed over the remaining 30 instances each, on which we perform all-but-one cross validation. The use of cross validation implies that the attacker will never train on the same non-monitored pages that the client visits.

For our attack, we decided that a point should be classified as a monitored page only if all k neighbours agree on which page it is, and otherwise it will be classified as a non-monitored page. This helped reduce false positives at a relatively small cost to the true positives. We vary the number of neighbours k from 1 to 15 as well as the number of non-monitored training pages $|C_0|$ used from 10 to 5000,[5] and we show our results in Figure 1. We measure the True Positive Rate (TPR), which is the probability that a monitored page is correctly classified as that particular monitored page, and the False Positive Rate (FPR), which is the probability that a non-monitored page is incorrectly identified as being monitored.[6] We can achieve TPR 0.85 ± 0.04 for FPR 0.006 ± 0.004, or respectively TPR 0.76 ± 0.06 for FPR 0.001 ± 0.001.

[5] We note that the choice of $|C_0|$ does *not* represent a world with fewer pages available to the client—it is the attacker's decision on how much he wishes the bias towards non-monitored sites to be. The visited sites are always drawn from Alexa's top 10,000.

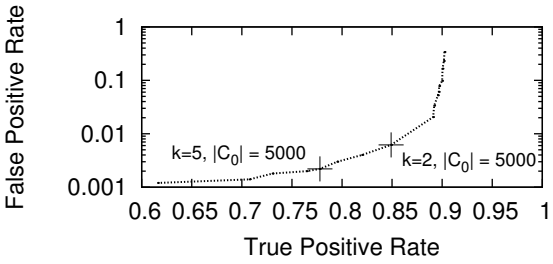

Figure 1: Performance of our attack while varying the attack parameters k and $|C_0|$. Only the y-axis is logarithmically scaled.

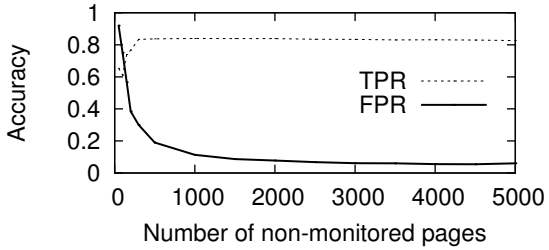

Figure 2: True Positive Rate and False Positive Rate changes in OSAD [23] as the open set size increases. There is almost no change in either value after $|C_0| > 2500$.

We compare these values to OSAD, which we apply to our data set as well, and show the results in Figure 2. Increasing the number of non-monitored pages $|C_0|$ increases TPR and reduces FPR. After $|C_0| > 2500$, we could not see a significant benefit in adding more elements. At $|C_0| = 5000$, the classifier achieves a TPR of 0.83 ± 0.03 and a FPR of 0.06 ± 0.02.

We see that OSAD cannot achieve FPR values nearly as low as ours, and it may be considered impractical for the attacker to monitor large sets in the open-world setting with the old classifier, especially if the base incidence rate is low. For example, if the base incidence rate of the whole sensitive set is 0.01 (99% of the time the client is visiting none of these pages), and our new classifier claims to have found a sensitive site, the decision is correct at least 80% of the time, the rest being false positives. For Wang and Goldberg's classifier, the same value would be about 12%. The difference is further exacerbated with a lower base incidence rate, which may be realistic for particularly sensitive web sites.

[6] If a monitored page is incorrectly classified as a *different* monitored page or as a non-monitored page, it is a false negative.

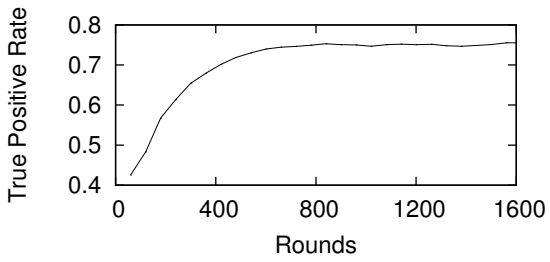

Figure 3: TPR when varying the number of rounds used for training our attack, with $k = 5$ and $|C_0| = 500$. FPR is not shown because there is very little change over time.

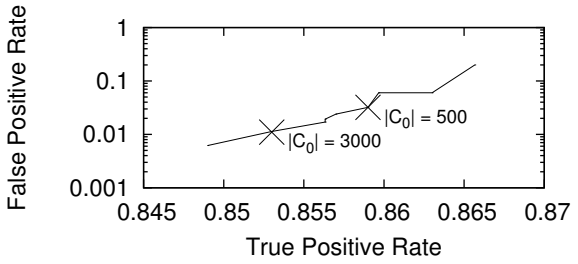

Figure 4: Results for FPR vs. TPR while varying bias towards non-monitored data set C_0. $k = 2$.

The training and testing time for our classifier (weight adjustment) is very small compared to previous state-of-the-art classifiers. The number of rounds, R, determines the quality of our weights. We show in Figure 3 how the true positive rate changes with R on $|C_0| = 500$ non-monitored sites and $k = 5$ neighbours. We see that the accuracy levels off at around 800 rounds, and did not drop up to 30,000 rounds.

The weight training time scales linearly with R and also scales linearly with the number of instances used for weight training. The training time is around $8 \cdot 10^{-6} \cdot |S_{train}| \cdot R$ CPU seconds, measured using a computing cluster with AMD Opteron 2.2 GHz cores. This amounts to around 120 CPU seconds for 1000 rounds in our set with $|C_0| = 5000$. This can be compared to around 1600 CPU hours on the same data set using OSAD and 500 CPU hours using that of Cai et al. Training time also scales quadratically with the number of training instances with these previous classifiers.

The testing time amounts to around 0.1 CPU seconds to classify one instance for our classifier and around 800 CPU seconds for OSAD, and 450 CPU seconds for Cai et al. The testing time per instance scales linearly with the number of training elements for all three classifiers. We can reduce the training and testing time for our classifier further by around 4 times if we remove the unique packet length features, which are useless for Tor cells.

We also perform experiments on the closed-world experimental setting. Under the closed-world experimental setting, the client does not visit non-monitored pages. We use the same data set of sensitive pages as above

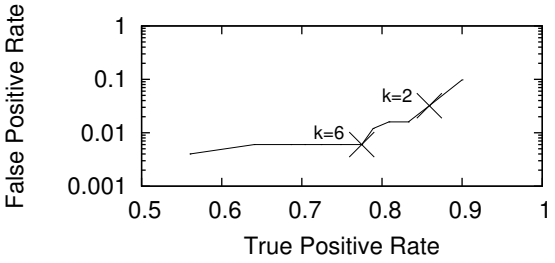

Figure 5: Best results for FPR vs. TPR while varying number of neighbours k. $|C_0| = 500$.

for these experiments. Although the closed-world setting does not carry the same realistic implications as the open-world setting, it focuses attention on the ability of the classifier to distinguish between pages and it has been a useful basis of comparison in the field. We also tested our classifier on the data set used by Wang and Goldberg to facilitate a more direct comparison, and the accuracy was 0.95 ± 0.02 compared to 0.91 ± 0.06 for OSAD and 0.88 ± 0.03 for Cai et al. We also compared them on our new data set, and the accuracy was 0.91 ± 0.03 for ours and 0.90 ± 0.02 for OSAD. There appears to be no significant difference in the closed-world scenario, although the superior accuracy of our classifier under the realistic open-world scenario is clear.

5.2 Training confidence

The numbers for true and false positive rates as shown above may not be desirable for some cases. The optimal numbers depend on the expected base rate of the monitored activity as well as the application intended by the attacker. Parameters of our attack can be adjusted to increase true positive rate at the cost of increasing false positive rate, or vice versa.

We can vary the size of the non-monitored training page set to affect accuracy as our implementation of the k-Nearest Neighbour classifier is susceptible to bias towards larger classes. We fix the number of neighbours at $k = 2$, vary the number of non-monitored training pages $|C_0|$ from 10 to 5000 and show the results in Figure 4.

We can also vary k, the number of neighbours. We fix the number of non-monitored pages, $|C_0|$, at 500, and vary k from 1 to 15, showing the results in Figure 5. Decreasing $|C_0|$ and decreasing k each increases both true positives and false positives.

We can see that varying the number of neighbours used is much more important for determining TPR than varying the size of C_0, the set of non-monitored pages. In fact, almost all of the graph in Figure 1 can be drawn only by varying k with $|C_0| = 5000$, suggesting that it is advantageous for the attacker to have a large number of non-monitored training pages.

Table 1: Accuracy of our attack on various defenses. Closed-world simulation is used to enable comparison with previous known results.

Defense	Accuracy	Bandwidth overhead
Traffic morphing [24]	0.82 ± 0.06	$50\% \pm 10\%$
HTTPOS split [16]	0.86 ± 0.03	$5.0\% \pm 0.6\%$
Decoy pages [17]	0.30 ± 0.06	$130\% \pm 20\%$
BuFLO [6]	0.10 ± 0.03	$190\% \pm 20\%$

5.3 Attack on Other Defenses

Our attack is specifically designed to break WF defenses that leave features open for classification. The analysis in previous sections was performed on Tor packets, which already uses padding, pipelining and order randomization. We add further defenses on top of Tor's defenses. The list of defenses we evaluate in this section are as follows:

- Traffic morphing [24]. Traffic morphing maps packet sizes from one site to a packet distribution drawn from another site, in an attempt to mimic the destination site. In our implementation, each site attempted to mimic `google.com` as it is reasonable to assume that the client wishes to mimic the most popular page.
- HTTPOS split [16]. Although HTTPOS has a large number of features, one of its core features is a random split on unique packet lengths by cleverly utilizing HTTP range requests. We analyze HTTPOS by splitting incoming packets and also padding outgoing packets.[7]
- Panchenko's decoy pages [17]. As a defense against their own attack, Panchenko et al. suggested that each real page should be loaded with a decoy page. We chose non-monitored pages randomly as decoy pages.
- BuFLO [6]. Maximum size packets are sent in both directions at equal, constant rates until the data has been sent, or until 10 seconds have passed, whichever is longer.

We implement these defenses as simulations. For Panchenko's noise and BuFLO we implement them using Tor cells as a basic unit in order to reduce unnecessary overhead from these defenses when applied on Tor. We assume that the attacker is aware of these defenses and collects training instances on which the defense is applied; this is realistic as the above defenses are all distinctive and identifiable.

We apply our attack, and show the results in Table 1. This can be compared to a minimum accuracy of 0.01 for random guessing. We see that even with large overhead, the defenses often fail to cover the page, and our attack always performs significantly better than random guessing. For BuFLO, our particular data set gave a larger overhead than previous work [22] because most packet sequences could be loaded within 10 seconds and therefore required end-of-sequence padding to 10 seconds. In particular, traffic morphing and HTTPOS split have almost no effect on the accuracy of our attack.

6 Defense

In this section, we design a provably private defense—a defense for which there exists an upper bound on the accuracy of any attack (given the data set). As Tor is bandwidth-starved [21], we attempt to give such a defense with the minimum bandwidth cost. This is an extension of the idea proposed by Wang and Goldberg [22] for their defense, Tamaraw.

In Section 6.1, we first show how such an upper bound can be given for *simulatable, deterministic defenses*—that is, this class of defenses can be made to be provably private. We then show in Section 6.2 that the optimal defense strategy (lowest bandwidth cost) in such a class is to compute supersequences over sets of packet sequences (anonymity sets). We try to approximate the optimal defense strategy, by describing how these sets can be chosen in Section 6.3, and how the supersequence can be estimated in Section 6.4.

6.1 Attacker's upper bound

We describe how we can obtain an upper bound on the accuracy of any attack given a defended data set. The attacker, given an observation (packet sequence) p, wishes to find the class it belonged to, $C(p)$.

To calculate the maximum success probability given the testing set, we assume the greatest possible advantage for the attacker. This is where the attacker is allowed to train on the testing set.[8] In this case the attacker's optimal classification strategy is to record the true class of each observation, $(p, C(p))$. The attacker will only ever make an error if the same observation is mapped to several different classes, which are indistinguishable for the observation. We denote the possibility set of p as the multiset of classes with the same observation p, $Q(p) =$

[7] HTTPOS has been significantly modified by its authors since their original publication, in part due to the fact that Cai et al. were able to break it easily [4].

[8] Our testing set is in fact a multiset as repeated observation-class pairs are possible.

$\{C_1, C_2, \ldots\}$ ($C(p) \in Q(p)$), where the occurrence count of a class is the same as in the testing set with observation p.

The attacker's optimal strategy is to find the class C_{max} that occurs the most frequently for the same observation p, and during classification the attacker will return C_{max} for the observation p. This will induce an accuracy value upon p:

$$Acc(p) = \frac{|\{C \in Q(p) | C = C_{max}\}|}{|Q(p)|}$$

This method returns the best possible accuracy for a given testing set as it makes the lowest possible error for observations mapping to multiple classes.

Cai et al. [3] have proposed two different ways to denote the overall accuracy of a set of packet sequences:

- Non-uniform accuracy. This is the mean of accuracies $Acc(p)$ for $p \in S_{test}$.
- Uniform accuracy. This is the maximum accuracy $Acc(p)$ for $p \in S_{test}$

Tamaraw can only achieve non-uniform accuracy. In this work, we design a defense for uniform accuracy, but the defense can be extended to other notions as well. While we will use different sets to train our defense and test it on client behaviour, we will say that the defense has a maximum uniform accuracy as long as it does so on the training set (as it is always possible to construct a testing set on simulatable, deterministic defenses on which at least one page has an accuracy of 1). A defense that achieves a maximum uniform accuracy of A_u automatically does so for non-uniform accuracy, but not vice-versa. In the following we work with a uniform prior on a fixed-size testing set to facilitate comparison with previous work.

6.2 Optimal defense

In this section, we show the bandwidth-optimal simulatable, deterministic defense. As we work with Tor cells, in the following a packet sequence can be considered a sequence of -1's and 1's (downstream and upstream packets respectively), which is useful for hiding unique packet lengths [22]. We say that sequence q is a subsequence of sequence p (or that p is a supersequence of q) if there exists a set of deletions of -1 and 1 in p to make them equal (maintaining order). With abuse of notation, we say that if S is the input packet sequence multiset, then $D(S) = \{D(p) | p \in S\}$ denotes the output packet sequence multiset after application of the defense. The cost (bandwidth overhead) of $D(p)$ is $B(D(p)) = \frac{|D(p)| - |p|}{|p|}$, and similarly for a set of packet sequences the overhead is $B(D(S)) = \frac{\sum_{p \in S} |D(p)| - \sum_{p \in S} |p|}{\sum_{p \in S} |p|}$. Given S, we want to identify D such that $B(D(S))$ is minimal.

For each packet sequence p_1, let us consider the set of packet sequences that map to the same observation after the defense is applied, which we call the *anonymity set* of p_1. We write the set as $A(p_1) = \{p_1, p_2, \ldots, p_E\}$; i.e. $D(p_1) = D(p_i)$ for each i. The shortest $D(p_1)$ that satisfies the above condition is in fact the shortest common supersequence, written as $f_{scs}(A(p_1)) = D(p_i)$ for each $1 \leq i \leq E$.

In other words, the optimal solution is to apply the shortest common supersequence function to anonymity sets of input sequences. This defense can be applied with the cooperation of a proxy on the other side of the adversary; on Tor, for example, this could be the exit node of the circuit. However, finding such an optimal solution requires solving two hard problems.

Anonymity set selection. First, given the set of all possible packet sequences, we want to group them into anonymity sets such that, for a given bound on attacker accuracy, the overhead will be minimized.

The shortest common supersequence (SCS) problem. Then, we must determine the SCS of all the packet sequences in the anonymity set. This is in general NP-hard. [13]

In the next two sections we describe our solutions to the above problems.

6.3 Anonymity set selection

We note that the client is not always able to choose anonymity sets freely. For example, the client cannot easily know which anonymity set a page load should belong to before seeing the packet sequence. While the client can gain information that assists in making this decision (the URL, previous page load data, training data, information about the client network, the first few packets of the sequence, etc.), the mere storage and usage of this information carries additional privacy risks. In particular, the Tor Browser keeps no disk storage (including no cache except from memory), so that storing extraneous information puts the client at additional risk. In this section, we describe how realistic conditions impose restrictions on the power of the client to choose anonymity sets.

We formalize this observation by imposing additional limits on anonymity set selection in the defense D trained on testing set S_{test}. We define four levels of information for a client applying a simulatable, deterministic website fingerprinting defense:

Table 2: Relationship between different levels of information and how we train and test our supersequences. Under "Supersequence", we describe what supersequences we would use at this level of information. Clustering is done if we want multiple supersequences.

Information	Supersequence	Training and Testing
No information	One supersequence	Different sites, instances
Sequence end information	One supersequence, stopping points	Different sites, instances
Class information	Multiple supersequences, stopping points	Same sites, different instances
Full information	Multiple supersequences	Same sites, instances

1. No information. The client has no information at all about the packet sequence to be loaded. This means $A(p) = S_{test}$, that is to say all sequences map to a single anonymity set.

2. Sequence end information. The client knows when the sequence has ended, but this is the only information the client gets about the packet sequence. This means that D can only vary in length; for any p, q, such that $|D(p)| \geq |D(q)|$, then the first $|D(q)|$ packets of $D(p)$ are exactly $D(q)$, that is, we say that $D(q)$ is a prefix of $D(p)$.

3. Class-specific information. Only the identity of the page is known to the client, and the client has loaded the page before with some information about the page, possibly with realistic offline training. The client cannot distinguish between different packet sequences of the same page (even though the page may be multi-modal). This is the same as the above restriction but only applied if p and q are packet sequences from the same web page.

4. Full information. No restrictions are added to D. The client has prescient information of the full packet sequence. Beyond class-specific information, the client can gain further information by looking into the future at the contents of the packet sequence, learning about her network, and possibly using other types of extraneous information. This level is not generally of practical interest except for serving as a bound for any realistic defense.

We use clustering, an unsupervised machine learning technique, to find our anonymity sets. We show how the above levels of information affect how supersequences will be computed and how testing needs to be performed in Table 2.

Optimality under the above levels of information requires the computation of supersequences over anonymity sets. If we have only sequence end information, there is only one supersequence, and we do not need to perform clustering. Instead, possible outputs of the defense simply correspond to a prefix of the one supersequence, terminating at one of a specified set of stopping points. We find the stopping points by selecting the earliest points where our maximum uniform accuracy would be satisfied. All packet sequences sent under this defense will be padded to the next stopping point. This is similar to a strategy suggested by Cai et al. [3]

If we have class-level information, we need to perform two levels of anonymity set selection. On the first level, we cluster the packet sequences within each class to decide which supersequence the client should use. For this level of clustering, we first decide on the number of supersequences in the set. Then, we randomly choose a number of "roots" equal to this number of supersequences. We cycle over every root, assigning the closest packet sequence that has not yet been classified. For this we need to define a distance between each pair of packet sequences p and q. Suppose p' and q' are the first $min(|p|,|q|)$ packets of p and q respectively. The distance between p and q is given as $2|f_{scs}(p',q')| - |p'| - |q'|$. We use this distance to measure how different two packet sequences are, without considering their respective lengths, which would be addressed by the second level. On the second level, we find stopping points, with the same strategy as that used under sequence end information. The use of an additional first level of clustering reduces the number of stopping points available for use, given a fixed number of clusters, so that using too many clusters may in fact have a higher bandwidth overhead (see Section 7).

For full information, we perform clustering with the distance between two packet sequences p and q as $2|f_{scs}(p,q)| - |p| - |q|$. Here we select roots with evenly spread out lengths.

6.4 SCS approximation

For the SCS of two packet sequences there is an exact solution that can be found using dynamic programming; however, the SCS of multiple sequences is in general NP-hard [13].

We present a simple algorithm that approximates a solution to the shortest common supersequence problem. To approximate $f_{scs}(\{p_1, p_2, \ldots, p_n\})$, we define a counter for each packet sequence $c_1, c_2, \ldots, c_n$, which starts at 1. We count the number of sequences for which

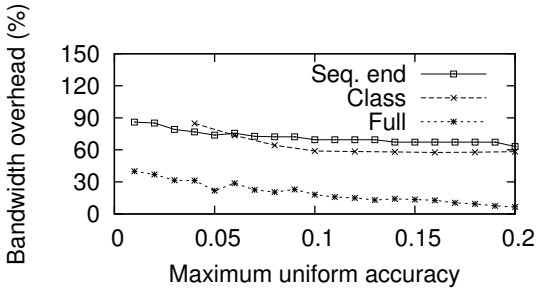

Figure 6: Bandwidth overhead for three levels of information: sequence end information (Seq. end), class-specific information (Class), and full information (Full). Using no information results in a bandwidth overhead that is much higher than that shown in the graph.

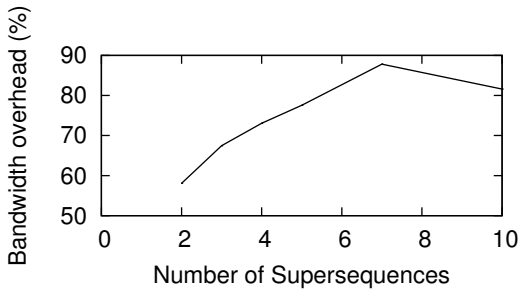

Figure 7: Bandwidth overhead for class-specific information if more than two supersequences are used, at 20 clusters. The number of stopping points available decreases, but the total number of supersequences times the number of stopping points is always at least 20.

the c_i-th element of p_i is an outgoing packet. If the number exceeds $n/4$, we append an outgoing packet to the common supersequence, and increment all c_i for which the c_i-th element of p_i is an outgoing packet by 1. Else, we append an incoming packet, and increase the corresponding counts by 1. We do this iteratively until each counter c_i becomes $|p_i|+1$, and the algorithm terminates. The choice of $n/4$ is because for web page loading, there are fewer outgoing packets than incoming packets, and this choice reduces our overhead significantly.

We note that it is easy to construct cases where the above algorithm performs very poorly. In fact, it is known that any polynomial-time approximation algorithm of shortest common supersequences cannot have bounded error [13].

7 Defense evaluation

In this section we evaluate our defense for bandwidth overhead, as well as its effectiveness in stopping our new attack.

We implemented our defenses with different levels of information as seen above. We used the same data set used to test our attacks—100 sites, 30 instances each—and attempted to protect them. The defender attempts to achieve a given maximum uniform accuracy (by determining the number of clusters or stopping points). We show the results in Figure 6. For class-level information, we used two supersequences and $N/2$ stopping points in each supersequence. We can see the full information setting has a much lower bandwidth overhead than sequence end information or class-level information. With our clustering strategy, using two supersequences under class-level information is only sometimes beneficial for the overhead. It is possible that a clever clustering strategy for class-level information could achieve lower bandwidth overheads.

For class-level information, we used two supersequences as above. It is interesting to know if increasing the number of supersequences (and correspondingly lowering the number of stopping points) will give better bandwidth overhead. In other words, we want to know if it is worth suffering greater overhead for padding to stopping points to have more finely tuned supersequences. We fix the target maximum uniform accuracy to 20%. The results are shown in Figure 7. We can see that using more than two supersequences only increases the bandwidth overhead. It is possible that if the defender can tolerate a higher maximum uniform accuracy, then it would be optimal to use more than two supersequences.

Finally, we apply our new attack to a class-level defense with a maximum uniform accuracy of 0.1, where the overhead is approximately $59\% \pm 3\%$. We achieved an accuracy of 0.068 ± 0.007. This can be compared to Table 1, where we can see that the attack achieved an accuracy of 0.30 ± 0.06 for Panchenko's decoy pages with an overhead of $130\% \pm 20\%$ and an accuracy of 0.10 ± 0.03 for BuFLO with an overhead of $190\% \pm 20\%$. Furthermore, we do not know if there exist better attacks for these defenses, but we know that no attack can achieve a better accuracy than 0.1 on our defense (using the same data set). We also compared our work with Tamaraw, which had a $96\% \pm 9\%$ overhead on the same data set for non-uniform accuracy. Our attack achieved an accuracy of 0.09 ± 0.02, although highly non-uniformly. Indeed, on 16 sites out of 100, the accuracy of the attacker was more than 0.2, and the most accurately classified site had accuracy 0.6.

8 Discussion

8.1 Realistically applying an attack

Like other website fingerprinting works in the field, we make the assumption that the attacker has an oracle that

can answer whether or not a particular sequence is generated from a single page load, and that the user does not prematurely halt the page load or perform other types of web activity. Here we discuss a few strategies to deal with possible sources of noise when applying website fingerprinting to the real world.

The attacker can use a number of signals to identify the start of a packet sequence. We found that the start of a packet sequence generally contains around three times more outgoing packets than the rest of the sequence. If the user is accessing a page for which she does not have a current connection (i.e. most likely the user is visiting a page from another domain), then the user will always send one or two outgoing connections (depending on the browser setting) to the server, followed by acceptance from the server, followed by a GET request from the main page, and then by data from the server. This particular sequence could be identifiable.

Unfortunately for Tor users, website fingerprinting is made easier due to a number of design decisions. On Tor, users are discouraged from loading videos, using torrents, and downloading large files over Tor, which are types of noise that would interfere with website fingerprinting. It is hard to change user settings on the Tor Browser; the configuration file is reset every time the Tor Browser is restarted, which implies that different Tor users have similar browser settings. As there is no disk caching, Tor users have to log in every time the Tor Browser is restarted before seeing personalized pages. For example, Facebook users on Tor must go through the front page, which has no variation and is easily identifiable. This is meant to preserve privacy from server-side browser fingerprinting attacks, but they also make website fingerprinting easier.

8.2 Realistic consequences of an attack

Here we discuss how our attack can be used realistically to break the privacy of web users. Our attack is not all-powerful; it is not likely to find a single sensitive page access among millions without error. The quality of the results depends on the base incidence rate of the client's access. With our classifier, if an attacker wishes to identify exactly which of a set of 100 pages a client is visiting, and she almost never visits those pages (less than 0.1% of page visits), then false alarms will overwhelm the number of true positives. We note that many sensitive pages have high rates of incidence as they are within Alexa's top 100 (torrent sites, adult sites, social media), especially if the client feels it necessary to use Tor.

We envision our attack as a strong source of information that becomes more powerful with the use of other orthogonal sources of information. For instance, a government agency observes that a whistleblower has released information on a web page, or that she has just posted a sensitive or incendiary article on a blog, and it is known that this whistleblower is likely to use Tor. The agency will only need to search amongst Tor streams in the last few minutes within the nation (or a smaller local area). As Tor streams are easily identifiable [7], the number of Tor users at any given moment is small enough for our accurate attack to lead to the capture of a Tor-using dissident. This strongly suggests that some sort of defense is necessary to protect the privacy of web clients.

8.3 Reproducibility of our results

To ensure reproducibility and scientific correctness, we publish the following: [9]

- The code for our new attack. This includes our feature set, parameters used for our weight learning process, and a number of weight vectors we learned which succeeded at classification against specific defenses, including the Tor data set.
- The code for our new defense. This includes the clustering strategy and the computation for stop points, as well as the supersequences we eventually used to achieve the results in this paper.
- Our implementations of known attacks and defenses, which we compared and evaluated against ours.
- The data sets we used for evaluation. This includes the list of monitored and non-monitored sites we visited over Tor, and the TCP packets we collected while visiting those sites and which we processed into Tor cells. We also include the feature vectors we computed over this data set.

9 Conclusion

In this work, we have shown that using an attack which exploits the multi-modal property of web pages with the k-Nearest Neighbour classifier gives us a much higher accuracy than previous work. We use a large feature set and learn feature weights by adjusting them based on shortening the distance towards points in the same class, and we show that our procedure is robust. The k-NN costs only seconds to train on a large database, compared to hundreds of hours for previous state-of-the-art attacks. The attack further performs well in the open-world experiments if the attacker chooses k and the bias towards non-monitored pages properly. Furthermore, as

[9] They can be found at `https://crysp.uwaterloo.ca/software/webfingerprint/`

the attack is designed to automatically converge on unprotected features, we have shown that our attack is powerful against all known defenses.

This indicates that we need a strong, provable defense to protect ourselves against ever-improving attacks in the field. We identify that the optimal simulatable, deterministic defense is one with supersequences computed over the correct anonymity sets. We show how to construct a class of such defenses based on how much information the defender is expected to have, and we evaluate these defenses based on approximations over supersequence computation and anonymity set selection. We show a significantly improved overhead over previous simulatable, deterministic defenses such as BuFLO and Tamaraw at the same security level.

Abstract

In response to increasingly sophisticated state-sponsored Internet censorship, recent work has proposed a new approach to censorship resistance: end-to-middle proxying. This concept, developed in systems such as Telex, Decoy Routing, and Cirripede, moves anticensorship technology into the core of the network, at large ISPs outside the censoring country. In this paper, we focus on two technical obstacles to the deployment of certain end-to-middle schemes: the need to selectively block flows and the need to observe both directions of a connection. We propose a new construction, TapDance, that removes these requirements. TapDance employs a novel TCP-level technique that allows the anticensorship station at an ISP to function as a passive network tap, without an inline blocking component. We also apply a novel steganographic encoding to embed control messages in TLS ciphertext, allowing us to operate on HTTPS connections even under asymmetric routing. We implement and evaluate a TapDance prototype that demonstrates how the system could function with minimal impact on an ISP's network operations.

1 Introduction

Repressive governments have deployed increasingly sophisticated technology to block disfavored Internet content [5, 50]. To circumvent such censorship, many users employ systems based on encrypted tunnels and proxies, such as VPNs, open HTTPS proxies, and a variety of purpose-built anticensorship tools [1, 2, 13, 25, 37]. However, censors are able to block many of these systems by discovering and banning the IP addresses of the servers on which they rely [46, 47]. Some services attempt to remain unblocked by frequently changing their IP addresses, but they face a tension between the desire to make their network locations known to would-be users and the need to keep the same information secret from the censor.

To avoid this tension and escape the cat-and-mouse game that results between censors and anticensorship tools, researchers have recently introduced a new approach called *end-to-middle* (E2M) *proxying* [21, 26, 49]. In an E2M system, friendly network operators agree to help users in other, censored countries access blocked information. These censored users direct traffic toward uncensored "decoy" sites, but include with such traffic a special signal (undetectable by censors) through which they request access to different, censored destinations. Participating friendly networks, upon detecting this signal, redirect the user's traffic to the censored destination. From the perspective of the censor — or anyone else positioned between the censored user and the friendly network — the user appears to be in contact only with the decoy site. In order to block the system, the censor would have to block all connections that pass through participating ISPs, which would result in a prohibitive level of overblocking if E2M systems were widely deployed at major carriers.

Deployment challenges While E2M approaches appear promising compared to traditional proxies, they face technical hurdles that have thus far prevented any of them from being deployed at an ISP. All existing schemes assume that participating ISPs will be able to selectively block connections between users and decoy sites. Unfortunately, this requires introducing new hardware in-line with backbone links, which adds latency and introduces a possible point of failure. ISPs typically have service level agreements (SLAs) with their customers and peers that govern performance and reliability, and adding in-line flow-blocking components may violate their contractual obligations. Additionally, adding such hardware increases the number of components to check when a failure does occur, even in unrelated parts of the ISP's network, potentially complicating the investigation of outages and increasing downtime. Given these risks, ISPs are reluctant to add in-line elements to their networks. In private discussions with ISPs, we found that despite being willing to assist Internet freedom in a technical and even financial capacity, none were willing to deploy existing E2M technologies due to these potential operational impacts.

Furthermore, our original E2M proposal, Telex, assumes that the ISP sees traffic in both directions, client-decoy and decoy-client. While this might be true when the ISP is immediately upstream from the decoy server, it does not generally hold farther away. IP flows are often asymmetric, such that the route taken from source to destination may be different from the reverse path. This asymmetry limits an ISP to observing only one side of a connection. The amount of asymmetry is ISP-dependent, but tier-2 ISPs typically see lower amounts of asymmetry (around 25% of packets) than tier-1s, where up to 90% of packets can be part of asymmetric flows [48]. This severely constrains where in the network E2M schemes that require symmetric flows can be deployed.

Our approach In this paper, we propose TapDance, a novel end-to-middle proxy approach that removes these obstacles to deployment at the cost of a moderate increase in its susceptibility to active attacks by the censor. TapDance is the first E2M proxy that works without an inline-blocking or redirecting element at an ISP. Instead, our design requires only a passive tap that observes traffic transiting the ISP and the ability to inject new packets. TapDance also includes a novel connection tagging mechanism that embeds steganographic tags into the ciphertext of a TLS connection. We make use of this to allow the system to support asymmetric flows and to efficiently include large steganographic payloads in a single packet.

Although TapDance appears to be more feasible to deploy than previous E2M designs, this comes with certain tradeoffs. As we discuss in Section 5, there are several active attacks that a censor could perform on live flows in order to distinguish TapDance connections from normal traffic. We note that each of the previous E2M schemes is also vulnerable to at least some active attacks. As a potential countermeasure, we introduce *active defense* mechanisms, which utilize E2M's privileged vantage point in the network to induce false positives for the attacker.

Even with these tradeoffs, TapDance provides a realistic path to deployment for E2M proxy systems. Given the choice between previous schemes that appear not to be practically fieldable and our proposal, which better satisfies the constraints of real ISPs but requires a careful defense strategy, we believe TapDance is the more viable route to building anticensorship into the Internet's core.

Organization Section 2 reviews the three existing E2M proposals. Section 3 introduces our chosen ciphertext steganography mechanism, and Section 4 explains the rest of the TapDance construction. In Section 5, we analyze the security of our scheme and propose active defense strategies. In Section 6, we compare TapDance to previous E2M designs. We describe our proof-of-concept implementation in Section 7 and evaluate its performance in Section 8. We discuss future work in Section 9 and related work in Section 10, and we conclude in Section 11.

2 Review of Existing E2M Protocols

There are three original publications on end-to-middle proxying: Telex [49], Decoy Routing [26], and Cirripede [21]. The designs for these three systems are largely similar, although some notable differences exist. Figure 1 show the Telex scheme, as one example.

In each design, a client wishes to reach a censored website. To do so, the client creates an encrypted connection to an unblocked *decoy* server, with the connection to this server passing through a cooperating ISP (outside the censored country) that has deployed an *ISP station*. The decoy can be any server and is oblivious to the operation of the anticensorship system. The ISP station determines that a particular client wishes to be proxied by recognizing a *tag*. In Telex, this is a public-key steganographic tag placed in the random nonce of the ClientHello message of a Transport Layer Security (TLS) connection [12]. In Cirripede, users register their IP address with a registration server by making a series of TCP connections, encoding a similar tag in the initial sequence numbers (ISNs). In Decoy Routing, the tag is placed in the TLS client nonce as in Telex, but the client and the ISP station are assumed to have a shared secret established out of band.

In both Telex and Cirripede, the tag consists of an elliptic curve Diffie-Hellman (ECDH) public key point and a hash of the ECDH secret shared with the ISP station. In Decoy Routing, the tag consists of an HMAC of the previously established shared secret key, the current hour, and a per-hour sequence number. In all cases, only the station can observe this tag, using its private key or shared secret.

Once the station has determined that a particular flow should be proxied, all three designs employ an inline blocking component at the ISP to block further communication between the client and the decoy server. Telex and Decoy Routing both block only the tagged flow using an inline-blocking component. Cirripede blocks all connections from a registered client. Cirripede's inline blocking is based on the client's IP address and has a long duration, possibly making it easier to implement than the flow-based blocking used in Telex and Decoy Routing.

After the TLS handshake has completed and the client-server communication is blocked, all three designs have the station impersonate the decoy server, receiving packets to and spoofing packets from its IP address. In Telex, the station uses the tag in the TLS client nonce to compute a shared secret with the client, which the client uses to seed its secret keys during the key exchange with the decoy server. Using this seed and the ability to observe both sides of the TLS handshake, Telex derives the master secret under which the TLS client-server communication is encrypted, and continues to use this shared secret between station and client. In Cirripede and Decoy Routing, the station changes the key stream to be encrypted under

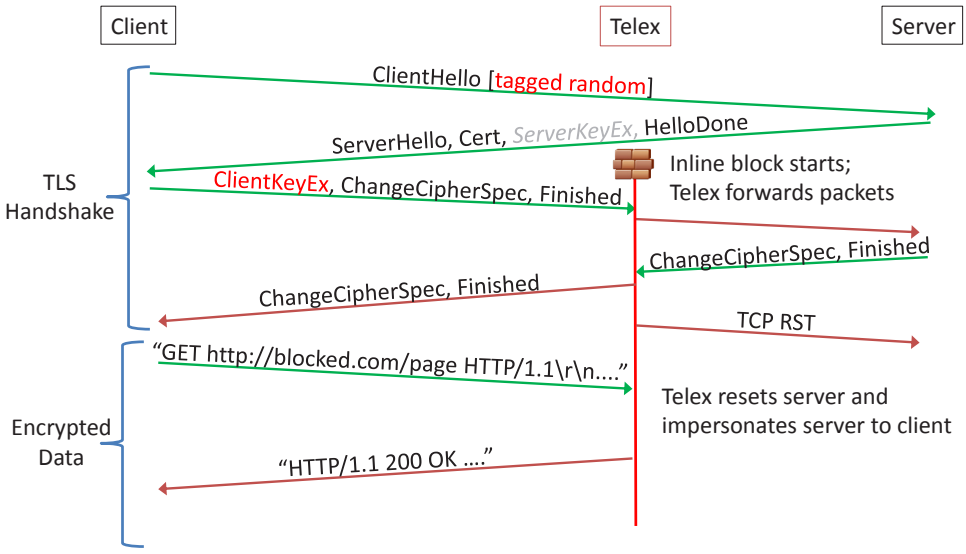

Figure 1: **Telex End-to-Middle Scheme** — To establish communication with an ISP-deployed Telex station, the client performs a TLS connection with an unblocked decoy server. In the TLS ClientHello message, it replaces the random nonce with a public-key steganographic tag that can be observed by the Telex station at the on-path ISP outside the censored country. When the station detects this tag with its private key, it blocks the true connection using an inline-blocking component and forwards packets for the remainder of the handshake. Once the handshake is complete, Telex stops forwarding and begins to spoof packets from the decoy server in order to communicate with the client. While here we only show the details of Telex, all of the first generation ISP proxies (Telex, Cirripede, and Decoy Routing) are similar in architecture; we note differences in Section 2.

the secret exchanged during registration (Cirripede) or previously shared (Decoy Routing).

Changing the communication to a new shared secret opens Cirripede and Decoy Routing to replay and preplay attacks by the adversary. If an adversary suspects a user is accessing these proxies, it can create a new connection that replays parts from the suspected connection and receive confirmation that a particular flow uses the proxy. For example, in Decoy Routing, the adversary can simply use the suspected connection's TLS client nonce in a new connection and send a request. If the first response cannot be decrypted with the client-server shared secret, it confirms that the particular nonce was tagged. For Cirripede, a similar replay of the tagged TCP SYN packets will register the adversary's client, and a connection to the decoy server over TLS will confirm this: if the adversary can decrypt the TLS response with the established master secret, the adversary is not registered with Cirripede, indicating that the TCP SYN packets were not a secret Cirripede tag. Otherwise, if the adversary cannot decrypt the response, this indicates that the SYN packets were indeed a Cirripede tag.

Telex is not vulnerable to either of these attacks, because the client uses the client-station shared secret to seed its half of the key exchange. This allows the station to also compute the client-server shared master secret and verify that the client has knowledge of the client-server shared secret by verifying the TLS finished messages. If an adversary attempted to replay the client random in a new connection, Telex would be able to determine that the user (in this case, the adversary) did not have knowledge of the client-station shared secret, because the user did not originally generate the Diffie-Hellman tag. Thus, Telex is unable to decrypt and verify the TLS finished messages as expected, and will not spoof messages from the server.

Both Cirripede and Decoy Routing function in the presence of asymmetric flows. In Cirripede, the station only needs to observe communication from the client to the decoy server in order to establish its shared secret with the client. In Decoy Routing, the client sends any missing information (i.e., information contained in messages from the server to the client) via another covert channel. In contrast, Telex's approach does not handle asymmetric paths, as the station needs to see both sides of the communication in order to learn the client-server shared master secret.

Unlike any of the existing schemes, TapDance functions without an inline blocking component, potentially making it much easier to deploy at ISPs. Unlike Telex, it supports asymmetric flows, but in doing so it sacrifices some of Telex's resistance to active attacks. We defer a complete comparison between TapDance and the first-generation E2M schemes until Section 6, after we have introduced the details of the system.

3 Ciphertext Covert Channel

Previous E2M covert channels have been limited in size, forcing implementations to use small payloads or several flows in order to steganographically communicate enough information to the ISP station. However, because TapDance does not depend on inline flow-blocking and must work with asymmetric flows, we need a way to communicate the client's request directly to the TapDance station while maintaining a valid TLS session between the client and the decoy server. We therefore introduce a novel technique, *chosen-ciphertext steganography*, which allows us to encode a much higher bandwidth steganographic payload in the ciphertexts of legitimate (i.e., censor-allowed) TLS traffic.

The classic problem in steganography is known as the *prisoners' problem*, formulated by Simmons [41]: two prisoners, Alice and Bob, wish to send hidden messages in the presence of a jailer. These messages are disguised in legitimate, public communication between Alice and Bob in such a way that the jailer cannot detect their presence. Many traditional steganographic techniques focus on embedding hidden messages in non-uniform cover channels such as images or text [4]; in the network setting, each layer of the OSI model may provide potential cover traffic [19] of varying bandwidths. To avoid detection, these channels must not alter the expected distribution of cover traffic [32]. In addition, use of header fields in network protocols for steganographic cover limits the carrying capacity of the covert channel.

We observe it is possible for the sender to use stream ciphers and CBC-mode ciphers as steganographic channels. This allows a sender Alice to embed an arbitrary hidden message to a *third party*, Bob, inside a *valid* ciphertext for Cathy. That is, Bob will be able to extract the hidden message and Cathy will be able to decrypt the ciphertext, without alerting outside entities (or, indeed, Cathy, subject to certain assumptions) to the presence of the steganographic messages.

Moreover, through this technique, we can place limited constraints on the plaintext (such as requiring it be valid base64 or numeric characters), while encoding arbitrary data in the corresponding ciphertext. This allows us to ensure not only that Cathy can decrypt the received ciphertext, but also that the plaintext is consistent with the protocol used. Note that this is a departure from the original prisoners' problem, as we assume Alice is allowed to securely communicate with Cathy, so long as this communication looks legitimate to outside entities.

As our technique works both with stream ciphers and CBC-mode ciphers, which are the two most common modes used in TLS [28], we will use this building block to encode steganographic tags and payloads in the ciphertext of TLS requests.

3.1 Chosen-Ciphertext Steganography

To describe our technique, we start with a stream cipher in counter mode. The key observation is that counter mode ciphers, even with authentication tags, have ciphertexts that are *malleable* from the perspective of the sender, Alice. That is, stream ciphers have the general property of *ciphertext malleability*, in that flipping a single bit in the ciphertext flips a single corresponding bit in the decrypted plaintext. Alice can likewise change bits in the plaintext to effect specific bits in the corresponding ciphertext. Since Alice knows the keystream for the stream cipher, she can choose an arbitrary string that she would like to appear in the ciphertext, and compute (decrypt) the corresponding plaintext. Note that this does not invalidate the MAC or authentication tag used in addition to this cipher, because Alice first computes a valid plaintext, and then encrypts and MACs it using the standard library, resulting in ciphertext that contains her chosen steganographic data.

Furthermore, Alice can "fix" particular bits in the plaintext and allow the remaining bits to be determined by the data encoded in the ciphertext. For example, Alice could require that each plaintext byte starts with 5 bits set to 00110, and allow the remaining 3 bits to be chosen by the ciphertext. In this way, the plaintext will always be an ASCII character from the set "01234567" and the ciphertext has a steganographic "carrying capacity" to encode 3 bits per byte.

While it seems intuitive that Alice can limit plaintext bits for stream ciphers, it may not be as intuitive to see how this is also possible for CBC-mode ciphers. However, while the ciphertext malleability of stream ciphers allows Alice partial control over the resulting plaintext, we show that it is also possible to use this technique in other cipher modes, with equal control over the plaintext values.

In CBC mode, it is possible to choose the value of an arbitrary ciphertext block (e.g., C_2), and decrypt it to compute an intermediary result. This intermediary result must also be the result of the current plaintext block (P_2) xored with the previous ciphertext block (C_1) in order to encrypt to the chosen ciphertext value. This means that, given a ciphertext block, we can choose either the plaintext value (P_2), or the previous ciphertext block (C_1), and compute the other. However, we can also choose a mixture of the two; that is, for each bit we pick in the plaintext, we are "forced" to choose that corresponding bit in the previous plaintext block and vise-versa. Choosing any bits in a ciphertext block (C_1) will force us to repeat this operation for the previous plaintext block (P_1) and twice previous ciphertext block (C_0). We can choose to pick the value of plaintext blocks (fixing the corresponding ciphertext blocks), all the way

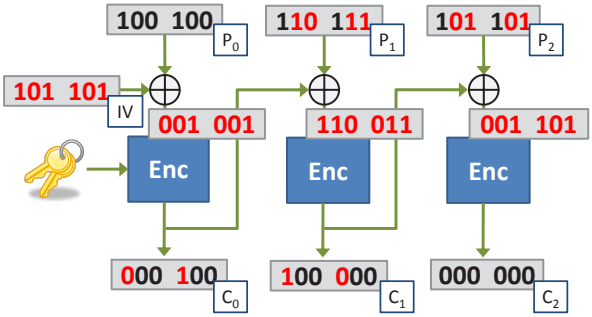

Figure 2: **CBC Chosen Ciphertext Example** — In this example, bits chosen by the encoding are in black, while bits "forced" by computation are red. For example, we choose all 6-bits to be 0 in the last ciphertext block. This forces the block's intermediary to be "forced" to a value beyond our control; in this case 001101. To obtain this value, we can choose a mixture of bits in the plaintext, which forces the corresponding bits in the previous ciphertext block. In this example, we choose the plaintext block to be of the form $1xx1xx$, allowing us to choose 4-bits in the ciphertext, which we choose to be 0s. Thus, the ciphertext has the form $x00x00$. We solve for the unknown bits in the ciphertext and plaintext ($1xx1xx \oplus x00x00 = 001101$) to fill in the missing "fixed" values. We can repeat this process backward until the first block, where we simply compute the IV in order to allow choosing all the bits in the first plaintext block.

back to the first plaintext block, where we are left to decide if we want to choose the value of the first plaintext block or the Initialization Vector (IV) value. At this point, fixing the IV is the natural choice, as this leaves us greater control over the first plaintext block. Figure 2 shows an example of this backpropagation, encoding a total of 4-bits per 6-bit ciphertext block (plus a full final block).

This scheme allows us to restrict plaintexts encrypted with CBC to the same ASCII range as before, while still allowing us to encode arbitrary-length messages in the ciphertext.

While the sender can encode any value in the ciphertext in this manner, we do not wish to change the expected ciphertext distribution. The counter and CBC modes of encryption both satisfy indistinguishability from random bits [38], so encoding anything that is distinguishable from a uniform random string would allow third parties (e.g., a network censor) to detect this covert channel. To prevent this, Alice encrypts her hidden message if necessary, using an encryption scheme that produces ciphertexts indistinguishable from random bits. The resulting ciphertext for Bob is then encoded in the CBC or stream-cipher ciphertext as outlined above. To an outside adversary, this resulting "ciphertext-in-ciphertext" should still be a string indistinguishable from random, as expected.

4 TapDance Architecture

4.1 Protocol Overview

The TapDance protocol requires only a passive network tap and traffic injection capability, and is carefully designed to work even if the station is unable to observe communication between the decoy server and the client. To accomplish this, we utilize several tricks gleaned from a close reading of the TCP specification [35] to allow the TapDance station to impersonate the decoy server without blocking traffic between client and server.

Figure 3 gives an overview of the TapDance protocol. In the first step, the client establishes a normal TLS connection to the decoy web server. Once this handshake is complete, the client and decoy server share a master secret, which they use to generate encryption keys, MAC keys, and initialization vector or sequence state.

The TapDance protocol requires the client to leak knowledge of the client-server master secret, thereby allowing the station to use this shared secret to encrypt all communications. The client encodes the master secret as part of a steganographic tag visible only to the TapDance station. This tag is hidden in an *incomplete* HTTP request sent to the decoy server through the encrypted channel. Since this request is incomplete, the decoy server will not respond with data to the client; this can be accomplished, for example, by simply withholding the two consecutive line breaks that mark the end of an HTTP request. The decoy server will acknowledge this data only at the TCP level by sending a TCP ACK packet and will then wait for the rest of the client's incomplete HTTP request until it times out. As shown in Figure 5, our evaluation reveals that most TLS hosts on the Internet will leave such incomplete request connections open for at least 60 seconds before sending additional data or closing the connection.

When the TapDance station observes this encrypted HTTP request, it is able to extract the tag (and hence the master secret), as discussed in detail in Section 4.2. The station then spoofs an encrypted response from the decoy server to the client. This message acts as confirmation for the client that the TapDance station is present. In particular, this message is consistent with a pipelined HTTPS connection, so by itself does not indicate that TapDance is in use.

At the TCP level, the client acknowledges this spoofed data with a TCP ACK packet, and because there is no inline-blocking between it and the server, the ACK will reach the server. However, because the acknowledgment number is above the server's $SND.NXT$, the server will not respond. Similarly, if the client responds with additional data, the acknowledgment field contained in those TCP packets will also be beyond what the server has sent. This allows the TapDance station to continue to imper-

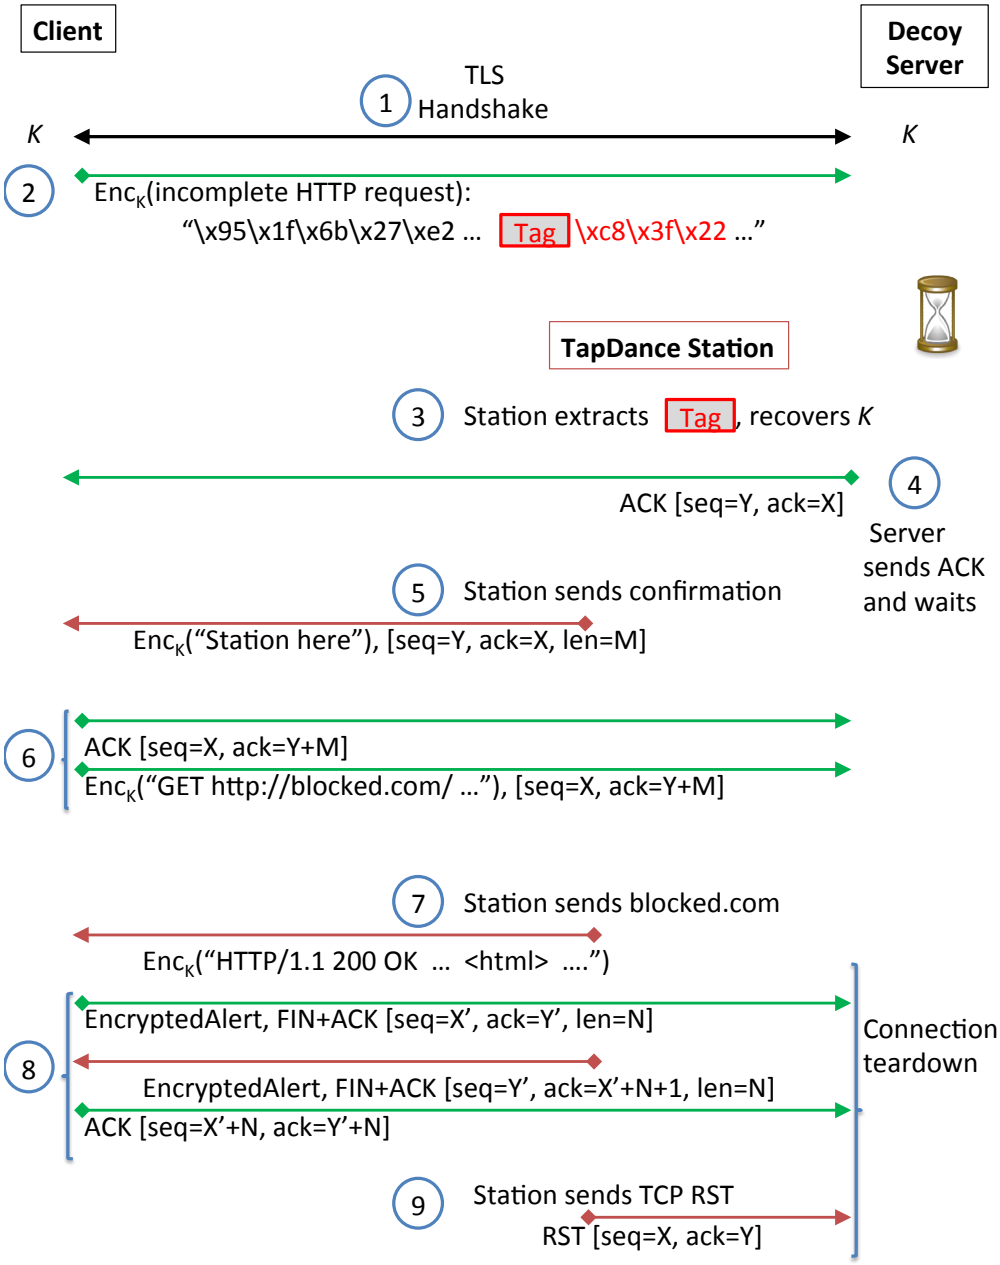

Figure 3: **TapDance Overview** — (1) The client performs a normal TLS handshake with an unblocked decoy server, establishing a session key K. (2) The client sends an *incomplete* HTTP request through the connection and encodes a steganographic tag in the *ciphertext* of the request, using a novel encoding scheme (Section 4.2). (3) The TapDance station observes and extracts the client's tag, and recovers the client-server session secret K. (4) The server sends a TCP ACK message in response to the incomplete HTTP request and waits for the request to be completed or until it times out. (5) The station, meanwhile, spoofs a response to the client from the decoy server. This message is encrypted under K and indicates the station's presence to the client. (6) The client sends a TCP ACK (for the spoofed data) and its real request (blocked.com). The server ignores both of these, because the TCP acknowledgment field is higher than the server's TCP SND.NXT. (7) The TapDance station sends back the requested page (blocked.com) as a spoofed response from the server. (8) When finished, the client and TapDance station simulate a standard TCP/TLS authenticated shutdown, which is again ignored by the true server. (9) After the connection is terminated by the client, the TapDance station sends a TCP RST packet that is valid for the server's SND.NXT, silently closing its end of the connection before its timeout expires.

sonate the server, acknowledging data the client sends, and sending its own data in response, without interference from the server itself.

4.2 Tag Format

In TapDance, we rely on elliptic curve Diffie-Hellman to agree on a per-connection shared secret between the client and station, which is used to encrypt the steganographic tag payload. The tag consists of the client's connection-specific elliptic curve public key point ($Q = eG$), encoded as a string indistinguishable from uniform, followed by a variable-length encrypted payload used to communicate the client-server TLS master secret (and intent for proxying) to the station.

In order to properly disguise the client's elliptic curve point, we use Elligator 2 [8] over Curve25519 [7]. Elligator 2 is an efficient encoding function that transforms, for certain types of elliptic curves, exactly half of the points on the curve to strings that are indistinguishable from uniform random strings.

The client uses the TapDance station's public key point ($P = dG$) and its own private key (e) to compute an ECDH shared secret with the station ($S = eP = dQ$), which is used to derive the payload encryption key. The encrypted payload contains an 8-byte magic value used by the station to detect successful decryption, the client and server random nonces, and the client-server master secret of the TLS connection. With this payload, typically contained in a single packet from the client, the station is able to derive the TLS master secret between client and server.

We insert the tag, composed of the encoded point and encrypted payload, into the ciphertext of the client's incomplete request to the server using the chosen ciphertext steganographic channel described in Section 3. In order to avoid the server generating unwanted error messages, we maintain some control over the plaintext that the server receives using the plaintext-limiting technique as described in Section 3. Specifically, we split the tag into 6-bit chunks and encode each chunk in the low order bits of a ciphertext byte. This allows the two most significant bits to be chosen freely in the plaintext (i.e. not decided by the decryption of the tag-containing ciphertext). We choose these two bits so that the plaintext always falls within the ASCII range 0x40 to 0x7f. We verified that Apache was capable of handling this range of characters in a header line without triggering an error.

5 Security Analysis

Our threat model is similar to that of previous end-to-middle designs. We assume an adversarial censor that can observe, alter, block, or inject network traffic within their domain or geographic region (i.e., country) and may gain access to foreign resources, such as VPNs or private servers, by leasing them from providers. Despite control over its network infrastructure, however, we assume the censor does not have control over end-users' computers, such as the ability to install arbitrary programs or Trojans.

The censor can block its citizens' access to websites it finds objectionable, proxies, or other communication endpoints it chooses, using IP blocking, DNS blacklists, and deep-packet inspection. We assume the censor uses blacklisting to block resources and that the censor does not wish to block legitimate websites or otherwise cut themselves off from the rest of the Internet, which may inhibit desirable commerce or communication. In addition, we assume that the censor allows end-to-end encrypted communication, specifically TLS communication. As websites increasingly support HTTPS, censors face increasing pressures against preventing TLS connections [14].

While the threat model for TapDance is similar to those assumed by prior end-to-middle schemes, our fundamentally new design has a different attack surface than the others. We perform a security analysis of TapDance and compare it to the previous generation designs, focusing on the adversarial goal of distinguishing normal TLS connections from TapDance connections. In particular, we do not attempt to hide the deployment locations of the TapDance stations themselves.

5.1 Passive Attacks

TLS handshake TLS allows implementations to support many different extensions and cipher suites. As a result, implementations can be easy to differentiate based on the ciphers and extensions they claim to support in their ClientHello or ServerHello messages. In order to prevent this from being used to locate suspicious implementations, our proxy must blend in to or mimic another popular client TLS implementation. For example, we could support the same set of ciphers and extensions as Chrome for the user's platform. Currently, our client mimics Chrome's cipher suite list for Linux.

Cryptographic attacks A computationally powerful adversary could attempt to derive the station's private key from the public key. However, our use of ECC Curve25519 should resist even the most powerful computation attacks using known discrete logarithm algorithms. The largest publicly known ECC key to be broken is only 112 bits, broken over 6 months in 2009 on a 200-PlayStation3 cluster [9]. In contrast to Telex, TapDance also supports increasing the key size as needed, as we are not limited to a fixed field size for our tag.

Forward secrecy An adversary who compromises an ISP station or otherwise obtains a station's private key can use it to trivially detect both future and previously

recorded flows in order to tell if they were proxy flows. Additionally, they can use the key to decrypt the user's request (and proxy's response), learning the censored websites users have visited. To address the first problem, we can use a technique suggested in Telex [49]. The ISP station generates many private keys ahead of time and stores them in either a hardware security module or offline storage, and provides all of the public keys to the clients. Clients can then cycle through the public keys they use based on a course-grained time (e.g., hours or days). The proxy could also cycle through keys, destroying expired keys and limiting access to future ones.

To address the second problem, TapDance is compatible with existing forward-secure protocols. For example, for each new connection it receives, the TapDance station can generate a new ECDH point randomly, and establish a new shared secret between this new point and the original point sent by the client in the connection tag. The station sends its new ECDH public point to the client in its Hello message, and the remainder of the connection is encrypted under the new shared secret. This scheme has the advantage that it adds no new round trips to the scheme and only 32-bytes to the original ISP station's response.

Packet timing and length The censor could passively measure the normal round-trip time between potential servers and observe the set of packet lengths of encrypted data that a website typically returns. During a proxy connection, the round-trip time or the packet lengths of the apparent server may change for an observant censor, as the station may be closer or have more processing delay than the true server. This attack is possible on all three of the first generation E2M schemes, as detailed in [40]. However, such an attack at the application level may be difficult to carry out in practice, as larger, legitimate websites may have many member-only pages that contain different payload lengths and different processing overhead. The censor must be able to distinguish between "blind pages" it cannot confirm are part of the legitimate site and decoy proxy connections. We note that this is difficult at the application level, but TCP round-trip times may have a more consistent and distinguishable difference.

Lack of server response If the TapDance station fails to detect a client's flow, it will not respond to the client. This may appear suspicious to a censor, as the client sends a request, but there is no response at the application level from the server. This scenario could occur for three reasons. First, the censor may disrupt the path between client and TapDance station in order to cause such a timeout, using one of the active attacks below (such as the routing-around attack), in order to confirm a particular flow is attempting to use TapDance. Second, such false pickups may happen intermittently (due to ISP station malfunction). Finally, a client may attempt to find new TapDance stations by probing many potential decoy servers with tagged TLS connections. Paths that do not contain ISP stations will have suspiciously long server response times.

To address the last issue, probing clients could send complete requests and tag their requests with a secret nonce. The station could record these secret nonces, and, at a later time (out of band, or through a different TapDance station), the client can query the station for the secret nonces it sent. In this way, the client learns new servers for which the ISP station is willing to proxy without revealing the probing pattern. To address the first two problems, we could have clients commonly use servers that support long-polling HTTP push notification. In these services, normal requests can go unanswered at the application layer as long as the server does not have data to send to the client, such as in online-gaming or XMPP servers. Another defense is to have the client send complete requests that force the server to keep the connection alive for additional requests, and to have the TapDance station inject additional data *after* the server's initial response. This requires careful knowledge of the timing and length of the server's initial response, which could either be provided by active probing from the station or information given by the client.

TCP/IP protocol fingerprinting The adversary could attempt to observe packets coming from potential decoy servers and build profiles for each server, including the set of TCP options supported by the server, IP TTL values, TCP window sizes, and TCP timestamp slope and offset. If these values ever change, particularly in the middle of a connection (and only for that connection), it could be a strong indication of a particular flow using a proxy at an on-path ISP. To prevent this attack, the station also needs to build these profiles for servers, either by actively collecting this profile from potential servers, or passively observing the server's responses to non-proxy connections and extracting the parameters. Alternatively, the client can signal to the station some of the parameters. First generation schemes varied in defense for this type of attack; for example, Telex's implementation is able to infer and mimic all of these parameters from observing the servers' responses, although Telex requires a symmetric path in order to accomplish this. In theory, parameters that the adversary can measure for fingerprinting can also be measured by the station and mimicked. However, given that the adversary has only to find one distinguisher in order to succeed, server mimicry remains difficult to achieve in practice.

5.2 Active Attacks

TLS attacks The censor may issue fake TLS certificates from a certificate authority under its control and then target TLS sessions with a man-in-the-middle attack.

While TapDance and previous designs are vulnerable to this attack, there may be external political pressure that discourages a censor from this attack, as it may be disruptive to foreign e-commerce in particular. We also argue that as the number of sites using TLS continues to increase, this attack becomes more expensive for the censor to perform without impacting performance. Finally, decoy servers that use certificate pinning or other CA-protection mechanisms such as Perspectives [45], CAge [27], or CA country pinning [42], can potentially avoid such attacks.

Packet injection Because TapDance does not block packets from the client to the true server, it is possible for the censor to inject spoofed probes from the client that will reach the server. If the censor can craft a probe that will result in the server generating a response that reveals the server's true TCP state, the censor will be able to use this response to differentiate real connections from proxy connections. While the previous designs also faced this threat [40], the censor had to inject the spoofed packet in a way that bypassed the station's ISP inline blocking element. In TapDance, there is no blocking element, and so the censor is able to simply send it without any routing tricks. An example of this attack is the censor sending a TCP ACK packet with a stale sequence number, or one for data outside the server's receive window. The server will respond to this packet with an ACK containing the server's TCP state (sequence and acknowledgment), which will be smaller than the last sequence and/or acknowledgments sent by the station.

There are a few ways to deal with this attack if the censor employs it. First, we can simply limit each proxy connection to a single request from the client and a response from the station, followed immediately by a connection close. This will dramatically increase the overhead of the system but will remove the potential for the adversary to use injected packets and their responses to differentiate between normal and proxy connections. This is because the TCP state between the station and real server will not diverge until the station has sent its response, leaving only a very small window where the censor can probe the real server for its state and get a different response.

Active defense Alternatively, in order to frustrate the censor from performing packet injection attacks, we can perform *active defense*, where the station observes active probes such as the TCP ACK and responds to them in a way that would "reveal" a proxy connection, even for flows that are not proxy connections. To the censor, this would make even legitimate non-proxy connections to the server appear as if they were proxy connections.

As an example, consider a censor that injects a stale ACK for suspected proxy connections. Connections that are actually proxy connections will respond with a stale ACK from the server, revealing the connection to the censor. However, the station could detect the original probe, and if it is not a proxied connection, respond with a stale ACK so as to make it appear to the censor as if it were. In this way, for every probe the censor makes, they will detect, sometimes incorrectly, that the connection was a proxy connection.

Replay attacks The censor could capture suspected tags and attempt to replay them in a new connection, to determine if the station responds to the tag. To specifically attack TapDance, the adversary could replay the client's tag-containing request packet after the connection has closed and observe if the station appears to send back a response. We note that both Cirripede and Decoy Routing are also vulnerable to tag replay attacks, although Telex provides some limited protection from them. To protect against duplicated tags, the station could record previous tags and refuse to respond to a repeated tag. To avoid saving all tags, the station could require clients to include a recent timestamp in the encrypted payload[1].

However, such a defense may enable a denial of service attack: the censor could delay the true request of a suspected client and send it in a different connection first. In this *preplay* version of the attack, the censor is also able to observe whether the station responds with the ClientHello message. If it does, the censor will know the suspected request contained a tag.

Denial of service The censor could attempt to exhaust the station's resources by creating many proxy connections, or by sending a large volume of traffic that the ISP station will have to check for tags using an expensive ECC function. We estimate that a single ISP station deployment of our implementation on a 16-core machine could be overwhelmed if an attacker sends approximately 1.2 Gbps of pure TLS application data packets past it. This type of attack is feasible for an attack with a small botnet, or even a few well-connected servers. Because ISPs commonly perform load balancing by flow-based hashing, we can scale our deployment linearly to multiple branches of machines and use standard intrusion detection techniques to ignore packets that do not belong to valid connections or that come from spoofed or blacklisted sources [34].

Routing around the proxy A recent paper by Schuchard et al. details a novel attack against our and previous designs [40]. In this attack, the censor is able to change local routing policy in a way that redirects outbound flows around potential station-deploying ISPs while still allowing them to reach their destinations. This prevents the ISP station from being able to observe the tagged flows and thus from being a proxy for the clients. However, Houmansadr et al. investigate the cost to the

[1] The client random which is sent in the encrypted payload already contains a timestamp for the first 4 bytes

censor of performing such an attack and find it to be prohibitively expensive [23]. Although both of these papers ultimately contribute to deciding which ISPs should deploy proxies in order to be most resilient, we consider such a discussion outside our current scope.

Tunneling around the proxy A more conceptually simple attack is for the censor to transparently tunnel specific suspected flows around the ISP station. For example, the censor could rent a VPN or VPS outside the country and send specific flows through them to avoid their paths crossing the ISP station. This attack is expensive for the adversary to perform, and so could not reasonably be performed for an entire country. However, it could be performed for particular targets and combined with previous passive detection attacks to aid the censor in confirming whether particular users are tagging their flows.

Complicit servers A censor may be able to compromise, coerce, or host websites that can act as servers for decoy connections. The vantage point from a server allows them to observe incomplete requests from clients, including the plaintext that the client mangled in order to produce the tag in the ciphertext. This allows the censor to both observe specific clients using the ISP station and also disrupt use of the proxy with the particular server. There is little TapDance or previous designs can do to avoid cooperation between servers and the censor, as the two can simply compare traffic received and detect proxy flows as ones that have different data at the two vantage points. However, using this vantage point to disrupt proxy use could be detected by clients and the server avoided (and potentially notified in the case of a compromise).

6 Comparison

On the protocol level, TapDance bears more similarity to Telex than Cirripede, in that clients participate in TapDance on a per-connection basis, rather than participating in a separate registration phase as in Cirripede, and in that client-station communication, after the initial Diffie-Hellman handshake, is secured using the client-server master secret. In order to conserve bandwidth, our design, like both Telex and Cirripede, leverages elliptic curve cryptography to signal intent to use the system and to establish a shared secret between client and station.

However, TapDance exhibits several important differences from previous protocols, which has implications for both security and functionality. As discussed in Section 1, one of the largest challenges to deploying E2M proxies at ISPs is the inline flow-blocking component. TapDance has the singular advantage in that it allows client-server communication to continue unimpeded. In fact, our design requires only that the TapDance station be able to passively observe communication from client to server and be able to inject messages into the network; the station can be oblivious to communication passing from server to client.

The advantages of the TapDance protocol stem from its careful use of chosen-ciphertext steganography (described in Section 3) to hide the client's tag and the fact that a high percentage of servers ignore stale TCP-level messages. In contrast, previous proposals rely on inline blocking to prevent server-client communication, and TCP sequence numbers and TLS ClientHello random nonces to disguise the client's steganographic tag. In general, these fields are useful in steganography because these strings should be uniformly random for legitimate connections, providing a good cover for the tag that replaces them, so long as this tag is indistinguishable from random.

However, both of these fields are fixed size; each TLS nonce can be replaced with a 224-bit uniform random tag, and each TCP sequence number with only 24 bits of a tag. Cirripede, which encodes the client's tag into TCP sequence numbers, uses multiple TCP connections to convey the full tag to the station. Telex and Decoy Routing both use a single TLS nonce to encode the client's tag. Given the limited bandwidth of these covert channels, they are useful to convey only short secrets, while the rest of the payload (such as the request for a blocked website) must take place in a future packet.

TapDance, on the other hand, leverages chosen-ciphertext steganography in order to encode steganographic tags in the ciphertext of a TLS connection, without invalidating the TLS session itself. Encoding the tag in the ciphertext has several advantages. First, the tag is no longer constrained to a fixed field size of either 24 or 224 bits, allowing us to encode more information in each tag, and use larger and more secure elliptic curves. Second, because the ciphertext is sent after the TLS handshake has completed, it is possible to encode the connection's master secret in this tag, allowing the station to decrypt the TLS session from a single packet, and without requiring the station to observe packets from the server.

In addition, TapDance takes advantage of recent work by Bernstein et al. [8], in order to disguise elliptic curve points as strings indistinguishable from uniform, namely Elligator 2. Traditional encoding of elliptic curve points is distinguishable from random for several reasons, which are outlined in detail in [8]. Telex and Cirripede address this concern by employing two closely related elliptic curves, which is less efficient than TapDance's use of Elligator 2, as the latter method requires only a single elliptic curve to achieve the same functionality.

From a security perspective, the only attacks unique to TapDance are the lack of server response and packet injection attacks. Besides these, we find our design has no additional vulnerabilities from which all previous designs were immune. While these two attacks do pose a

	Telex [49]	Cirripede [21]	Decoy Routing [26]	TapDance

Table 1: **Comparing E2M Schemes** — Unlike previous work, TapDance operates without an inline flow-blocking component at cooperating ISPs. However, it is vulnerable to active attacks that some previous designs resist. No E2M system yet defends against traffic analysis or website fingerprinting, making this an important area for further study.

threat to TapDance, the benefits of a practical ISP station deployment — at least as a bridge to stronger future systems — may outweigh the potential risks.

In summary, our approach obviates the need for an inline blocking element at the ISP, which is a requirement of Telex, Cirripede, and Decoy Routing, while preserving system functionality in the presence of asymmetric flows, which is an advantage over Telex. In addition, the covert channel used in TapDance is higher bandwidth than that of previous proposals and holds potential for future improvements (e.g., in terms of number of communication rounds required and flexible security levels) of client-station protocols.

7 Implementation

We have implemented TapDance in two parts: a client that acts as a local HTTP proxy for a user's browser, and a station that observes a packet tap at an ISP and injects traffic when it detects tagged connections. Our station code is written in approximately 1,300 lines of C, using libevent, OpenSSL, PF_RING [33], and forge_socket[2].

7.1 Client Implementation

Our client is written in approximately 1,000 lines of C using libevent [29] and OpenSSL [36]. The client currently takes the domain name of the decoy server as a command line argument, and for each new local connection from the browser, creates a TLS connection to the decoy server. Once the handshake completes, the client sends the incomplete response to prevent the server from sending additional data, and to encode the secret tag in the ciphertext as specified in Section 4.2. The request is simply an HTTP request with a valid HTTP request line, "Host" header, and an "X-Ignore" header that precedes the "garbage" plaintext that will be computed to result in the chosen tag appearing in the ciphertext. We have implemented our ciphertext encoding for AES_128_GCM [39], although it also works without modification for AES_256_GCM cipher suites. We have implemented Elligator 2 to work with Curve25519, in order to encode the client's public point in the ciphertext as a string that is indistinguishable from uniform random. After this 32-byte encoded point, the client places a 144-byte encrypted payload. This payload is encrypted using a SHA-256 hash of the 32-byte shared secret (derived from the client's secret and station's public point) using AES-128 in CBC mode. We use the first 16-bytes of the shared secret hash as the key, and the last 16 bytes as the initialization vector (IV). The payload contains an 8-byte magic value, the 48-byte TLS master secret, 32-byte client random, 32-byte server random, and a 16-byte randomized connection ID that allows a client to reconnect to a previous proxy connection in case the underlying decoy connection is prematurely closed.

[2] https://github.com/ewust/forge_socket/

7.2 Station Implementation

Our TapDance station consists of a 16-core Supermicro server connected over a gigabit Ethernet to a mirror port on an HP 6600-24G-4XG switch in front of a well-used Tor exit node generating about 160 Mbps of traffic. The station uses PF_RING, a fast packet capture Linux kernel module, to read packets from the mirror interface. In addition to decreasing packet capture overhead, PF_RING supports flow clustering, allowing our implementation to spread TCP flow capture across multiple processes. Using this library, our station can have several processes on separate cores share the aggregate load.

For each unique flow (4-tuple), we keep a small amount of state whether we have seen an Application Data packet for the flow yet. If we have not, we verify the current packet's TCP checksum, and inspect the packet to determine if it is an Application Data packet. If it is, we mark this flow as having been inspected, and pass the packet ciphertext to the tag extractor function. This function extracts the potential tag from the ciphertext, decoding the client's public point using Elligator 2, generating the shared secret using Curve25519, and hashing it to get the AES decryption key for the payload. The extractor

decrypts the 144-byte payload included by the client, and verifies that the first 8 bytes are the expected magic value. If it is, the station knows this is a tagged flow, and uses the master secret and nonces extracted from the encrypted payload to compute the key block, which contains encryption and decryption keys, sequence numbers or IVs, and MAC keys (if not using authenticated encryption) for the TLS session between the client and server.

This "ciphertext-in-ciphertext" is indistinguishable from random to everyone except the client and station. The 144-byte payload is encrypted using a strong symmetric block cipher (AES-128) in CBC mode, whose key is derived from the client-station shared secret. The remainder of the tag is the client's ECDH public point, encoded using Elligator 2 [8] over Curve25519 [7]. The encoded point is indistinguishable from uniform random due to the properties of the Elligator 2 encoding function.

Once the station has determined the connection is a tagged flow, it sets up a socket in the kernel to allow it to spoof packets from and receive packets for the server using the forge_socket kernel module. The station makes this socket non-blocking, and attaches an SSL object initialized with the extracted key block to it. The station then sends a response to the client over this channel, containing a confirmation that the station has picked up, and the number of bytes that the client is allowed to send toward this station before it must create a new connection.

7.3 Connection Limits

Because the server's connection with the client remains open, the server receives packets from the client, including data and acknowledgments for the station's data. The server will initially ignore these messages, however there are two instances where the server will send data. When it does so, the censor would be able to see this anomalous behavior, because the server will send data with stale sequence numbers and different payloads from what the station sent.

The first instance of the server sending data is when the server times out the connection at the application level. For example, web servers can be configured to timeout incomplete requests after a certain time, by using the mod_reqtimeout[3] module in Apache. We found through our development and testing the shortest timeout was 20 seconds, although most servers had much longer timeouts. We measured TLS hosts to determine how long they would take to time out or respond to an incomplete request similar to one used in TapDance. We measured a 1% sample of the IPv4 address space listening on port 443, and the Alexa top million domains using ZMap [15], and found that many servers had timeouts longer than 5 minutes. Figure 5 shows the fraction of server timeouts.

[3]http://httpd.apache.org/docs/2.2/mod/mod_reqtimeout.html

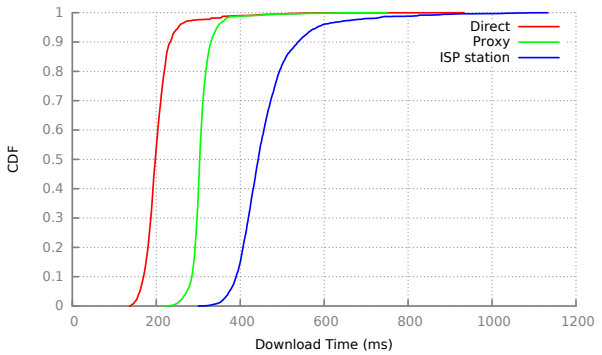

Figure 4: **Download Times Through TapDance** — We used Apache Benchmark to download www.facebook.com 5000 times (with a concurrency of 100) over normal HTTPS, through a single-hop proxy, and through our TapDance proof-of-concept.

The second reason a server will send observable packets back to the client is if the client sends it a sequence number that is outside of the server's current TCP receive window. This happens when the client has sent more than a window's worth of data to the station, at which point the server will respond with a TCP ACK packet containing the server's stale sequence and acknowledgment numbers, alerting an observant censor to the anomaly.

To prevent both of these instances from occurring in our implementation, we limit the connection duration to less than the server's timeout, and we limit the number of bytes that a client can send to the station to up to the server's receive window size. Receive window sizes after the TLS handshake completes are typically above about 16 KB. We note that the station is not limited to the number of bytes it can send to the client per connection, making the 16 KB limit have minimal impact on most download-heavy connections.

In the event that the client wants to maintain its connection for longer than the duration or send more than 16 KB, the client can reuse the 16-byte connection ID in a new E2M TLS connection to the server. The station will decode the connection ID and reconnect the new flow to the old proxy connection seamlessly. This allows the browser to communicate to the HTTP proxy indefinitely, without having to deal with the limitations of the underlying decoy connection.

8 Evaluation

Throughout our evaluation, we used a client running Ubuntu 13.10 connected to a university network over gigabit Ethernet. For our decoy server, we used a Tor exit server at our institution, with a gigabit upstream through an HP 6600-24G-4XG switch. For our ISP station, we used a 16-core Supermicro server with 64 GB of RAM,

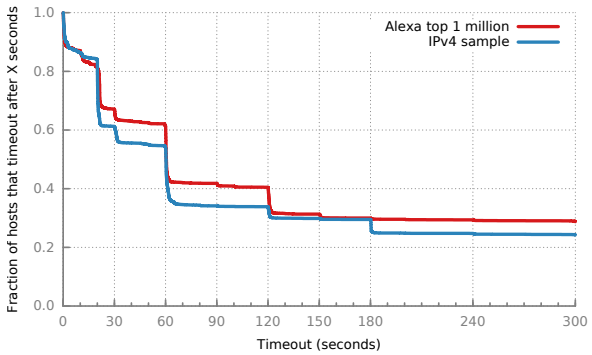

Figure 5: **Timeouts for Decoy Destinations** — To measure how long real TLS hosts will leave a connection open after receiving the incomplete request used in TapDance, we connected to two sets of TLS hosts (the Alexa top 1 million and a 1% sample of the IPv4 address space). We sent TapDance's incomplete request and timed how long the host would leave the connection open before either sending data or closing the connection. We find that over half the hosts will allow connections 60 seconds or longer.

connected via gigabit NICs to an upstream and to a mirror port from the HP switch. Our ISP station is therefore able to observe (but not block) packets to the Tor exit server, which provides a reasonable amount of background traffic on the order of 160 Mbps. In our tests, the Tor exit node generates a modest amount of realistic user traffic. Although not anywhere near the bandwidth of a Tier-1 ISP, Tor exit nodes generate a greater ratio of HTTPS flows than a typical ISP (due to the Tor browser's inclusion of the HTTPS Everywhere plugin), and we can use this microbenchmark to perform a back-of-the-envelope calculation to the loads we would see at a 40 Gbps Transit ISP tap.

We evaluate our proof-of-concept implementation with the goal of demonstrating that our system operates as described, and that our implementation is able to function within the constraints of our mock-ISP. To demonstrate that our system operates as described, we set Firefox to use our client as a proxy, and browsed several websites while capturing packets on the client and the decoy server. We then manually inspected the recorded packets to confirm that there were no additional packets sent by the server that would reveal our connections to be proxied connections. Empirically, we note that we are able to easily browse the Internet through this proxy, for example watching high-definition YouTube videos.

To evaluate the performance of our system, we created 8 proxy processes on our ISP station, using the same PF_RING cluster ID in order to share the load across 8 cores. The background traffic from the Tor exit server does not appear to have a significant impact on the proxy's load: each process handles between 20 and 50 flows at a given time, comprising up to 35 Mbps of TLS traffic. The CPU load during this time was less than 1%.

We used Apache Benchmark[4] in order to issue 5,000 requests through our station proxy, with a concurrency of 100, and compared the performance for fetching a simple page over HTTP and over HTTPS. We also compare fetching the same pages directly from the server and through a single-hop proxy. Figure 4 shows the cumulative distribution function for the total time to download the page. Although there is a modest overhead for end-to-middle proxy connections compared to direct or simple proxies, the overhead is not prohibitive to web browsing habits; users are still able to interact with the page, and pages can be expected to load in a reasonable time period. In particular, our proxy adds a median latency of 270 milliseconds to a page download in our tests when compared with a direct download.

We find that the CPU performance is bottlenecked by our single-threaded client. During our tests, the client consumes 100% CPU on a single core, while each of the 8 processes on the ISP station consume between 4-7% CPU. We also observe that a majority of the download time is spent waiting for the connection handshake to complete with the server. To improve this performance, we could speculatively maintain a connection pool in order to decrease the wait-time between requests. However, care must be taken in order to mimic the same connection pool behaviors that a browser might exhibit.

We also note that although the distribution of download times appear different for ISP station vs. normal connections, this does not necessarily indicate an observable feature for a censor. This is because our download involves a second round trip between client and server before the data reaches the client. The censor would still have to distinguish between this type of connection behavior and innocuous HTTP pipelined connections. It still may be possible for the censor to distinguish, however, as we discussed in Section 5, traffic analysis is an open problem for existing network proxies, and outside the scope of this paper.

Tag creation and processing In order to evaluate the overhead of creating and checking for tags, we timed the creation and evaluation of 10,000 tags. We were able to create over 2,400 tags/second on our client and verify over 12,000 tags/second on a single core of our ISP station. We find that the majority of time (approximately 80%) during tag creation is spent performing the expected three ECC point multiplications (an expected two to generate the client's Elligator-encodable public point and one to generate the shared secret). Similarly, during tag checking, nearly 90% of the computation time is spent on the single ECC point multiplication. Faster ECC implementations

[4] http://httpd.apache.org/docs/2.2/programs/ab.html

(such as tuned-assembly or ASICs) could have a significant impact toward improving the performance of tag verification on the ISP station.

Server support In order to measure how many servers can act as decoy destinations, we probed samples of the IPv4 address space as well as the Alexa top million hosts with tests to indicate support for TapDance. In our first experiment, we tested how long servers would wait to timeout an incomplete request, such as the one used by the client in TapDance. We scanned TLS servers in a 1% sample of the IPv4 address space, as well as the Alexa top million hosts, and sent listening servers a TLS handshake, followed by an incomplete HTTP request containing the full range of characters used in the TapDance client. We timed how long each server waited to either respond or close the connection. Servers that responded immediately do not support the TapDance incomplete request, either because they do not support incomplete requests, or the request contained characters outside the allowed range. Figure 5 shows the results of this experiment. For the 20-second timeout used in our implementation, over 80% of servers supported our incomplete request.

We also measured how servers handled the out-of-sequence TCP packets sent by the TapDance client, including packets acknowledging data not yet sent by the server. Again, we used a 1% sample of the IPv4 address space and the Alexa top million hosts. For each host, we connected to port 80 and sent an incomplete HTTP request, followed by a TCP ACK packet and a data-containing packet, both with acknowledgements set 100 bytes ahead of the true value. We find that the majority of Alexa servers still allow such packets, however, older or embedded systems often respond to our probes, in violation of the TCP specification. We conclude that TapDance clients must carefully select which servers they use as end points, but that there is no shortage of candidates from which to select.

9 Future Work

The long-term goal of end-to-middle proxies is to be implemented and deployed in a way that effectively combats censorship. While we have suggested a design that we believe is more feasible than previous work, more engineering must be done to bring it to maturity.

For example, deploying an end-to-middle proxy such as TapDance at an ISP requires not only scaling up to meet the demands of proxy users, but also of the deploying ISP's non-proxy traffic, which can be on the order of gigabits per second. One potential solution to this problem is to make the ISP component as stateless as possible. Extending TapDance, it may be possible to construct a "single-packet" version of an end-to-middle proxy. In this version the client uses the ciphertext steganographic channel to encode its entire request to the proxy. The proxy needs only detect these packets, fetch the requesting page, and inject a response. Such a design would not need to reconstruct TCP flows or keep state across multiple packets, allowing it to handle higher bandwidths of traffic, at the expense of making active attacks easier to perform by an adversary. Further investigation may discover an optimal balance between these tradeoffs.

Another open research question is where specifically in the network such proxies should be deployed. Previously, "Routing around Decoys" [40] outlined several novel attacks that a censor could perform in order to circumvent many anticensorship deployment strategies. There is ongoing discussion in the literature about the practical costs of these attacks, and practical countermeasures deployments could take to protect against them [11, 23].

As mentioned in Section 5, traffic fingerprinting is a concern for all proxies, and remains an open problem. Previous work has discussed these attacks as they apply to ISP-located proxies [40] and other covert channel proxies [18, 20]. Future work in this direction could provide insight into how to generate or mimic network traffic and protocols.

Finally, there is room to explore more active defense techniques, as outlined in Section 5. As end-to-middle proxies become more prominent, this is likely to become an important problem, as China has already started to employ active attacks in order to detect and censor Tor bridge relays [13, 46, 47]. Collaborating with ISPs will allow us to explore the technical capabilities and policies that would permit active defense against these attacks.

10 Related Work

Other anticensorship schemes Besides end-to-middle proxies, previous anticensorship approaches, including Collage [10] and Message in a Bottle [24], have leveraged using user-generated content on websites to bootstrap communication between censored users and a centrally-operated proxy. However, these designs are not intended to work with low-latency applications such as web browsing. SkypeMorph [30], FreeWave [22], CensorSpoofer [43] and StegoTorus [44] are proxies or proxy-transports that attempt to mimic other protocols, such as Skype, VoIP, or HTTP in order to avoid censorship by traffic fingerprinting. However, recent work appears to suggest that such mimicry may be detectable under certain circumstances by an adversary [18, 20]. Finally, browser-based proxies work by running a small flash proxy inside non-censored users browsers (for example, when they visit a website), and serve as short-lived proxies for cen-

sored users [17]. These rapidly changing proxies can be difficult for a censor to block in practice, though it is essentially a more fast-paced version of the traditional censor cat-and-mouse game.

Related steganographic techniques Other techniques [3, 6, 31] leverage pseudorandom public-key encryption (i.e., encryption that produces ciphertext indistinguishable from random bits) in order to solve the classic prisoners' problem. These techniques allow protocol participants to produce messages that mimic the distribution of an "innocent-looking" communication channel. The problem setting differs from ours, however, and the encoding of hidden messages inside an allowed encrypted channel (as valid ciphertexts) is not considered.

Dyer et al. [16] introduce a related technique called format transforming encryption (FTE), which disguises encrypted application-layer traffic to look like an innocent, allowed protocol from the perspective of deep packet inspection (DPI) technologies. The basic notion is to transform ciphertexts to match an expected format; as DPI technologies typically use membership in a regular language to classify application-layer traffic, FTE works by using a (bijective) encoding function that maps a ciphertext to a member of a pre-specified language. This steganographic technique differs significantly from ours, in that we do not attempt to disguise the use of a particular internet protocol itself (i.e., TLS), but rather ensure that our encoded ciphertext does not alter the expected distribution of the selected protocol traffic (i.e., TLS ciphertexts, in our system design).

11 Conclusion

End-to-middle proxies are a promising concept that may help tilt the balance of power from censors to citizens. Although previous designs including Telex, Cirripede, and Decoy Routing have laid the ground for this new direction, there are several problems when it comes to deploying any of these designs in practice. Previous designs have required inline blocking elements and sometimes assumed symmetric network paths. To address these concerns, we have developed TapDance, a novel end-to-middle proxy that operates without the need for inline flow blocking. We also described a novel way to support asymmetric flows without inline-flow blocking, by encoding arbitrary-length steganographic payloads in ciphertext. This covert channel may be independently useful for future E2M schemes and other censorship resistance applications.

Ultimately, anticensorship proxies are only useful if they are actually deployed. We hope that removing these barriers to end-to-middle proxying is a step towards that goal.

A Bayesian Approach to Privacy Enforcement in Smartphones

Omer Tripp
IBM Research, USA

Julia Rubin
IBM Research, Israel

Abstract

Mobile apps often require access to private data, such as the device ID or location. At the same time, popular platforms like Android and iOS have limited support for user privacy. This frequently leads to unauthorized disclosure of private information by mobile apps, e.g. for advertising and analytics purposes. This paper addresses the problem of privacy enforcement in mobile systems, which we formulate as a classification problem: When arriving at a privacy sink (e.g., database update or outgoing web message), the runtime system must classify the sink's behavior as either legitimate or illegitimate. The traditional approach of information-flow (or taint) tracking applies "binary" classification, whereby information release is legitimate iff there is no data flow from a privacy source to sink arguments. While this is a useful heuristic, it also leads to false alarms.

We propose to address privacy enforcement as a learning problem, relaxing binary judgments into a quantitative/probabilistic mode of reasoning. Specifically, we propose a Bayesian notion of statistical classification, which conditions the judgment whether a release point is legitimate on the evidence arising at that point. In our concrete approach, implemented as the BAYESDROID system that is soon to be featured in a commercial product, the evidence refers to the similarity between the data values about to be released and the private data stored on the device. Compared to TaintDroid, a state-of-the-art taint-based tool for privacy enforcement, BAYESDROID is substantially more accurate. Applied to 54 top-popular Google Play apps, BAYESDROID is able to detect 27 privacy violations with only 1 false alarm.

1 Introduction

Mobile apps frequently demand access to private information. This includes unique device and user identifiers, such as the phone number or IMEI number (identifying the physical device); social and contacts data; the user's location; audio (microphone) and video (camera) data; etc. While private information often serves the core functionality of an app, it may also serve other purposes, such as advertising, analytics or cross-application profiling [9]. From the outside, the user is typically unable to distinguish legitimate usage of their private information from illegitimate scenarios, such as sending of the IMEI number to a remote advertising website to create a persistent profile of the user.

Existing platforms provide limited protection against privacy threats. Both the Android and the iOS platforms mediate access to private information via a permission model. Each permission is mapped to a designated resource, and holds per all application behaviors and resource accesses. In Android, permissions are given or denied at installation time. In iOS, permissions are granted or revoked upon first access to the respective resource. Hence, both platforms cannot disambiguate legitimate from illegitimate usage of a resource once an app is granted the corresponding permission [8].

Threat Model In this paper, we address privacy threats due to authentic (as opposed to malicious) mobile applications [4, 18]. Contrary to malware, such applications execute their declared functionality, though they may still expose the user to unnecessary threats by incorporating extraneous behaviors — neither required by their core business logic nor approved by the user [11] — such as analytics, advertising, cross-application profiling, social computing, etc. We consider unauthorized release of private information that (almost) unambiguously identifies the user as a privacy threat. Henceforth, we dub such threats *illegitimate*.

While in general there is no bullet-proof solution for privacy enforcement that can deal with any type of covert channel, implicit flow or application-specific data transformation, and even conservative enforcement approaches can easily be bypassed [19], there is strong evidence that authentic apps rarely exhibit these challenges.

According to a recent study [9], and also our empirical data (presented in Section 5), private information is normally sent to independent third-party servers. Consequently, data items are released in clear form, or at most following well-known encoding/encryption transformations (like Base64 or MD5), to meet the requirement of a standard and general client/server interface.

The challenge, in this setting, is to determine whether the app has taken sufficient means to protect user privacy. Release of private information, even without user authorization, is still legitimate if only a small amount of information has been released. As an example, if an application obtains the full location of the user, but then releases to an analytics server only coarse information like the country or continent, then in most cases this would be perceived as legitimate.

Privacy Enforcement via Taint Analysis The shortcomings of mobile platforms in ensuring user privacy have led to a surge of research on realtime privacy monitoring. The foundational technique grounding this research is *information-flow tracking*, often in the form of *taint analysis* [23, 15]: Private data, obtained via privacy *sources* (e.g. `TelephonyManager.getSubscriberId()`, which reads the device's IMSI), is labeled with a taint tag denoting its source. The tag is then propagated along data-flow paths within the code. Any such path that ends up in a release point, or privacy *sink* (e.g. `WebView.loadUrl(...)`, which sends out an HTTP request), triggers a leakage alarm.

The tainting approach effectively reduces leakage judgments to boolean reachability queries. This can potentially lead to false reports, as the real-world example shown in Figure 1 illustrates. This code fragment, extracted from a core library in the Android platform, reads the device's IMSI number, and then either (ii) persists the full number to an error log if the number is invalid (the `loge(...)` call), or (ii) writes a prefix of the IMSI (of length 6) to the standard log while carefully masking away the suffix (of length 9) as `'x'` characters. Importantly, data flow into the `log(...)` sink is not a privacy problem, because the first 6 digits merely carry model and origin information. Distinctions of this sort are beyond the discriminative power of taint analysis [26].

Quantitative extensions of the core tainting approach have been proposed to address this limitation. A notable example is McCamant and Ernst's [13] information-flow tracking system, which quantities flow of secret information by dynamically tracking taint labels at the bit level. Other approaches — based e.g. on distinguishability between secrets [1], the rate of data transmission [12] or the influence inputs have on output values [14] — have also been proposed. While these systems are useful as offline analyses, it is highly unlikely that any of them can be engineered to meet the performance requirements of a realtime monitoring solution due to the high complexity of their underlying algorithms. As an example, McCamant and Ernst report on a workload on which their analysis spent over an hour.

```
1 String mImsi = ...; // source
2 // 6 digits <= IMSI (MCC+MNC+MSIN) <= 15 (usually 15)
3 if (mImsi != null &&
4     (mImsi.length() < 6 || mImsi.length() > 15)) {
5   loge(" invalid IMSI " + mImsi); // sink
6   mImsi = null; }
7 log("IMSI: " + mImsi.substring(0, 6) + "xxxxxxxxx"); // sink
```

Figure 1: Fragment from an internal Android library, `com.android.internal.telephony.cdma.RuimRecords`, where a prefix of the mobile device's IMSI number flows into the standard log file

Our Approach We formulate data leakage as a classification problem, which generalizes the source/sink reachability judgment enforced by standard information-flow analysis, permitting richer and more relaxed judgments in the form of statistical classification. The motivating observation is that reasoning about information release is fuzzy in nature. While there are clear examples of legitimate versus illegitimate information release, there are also less obvious cases (e.g., a variant of the example in Figure 1 with a 10- rather than 6-character prefix). A statistical approach, accounting for multiple factors and based on rich data sets, is better able to address these subtleties.

Concretely, we propose Bayesian classification. To label a release point as either legitimate or illegitimate, the Bayesian classifier refers to the "evidence" at that point, and computes the likelihood of each label given the evidence. The evidence consists of feature/value pairs. There are many ways of defining the evidence. In this study, we concentrate on the data arguments flowing into release operations, though we intend to consider other classes of features in the future. (See Section 7.)

Specifically, we induce features over the private values stored on the device, and evaluate these features according to the level of similarity between the private values and those arising at release points. This distinguishes instances where data that is dependent on private values flows into a release point, but its structural and/or quantitative characteristics make it eligible for release, from illegitimate behaviors. Failure to make such distinctions is a common source of false alarms suffered by the tainting approach [4].

To illustrate this notion of features, we return to the example in Figure 1. Because the IMSI number is consid-

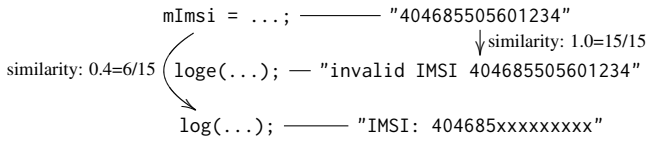

Figure 2: Similarity analysis applied to the code in Figure 1

ered private, we define a respective feature *IMSI*. Assume that the concrete IMSI value is "404685505601234". Then the value arising at the `log(...)` release point is "IMSI: 404685xxxxxxxxx". The quantitative similarity between these two values serves as evidence for the decision whether or not `log(...)` is behaving legitimately. This style of reasoning is depicted in Figure 2.

Evaluation To evaluate our approach, we have implemented the BAYESDROID system for privacy enforcement. We report on two sets of experiments over BAYESDROID.

First, to measure the accuracy gain thanks to Bayesian analysis, we compared BAYESDROID with the TaintDroid system [4], a highly popular and mature implementation of the tainting approach that is considered both efficient (with average overhead of approximately 10%) and accurate. We applied both BAYESDROID and TaintDroid to the DroidBench suite,[1] which comprises the most mature and comprehensive set of privacy benchmarks currently available. The results suggest dramatic improvement in accuracy thanks to Bayesian elimination of false reports, yielding accuracy scores of 0.96 for BAYESDROID versus 0.66 for TaintDroid.

The second experiment examines the practical value of BAYESDROID by applying it to 54 top-popular mobile apps from Google Play. We evaluate two variants of BAYESDROID, one of which is able to detect a total of 27 distinct instances of illegitimate information release across 15 of the applications with only 1 false alarm.

Contributions This paper makes the following principal contributions:

1. Novel approach to leakage detection (Section 2): We present a Bayesian classification alternative to the classic tainting approach. Our approach is more flexible than taint tracking by permitting statistical weighting of different features as the basis for privacy judgments.
2. Similarity-based reasoning (Section 3): We instantiate the Bayesian approach by applying quantitative similarity judgments over private values and values about to be released. This enables consideration of actual data, rather than only data flow, as evidence for privacy judgments.
3. Implementation and evaluation (Sections 4–5): We have instantiated our approach as the BAYESDROID system, which is about to be featured in an IBM cloud-based security service. We report on two sets of experiments, whose results (i) demonstrate substantial accuracy gain thanks to Bayesian reasoning, and (ii) substantiate the overall effectiveness of BAYESDROID when applied to real-world apps. All the leakage reports by BAYESDROID are publicly available for scrutiny.[2]

2 The Bayesian Setting

Our starting point is to treat privacy enforcement as a classification problem, being the decision whether or not a given release point is legitimate. The events, or instances, to be classified are (runtime) release points. The labels are *legitimate* and *illegitimate*. Misclassification either yields a false alarm (mistaking benign information release as a privacy threat) or a missed data leak (failing to intercept illegitimate information release).

2.1 Bayes and Naive Bayes

Our general approach is to base the classification on the *evidence* arising at the release point. Items of evidence may refer to qualitative facts, such as source/sink dataflow reachability, as well as quantitative measures, such as the degree of similarity between private values and values about to be released. These latter criteria are essential in going beyond the question of *whether* private information is released to also reason about the *amount* and *form* of private information about to be released.

A popular classification method, representing this mode of reasoning, is based on Bayes' theorem (or rule). Given events X and Y, Bayes' theorem states the following equality:

$$\Pr(Y|X) = \frac{\Pr(X|Y)\cdot\Pr(Y)}{\Pr(X)} \qquad (1)$$

where $\Pr(Y|X)$ is the conditional probability of Y given X (i.e., the probability for Y to occur given that X has occurred). X is referred to as the *evidence*. Given evidence X, Bayesian classifiers compute the conditional likelihood of each label (in our case, *legitimate* and *illegitimate*).

We begin with the formal background by stating Equation 1 more rigorously. Assume that Y is a discrete-valued random variable, and let $X = [X_1, \ldots, X_n]$ be a

[1] http://sseblog.ec-spride.de/tools/droidbench/

[2] researcher.ibm.com/researcher/files/us-otripp/Artifacts.zip

vector of n discrete or real-valued attributes X_i. Then

$$\Pr(Y = y_k | X_1 \ldots X_n) = \frac{\Pr(Y = y_k) \cdot \Pr(X_1 \ldots X_n | Y = y_k)}{\Sigma_j \Pr(Y = y_j) \cdot \Pr(X_1 \ldots X_n | Y = y_j)} \quad (2)$$

As Equation 2 hints, training a Bayesian classifier is, in general, impractical. Even in the simple case where the evidence X is a vector of n boolean attributes and Y is boolean, we are still required to estimate a set

$$\theta_{ij} = \Pr(X = x_i | Y = y_j)$$

of parameters, where i assumes 2^n values and j assumes 2 values for a total of $2 \cdot (2^n - 1)$ independent parameters.

Naive Bayes deals with the intractable sample complexity by introducing the assumption of conditional independence, as stated in Definition 2.1 below, which reduces the number of independent parameters sharply to $2n$. Intuitively, conditional independence prescribes that events X and Y are independent given knowledge that event Z has occurred.

Definition 2.1 (Conditional Independence)**.** *Given random variables X, Y and Z, we say that X is* conditionally independent *of Y given Z iff the probability distribution governing X is independent of the value of Y given Z. That is,*

$$\forall i, j, k.\ \Pr(X = x_i | Y = y_j, Z = z_k) = \Pr(X = x_i | Z = z_k)$$

Under the assumption of conditional independence, we obtain the following equality:

$$\Pr(X_1 \ldots X_n | Y) = \Pi_{i=1}^{n} \Pr(X_i | Y) \quad (3)$$

Therefore,

$$\Pr(Y = y_k | X_1 \ldots X_n) = \frac{\Pr(Y = y_k) \cdot \Pi_i \Pr(X_i | Y = y_k)}{\Sigma_j \Pr(Y = y_j) \cdot \Pi_i \Pr(X_i | Y = y_j)} \quad (4)$$

2.2 Bayesian Reasoning about Leakage

For leakage detection, conditional independence translates into the requirement that at a release point *st*, the "weight" of evidence e_1 is not affected by the "weight" of evidence e_2 knowing that *st* is legitimate/illegitimate. As an example, assuming the evidence is computed as the similarity between private and released values, if *st* is known to be a statement sending private data to the network, then the similarity between the IMSI number and respective values about to be released is assumed to be independent of the similarity between location coordinates and respective values about to be released.

The assumption of conditional independence induces a "modular" mode of reasoning, whereby the privacy features comprising the evidence are evaluated independently. This simplifies the problem of classifying a release point according to the Bayesian method into two quantities that we need to clarify and estimate: (i) the likelihood of legitimate/illegitimate release ($\Pr(Y = y_k)$) and (ii) the conditional probabilities $\Pr(X_i | Y = y_k)$.

3 Privacy Features

In this section we develop, based on the mathematical background in Section 2, an algorithm to compute the conditional likelihood of legitimate versus illegitimate data release given privacy features F_i. With such an algorithm in place, given values v_i for the features F_i, we obtain

$$v_{leg} = \Pr(legitimate | [F_1 = v_1, \ldots, F_n = v_n])$$
$$v_{illeg} = \Pr(illegitimate | [F_1 = v_1, \ldots, F_n = v_n])$$

Bayesian classification then reduces to comparing between v_{leg} and v_{illeg}, where the label corresponding to the greater of these values is the classification result.

3.1 Feature Extraction

The first challenge that arises is how to define the features (denoted with italicized font: F) corresponding to the private values (denoted with regular font: F). This requires simultaneous consideration of both the actual private value and the "relevant" values arising at the sink statement (or release point). We apply the following computation:

1. Reference value: We refer to the actual private value as the *reference value*, denoting the value of private item F as $[\![\mathrm{F}]\!]$. For the example in Figures 1–2, the reference value, $[\![\mathrm{IMSI}]\!]$, of the *IMSI* feature would be the device's IMSI number: $[\![\mathrm{IMSI}]\!]$ = "404685505601234".
2. Relevant value: We refer to value v about to be released by the sink statement as *relevant* with respect to feature F if there is data-flow connectivity between a source statement reading the value $[\![\mathrm{F}]\!]$ of F and v. Relevant values can thus be computed via information-flow tracking by propagating a unique tag (or label) per each private value, as tools like TaintDroid already do. Note that for a given feature F, multiple different relevant values may arise at a given sink statement (if the private item F flows into more than one sink argument).
3. Feature value: Finally, given the reference value $[\![\mathrm{F}]\!]$ and a set $\{v_1, \ldots, v_k\}$ of relevant values for feature F, the value we assign to F (roughly) reflects the highest degree of pairwise similarity (i.e., minimal

distance) between $[\![\mathrm{F}]\!]$ and the values v_i. Formally, we assume a distance metric d. Given d, we define:

$$[\![F]\!] \equiv \min_{1 \le i \le k} \{d([\![\mathrm{F}]\!], v_i)\}$$

We leave the distance metric $d(\ldots)$ unspecified for now, and return to its instantiation in Section 3.2.

According to our description above, feature values are unbounded in principle, as they represent the distance between the reference value and any data-dependent sink values. In practice, however, assuming (i) the distance metric $d(\ldots)$ satisfies $d(x,y) \le \max\{|x|,|y|\}$, (ii) $\exists c \in \mathbb{N}.\ |[\![\mathrm{F}]\!]| \le c$ (as with the IMEI, IMSI, location, etc.), and (iii) $[\![\mathrm{F}]\!]$ is not compared with values larger than it, we can bound $[\![F]\!]$ by c. In general, any feature can be made finite, with (at most) $n+1$ possible values, by introducing a privileged "$\ge n$" value, which denotes that the distance between the reference and relevant values is at least n.

3.2 Measuring Distance between Values

To compute a quantitative measure of similarity between data values, we exploit the fact that private data often manifests as strings of ASCII characters [4, 9, 27]. These include e.g. device identifiers (like the IMEI and IMSI numbers), GPS coordinates, inter-application communication (IPC) parameters, etc. This lets us quantify distance between values in terms of string metrics.

Many string metrics have been proposed to date [17]. Two simple and popular metrics, which we have experimented with and satisfy the requirement that $d(x,y) \le \max\{|x|,|y|\}$, are the following:

Hamming Distance This metric assumes that the strings are of equal length. The Hamming distance between two strings is equal to the number of positions at which the corresponding symbols are different (as indicated by the indicator function $\delta_{c_1 \ne c_2}(\ldots)$):

$$\mathsf{ham}(a,b) = \Sigma_{0 \le i < |a|} \delta_{c_1 \ne c_2}(a(i), b(i))$$

In another view, Hamming distance measures the number of substitutions required to change one string into the other.

Levenshtein Distance The Levenshtein string metric computes the distance between strings a and b as $\mathsf{lev}_{a,b}(|a|,|b|)$ (abbreviated as $\mathsf{lev}(|a|,|b|)$), where

$$\mathsf{lev}(i,j) = \begin{cases} \max(i,j) & \textit{if } \min(i,j) = 0 \\ \min \begin{pmatrix} \mathsf{lev}(i-1,j)+1 \\ \mathsf{lev}(i,j-1)+1 \\ \mathsf{lev}(i-1,j-1)+\delta_{a_i \ne b_j} \end{pmatrix} & \textit{otherwise} \end{cases}$$

Informally, $\mathsf{lev}(|a|,|b|)$ is the minimum number of single-character edits — either insertion or deletion or substitution — needed to transform one string into the other. An efficient algorithm for computing the Levenshtein distance is bottom-up dynamic programming [24]. The asymptotic complexity is $O(|a| \cdot |b|)$.

Data: Strings u and v
Data: Distance metric d

```
begin
    x ⟵ |u| < |v| ? u : v // min
    y ⟵ |u| ≥ |v| ? u : v // max
    r ⟵ y
    for i = 0 to |y| − |x| do
        y′ ⟵ y[i, i + |x| − 1]
        if d(x, y′) < r then
            r ⟵ d(x, y′)
        end
    end
    return r
end
```

Algorithm 1: The BAYESDROID distance measurement algorithm

Given string metric $d(x,y)$ and pair (u,v) of reference value u and relevant value v, BAYESDROID computes their distance according to the following steps:

1. BAYESDROID ensures that both u and v are `String` objects by either (i) invoking `toString()` on reference types or (ii) converting primitive types into `Strings` (via `String.valueOf(...)`), if the argument is not already of type `String`.
2. To meet the conservative requirement that $|x| = |y|$ (i.e., x and y are of equal length), BAYESDROID applies Algorithm 1. This algorithm induces a sliding window over the longer of the two strings, whose width is equal to the length of the shorter string. The shorter string is then compared to contiguous segments of the longer string that have the same length. The output is the minimum across all comparisons.

To ensure that comparisons are still meaningful under length adjustment, we decompose private values into indivisible *information units*. These are components of the private value that cannot be broken further, and so comparing them with a shorter value mandates that the shorter value be padded. In our specification, the phone, IMEI and IMSI numbers consist of only one unit of information. The `Location` object is an example of a data structure that consists of several distinct information units. These include the integral and fractional parts of the longitude and latitude values, etc. BAYESDROID handles objects that decompose into multiple information units by treating each unit as a separate object and applying the steps above to each unit in turn. The notion of information units guards BAYESDROID against ill-founded judgments, such as treating release of a single IMEI digit as strong evidence for leakage.

3.3 Estimating Probabilities

The remaining challenge, having clarified what the features are and how their values are computed, is to estimate the probabilities appearing in Equation 4:

- We need to estimate the probability of the *legitimate* event, $\Pr(legitimate)$, where *illegitimate* is the complementary event and thus $\Pr(illegitimate) = 1 - \Pr(legitimate)$.
- We need to estimate the conditional probabilities $\Pr(F = u|legitimate)$ and $\Pr(F = u|illegitimate)$ for all features F and respective values u.

$\Pr(legitimate)$ can be approximated straightforwardly based on available statistics on the frequency of data leaks in the wild. For the conditional probabilities, assuming feature X_i is discrete valued with j distinct values (per the discussion in Section 3.1 above), we would naively compute the estimated conditional probability θ_{ijk} according to the following equation:

$$\theta_{ijk} = \widehat{\Pr}(X_i = x_{ij}|Y = y_k) \quad = \quad \frac{\#D\{X_i=x_{ij} \wedge Y=y_k\}}{\#D\{Y=y_k\}} \qquad (5)$$

The danger, however, is that this equation would produce estimates of zero if the data happens not to contain any training examples satisfying the condition in the numerator. To fix this, we modify Equation 5 as follows:

$$\theta_{ijk} = \widehat{\Pr}(X_i = x_{ij}|Y = y_k) \quad = \quad \frac{\#D\{X_i=x_{ij} \wedge Y=y_k\}+l}{\#D\{Y=y_k\}+l \cdot J} \qquad (6)$$

where l is a factor that "smoothens" the estimate by adding in a number of "hallucinated" examples that are assumed to be spread evenly across the J possible values of X_i. In Section 5.1, we provide concrete detail on the data sets and parameter values we used for our estimates.

4 The BAYESDROID Algorithm

In this section, we describe the complete BAYESDROID algorithm. We then discuss enhancements of the core algorithm.

4.1 Pseudocode Description

Algorithm 2 summarizes the main steps of BAYESDROID. For simplicity, the description in Algorithm 2 assumes that source statements serve private data as their return value, though the BAYESDROID implementation also supports other sources (e.g. callbacks like `onLocationChanged(...)`, where the private `Location` object is passed as a parameter). We also assume that each source maps to a unique privacy feature. Hence, when a source is invoked (i.e., the `OnSourceStatement` event fires), we obtain the unique tag corresponding to its respective feature via the `GetFeature(...)` function. We

```
Input: S // privacy specification

begin
    while true do
        OnSourceStatement r := src p̄ :
            // map source to feature
            f ⟵ GetFeature src
            attach tag f to r
        OnNormalStatement r := nrm p̄ :
            propagate feature tags according to data flow
        OnSinkStatement r := snk p̄ :
            // map feat.s to param.s with resp. tag
            {f ↦ p̄_f} ⟵ ExtractTags p̄
            foreach f → p̄_f ∈ {f → p̄_f} do
                u ⟵ ref f
                δ ⟵ min{d(u, [[p]])}_{p∈p̄_f}
                f ⟵ δ ≥ c_f ? "≥_{c_f}" : δ
            end
            if IsLeakageClassification {f} then
                Alarm snk p̄
            end
    end
end
```

Algorithm 2: Outline of the core BAYESDROID algorithm

then attach the tag to the return value r. Normal data flow obeys the standard rules of tag propagation, which are provided e.g. by Enck et al. [4]. (See Table 1 there.)

When an `OnSinkStatement` event is triggered, the arguments flowing into the sink `snk` are searched for privacy tags, and a mapping from features f to parameters p_f carrying the respective tag is built. The value of f is then computed as the minimal pairwise distance between the parameters $p \in p_f$ and `ref` f. If this value is greater than some constant c_f defined for f, then the privileged value "$\geq c_f$" is assigned to f. (See Section 3.1.) Finally, the judgment `IsLeakageClassification` is applied over the features whose tags have reached the sink `snk`. This judgment is executed according to Equation 4.

We illustrate the BAYESDROID algorithm with reference to Figure 3, which demonstrates a real leakage instance in `com.g6677.android.princesshs`, a popular gaming application. In this example, two different private items flow into the sink statement: both the IMEI, read via `getDeviceId()`, and the Android ID, read via `getString(...)`.

At sink statement `URL.openConnection(...)`, the respective tags *IMEI* and *AndroidID* are extracted. Values are assigned to these features according to the description in Section 3, where we utilize training data, as discussed later in Section 5.1, for Equation 6:

$$\Pr(IMEI \geq 5|leg) = 0.071 \quad \Pr(AndID \geq 5|leg) = 0.047$$
$$\Pr(IMEI \geq 5|ilg) = 0.809 \quad \Pr(AndID \geq 5|ilg) = 0.833$$

```
source : private value
    TelephonyManager.getDeviceId() : 000000000000000
    Settings$Secure.getString (...)  : cdf15124ea4c7ad5

sink : arguments
 URL.openConnection(...) : app_id=2aec0559c930 ... &
 android_id =cdf15124ea4c7ad5 \& udid= ... &
  serial_id = ... & ... &
  publisher_user_id =000000000000000
```

Figure 3: True leakage detected by BAYESDROID in `com.g6677.android.princesshs`

We then compute Equation 4, where the denominator is the same for both *leg* and *illeg*, and so it suffices to evaluate the nominator (denoted with $\tilde{\Pr}(...)$ rather than $\Pr(...)$):

$$\tilde{\Pr}(leg|IMEI \geq 5, AndID \geq 5) =$$
$$\Pr(leg) \times \Pr(IMEI \geq 5|leg) \times \Pr(AndID \geq 5|leg) =$$
$$0.66 \times 0.071 \times 0.047 = 0.002$$
$$\tilde{\Pr}(ilg|IMEI \geq 5, AndID \geq 5) =$$
$$\Pr(ilg) \times \Pr(IMEI \geq 5|ilg) \times \Pr(AndID \geq 5|ilg) =$$
$$0.33 \times 0.809 \times 0.833 = 0.222$$

Our estimates of 0.66 for $\Pr(leg)$ and 0.33 for $\Pr(ilg)$ are again based on training data as explained in Section 5.1. The obtained conditional measure of 0.222 for *ilg* is (far) greater than 0.002 for *leg*, and so BAYESDROID resolves the release instance in Figure 3 as a privacy threat, which is indeed the correct judgment.

4.2 Enhancements

We conclude our description of BAYESDROID by highlighting two extensions of the core algorithm.

Beyond Plain Text While many instances of illegitimate information release involve plain text, and can be handled by the machinery in Section 3.1, there are also more challenging scenarios. Two notable challenges are (i) data transformations, whereby data is released following an encoding, encryption or hashing transformation; and (ii) high-volume binary data, such as camera or microphone output. We have extended BAYESDROID to address both of these cases.

We begin with data transformations. As noted earlier, in Section 1, private information is sometimes released following standard hashing/encoding transformations, such as the Base64 scheme. This situation, illustrated in Figure 4, can distort feature values, thereby

```
TelephonyManager tm =
    getSystemService(TELEPHONY_SERVICE);
String imei = tm.getDeviceId(); // source
String encodedIMEI = Base64Encoder.encode(imei);
Log.i(encodedIMEI); // sink
```

Figure 4: Adaptation of the DroidBench `Loop1` benchmark, which releases the device ID following Base64 encoding

leading BAYESDROID to erroneous judgments. Fortunately, the transformations that commonly manifest in leakage scenarios are all standard, and there is a small number of such transformations [9].

To account for these transformations, BAYESDROID applies each of them to the value obtained at a source statement, thereby exploding the private value into multiple representations. This is done lazily, once a sink is reached, for performance. This enhancement is specified in pseudocode form in Algorithm 3. The main change is the introduction of a loop that traverses the transformations $\tau \in T$, where the identity transformation, $\lambda x.\ x$, is included to preserve the (non-transformed) value read at the source. The value assigned to feature f is then the minimum with respect to all transformed values.

Binary data — originating from the microphone, camera or bluetooth adapter — also requires special handling because of the binary versus ASCII representation and, more significantly, its high volume. Our solution is guided by the assumption that such data is largely treated as "uninterpreted" and immutable by application code due to its form and format. This leads to a simple yet effective strategy for similarity measurement, whereby a fixed-length prefix is truncated out of the binary content. Truncation is also applied to sink arguments consisting of binary data.

Heuristic Detection of Relevant Values So far, our description of the BAYESDROID algorithm has relied on tag propagation to identify relevant values at the sink statement. While this is a robust mechanism to drive feature computation, flowing tags throughout the code also has its costs, incurring runtime overheads of $\geq 10\%$ and affecting the stability of the application due to intrusive instrumentation [4].

These weaknesses of the tainting approach have led us to investigate an alternative method of detecting relevant values. A straightforward relaxation of data-flow tracking is bounded ("brute-force") traversal of the reachable values from the arguments to a sink statement up to some depth bound k: All values pointed-to by a sink argument or reachable from a sink argument via a sequence of $\leq k$ field dereferences are deemed relevant. Though in theory

Input: $T \equiv \{\lambda x.\, x, \tau_1, \ldots, \tau_n\}$ `// std. transformations`

begin
  ...
  `OnSinkStatement r := snk` $\overline{p}$:
    $\{f \mapsto \overline{p_f}\} \longleftarrow$ `ExtractTags` $\overline{p}$
    foreach $f \to \overline{p_f} \in \{f \to \overline{p_f}\}$ **do**
      foreach $\tau \in T$ **do**
        $u \longleftarrow \tau$ (`ref` f)
        $\delta \longleftarrow \min\{d(u, [\![p]\!])\}_{p \in \overline{p_f}}$
        $f \longleftarrow \min\{[\![f]\!], \delta \geq c_f \; ? \text{“} \geq_{c_f} \text{”} : \delta\}$
      end
    end
  ...
end

Algorithm 3: BAYESDROID support for standard data transformations

this might introduce both false positives (due to irrelevant values that are incidentally similar to the reference value) and false negatives (if k is too small, blocking relevant values from view), in practice both are unlikely, as we confirmed experimentally. (See Section 5.)

For false positives, private values are often unique, and so incidental similarity to irrelevant values is improbable. For false negatives, the arguments flowing into privacy sinks are typically either `String` objects or simple data structures. Also, because the number of privacy sinks is relatively small, and the number of complex data structures accepted by such sinks is even smaller, it is possible to specify relevant values manually for such data structures. We have encountered only a handful of data structures (e.g. the `android.content.Intent` class) that motivate a specification.

5 Experimental Evaluation

In this section, we describe the BAYESDROID implementation, and present two sets of experiments that we have conducted to evaluate our approach.

5.1 The BAYESDROID System

Implementation Similarly to existing tools like TaintDroid, BAYESDROID is implemented as an instrumented version of the Android SDK. Specifically, we have instrumented version 4.1.1_r6 of the SDK, which was chosen intentionally to match the most recent version of TaintDroid.[3] The experimental data we present indeed utilizes TaintDroid for tag propagation (as required for accurate resolution for relevant values).

[3] http://appanalysis.org/download.html

Beyond the TaintDroid instrumentation scheme, the BAYESDROID scheme specifies additional behaviors for sources and sinks within the SDK. At source points, a hook is added to record the private value read by the source statement (which acts as a reference value). At sink points, a hook is installed to apply Bayesian reasoning regarding the legitimacy of the sink.

Analogously to TaintDroid, BAYESDROID performs privacy monitoring over APIs for file-system access and manipulation, inter-application and socket communication, reading the phone's state and location, and sending of text messages. BAYESDROID also monitors the HTTP interface, camera, microphone, bluetooth and contacts. As explained in Section 4.1, each of the privacy sources monitored by BAYESDROID is mirrored by a tag/feature. The full list of features is as follows: *IMEI*, *IMSI*, *AndroidID*, *Location*, *Microphone*, *Bluetooth*, *Camera*, *Contacts* and *FileSystem*.

The BAYESDROID implementation is configurable, enabling the user to switch between distance metrics as well as enable/disable information-flow tracking for precise/heuristic determination of relevant values. (See Section 4.2.) In our experiments, we tried both the Levenshtein and the Hamming metrics, but found no observable differences, and so we report the results only once. Our reasoning for why the metrics are indistinguishable is because we apply both to equal-length strings (see Section 3.2), and have made sure to apply the same metric both offline and online, and so both metrics achieve a very similar effect in the Bayesian setting.

Training To instantiate BAYESDROID with the required estimates, as explained in Section 3.3, we applied the following methodology: First, to estimate $\Pr(\mathit{legitimate})$, we relied on (i) an extensive study by Hornyack et al. spanning 1,100 top-popular free Android apps [9], as well as (ii) a similarly comprehensive study by Enck et al. [5], which also spans a set of 1,100 free apps. According to the data presented in these studies, approximately one out of three release points is illegitimate, and thus $\widehat{\Pr}(\mathit{legitimate}) = 0.66$ and complementarily $\widehat{\Pr}(\mathit{illegitimate}) = 1 - 0.66 \approx 0.33$.

For the conditional probabilities $\widehat{\Pr}(X_i = x_{ij} | Y = y_k)$, we queried Google Play for the 100 most popular apps (across all domains) in the geography of one of the authors. We then selected at random 35 of these apps, and analyzed their information-release behavior using debug breakpoints (which we inserted via the `adb` tool that is distributed as part of the Android SDK).

Illegitimate leaks that we detected offline mainly involved (i) location information and (ii) device and user identifiers, which is consistent with the findings reported by past studies [9, 5]. We confirmed that illegitimate leaks are largely correlated with high similarity between

private data and sink arguments, and so we fixed six distance levels for each private item: $[0,4]$ and "≥ 5". (See Section 3.1.) Finally, to avoid zero estimates for conditional probabilities while also minimizing data perturbation, we set the "smoothing" factor l in Equation 6 at 1, where the illegitimate flows we detected were in the order of several dozens per private item.

5.2 Experimental Hypotheses

In our experimental evaluation of BAYESDROID, we tested two hypotheses:

1. H1: Accuracy. Bayesian reasoning, as implemented in BAYESDROID, yields a significant improvement in leakage-detection accuracy compared to the baseline of information-flow tracking.
2. H2: Applicability. For real-life applications, BAYESDROID remains effective under relaxation of the tag-based method for detection of relevant values and its stability improves.

5.3 H1: Accuracy

To assess the accuracy of BAYESDROID, we compared it to that of TaintDroid, a state-of-the-art information-flow tracking tool for privacy enforcement. Our experimental settings and results are described below.

Subjects We applied both TaintDroid and BAYESDROID to DroidBench, an independent and publicly available collection of benchmarks serving as testing ground for both static and dynamic privacy enforcement algorithms. DroidBench models a large set of realistic challenges in leakage detection, including precise tracking of sensitive data through containers, handling of callbacks, field and object sensitivity, lifecycle modeling, inter-app communication, reflection and implicit flows.

The DroidBench suite consists of 50 cases. We excluded from our experiment (i) 8 benchmarks that crash at startup, as well as (ii) 5 benchmarks that leak data via callbacks that we did not manage to trigger (e.g., `onLowMemory()`), as both TaintDroid and BAYESDROID were naturally unable to detect leakages in these two cases. The complete list of benchmarks that we used can be found in Table 4 of Appendix B.

Methodology For each benchmark, we measured the number of true positive (TP), false positive (FP) and false negative (FN) results. We then summarized the results and calculated the overall *precision* and *recall* of each tool using the formulas below:

$$Precision = \frac{TP}{TP+FP} \qquad Recall = \frac{TP}{TP+FN}$$

	TPs	FPs	FNs	Precision	Recall	F-measure
TaintDroid	31	17	0	0.64	1.00	0.78
BAYESDROID	29	1	2	0.96	0.93	0.94

Table 1: Accuracy of BAYESDROID and TaintDroid on DroidBench

High precision implies that a technique returns few irrelevant results, whereas high recall implies that it misses only few relevant ones.

Since ideal techniques have both high recall and high precision, the F-measure is commonly used to combine both precision and recall into a single measure. The F-measure is defined as the harmonic mean of precision and recall, and is calculated as follows:

$$F\text{-}Measure = 2 \times \frac{Precision \times Recall}{Precision + Recall}$$

The value of F-measure is high only when both precision and recall are high. We thus use the F-measure for accuracy evaluation.

Results The results obtained for both TaintDroid and BAYESDROID on version 1.1 of DroidBench are summarized in Table 1 and presented in detail in Table 4. The findings reported by BAYESDROID are also publicly available.[4]

Overall, TaintDroid detects 31 true leakages while also reporting 17 false positives, whereas BAYESDROID suffers from 2 false negatives, discovering 29 of the true leakages while flagging only 1 false alarm. The recall of both TaintDroid and BAYESDROID is high (1 and 0.93, respectively) due to a low number of false-negative results. Yet the precision of TaintDroid is much lower than that of BAYESDROID (0.64 vs. 0.96), due to a high number of false positives. The overall F-measure is thus lower for TaintDroid than for BAYESDROID (0.78 vs. 0.94).

The results mark BAYESDROID as visibly more accurate than TaintDroid. To further confirm this result, we performed a two-tail McNemar test, considering 48 observations for each tool. These observations correspond to findings reported in Table 4: 31 true positives and 17 classified as false alarms. Each observation is a boolean value that represents the accuracy of the tool and is assumed to be from a Bernoulli distribution. We then checked whether the difference in accuracy is statistically significant by testing the null hypothesis that the set of 48 observations from TaintDroid are sampled from the same Bernoulli distribution as the set of 48 observations from BAYESDROID.

[4] See archive file researcher.ibm.com/researcher/files/us-otripp/droidbench.zip.

```
1 TelephonyManager tm =
2     getSystemService(TELEPHONY_SERVICE);
3 String imei = tm.getDeviceId(); //source
4 String obfuscatedIMEI = obfuscateIMEI(imei); ...;
5 Log.i(imei); // sink
6
7 private String obfuscateIMEI(String imei) {
8   String result = "";
9   for (char c : imei.toCharArray()) {
10    switch(c) {
11      case '0': result += 'a'; break;
12      case '1': result += 'b'; break;
13      case '2': result += 'c'; break; ...; } }
```

Figure 5: Fragment from the DroidBench `ImplicitFlow1` benchmark, which applies a custom transformation to private data

We found that TaintDroid was accurate in 31 out of 48 cases, and BAYESDROID was accurate in 45 out of 48 cases. We built the 2×2 contingency table showing when each tool was correct and applied a two-tail McNemar test. We found a p-value of 0.001, which rejects the null hypothesis that the observations come from the same underlying distribution and provides evidence that BAYESDROID is more accurate than TaintDroid, thereby confirming H1.

Discussion Analysis of the per-benchmark findings reveals the following: First, the 2 false negatives of BAYESDROID on `ImplicitFlow1` are both due to custom (i.e., non-standard) data transformations, which are outside the current scope of BAYESDROID. An illustrative fragment from the `ImplicitFlow1` code is shown in Figure 5. The `obfuscateIMEI(...)` transformation maps IMEI digits to English letters, which is a non-standard behavior that is unlikely to arise in an authentic app.

The false positive reported by BAYESDROID, in common with TaintDroid, is on release of sensitive data to the file system, albeit using the `MODE_PRIVATE` flag, which does not constitute a leakage problem in itself. This can be resolved by performing Bayesian reasoning not only over argument values, but also over properties of the sink API (in this case, the storage location mapped to a file handle). We intend to implement this enhancement.

Beyond the false alarm in common with BAYESDROID, TaintDroid has multiple other sources of imprecision. The main reasons for its false positives are

- coarse modeling of containers, mapping their entire contents to a single taint bit, which accounts e.g. for the false alarms on `ArrayAccess{1,2}` and `HashMapAccess1`;
- field and object insensitivity, resulting in false alarms on `FieldSensitivity{2,4}` and `ObjectSensitivity{1,2}`; and more fundamentally,
- ignoring of data values, which causes TaintDroid to issue false warnings on `LocationLeak{1,2}` even when location reads fail, yielding a `Location` object without any meaningful information.

The fundamental reason for these imprecisions is to constrain the overhead of TaintDroid, such that it can meet the performance demands of online privacy enforcement. BAYESDROID is able to accommodate such optimizations while still ensuring high accuracy.

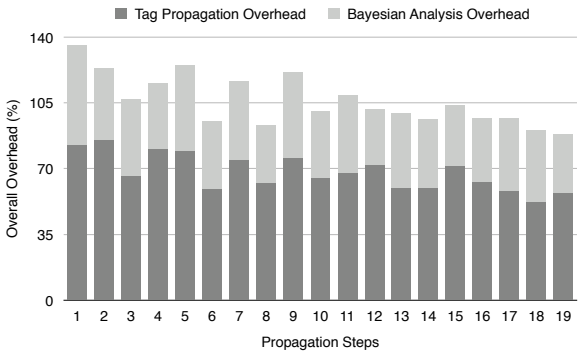

Figure 6: Overhead breakdown into tag propagation and Bayesian analysis at sink

5.4 H2: Applicability

The second aspect of the evaluation compared between two versions of BAYESDROID, whose sole difference lies in the method used for detecting relevant values: In one configuration (T-BD), relevant values are detected via tag propagation. The other configuration (H-BD) uses the heuristic detailed in Section 4.2 of treating all values reachable from sink arguments (either directly or via the heap graph) up to a depth bound of k as relevant, which places more responsibility on Bayesian reasoning. We set k at 3 based on manual review of the data structures flowing into privacy sinks.

We designed a parametric benchmark application to quantify the overhead reduction imposed by the H-BD variant of BAYESDROID. The application consists of a simple loop that flows the device IMEI into a log file. Loop iterations perform intermediate data propagation steps. We then performed a series of experiments — over the range of 1 to 19 propagation steps — to quantify the relative overhead of tag propagation versus Bayesian analysis.

The results, presented in Figure 6, suggest that the overhead of tag propagation is more dominant than that of Bayesian analysis (with a ratio of roughly 2:1), even when the set of relevant values is naively over approximated. Discussion of the methodology underlying this

experiment is provided in Appendix A.

In general, H-BD trades overhead reduction for accuracy. H2 then asserts that, *in practice*, the tradeoff posed by H-BD is effective. Below, we discuss our empirical evaluation of this hypothesis over real-life subjects.

Subjects To avoid evaluators' bias, we applied the following selection process: We started from the 65 Google Play apps not chosen for the training phase. We then excluded 8 apps that do not have permission to access sensitive data and/or perform release operations (i.e., their manifest does not declare sufficient permissions out of `INTERNET`, `READ_PHONE_STATE`, `SEND_SMS`, etc), as well as 3 apps that we did not manage to install properly, resulting in 54 apps that installed successfully and exercise privacy sources and sinks.

The complete list of the application we used is given in Table 5 of Appendix B. A subset of the applications, for which at least one leakage was detected, is also listed in Table 3.

Methodology We deployed the apps under the two BAYESDROID configurations. Each execution was done from a clean starting state. The third column of both Tables 3 and 5 denotes whether our exploration of the app was exhaustive. By that we mean exercising all the UI points exposed by the app in a sensible order. Ideally we would do so for all apps. However, (i) some of the apps, and in particular gaming apps, had stability issues, and (ii) certain apps require SMS-validated sign in, which we did not perform. We did, however, create Facebook, Gmail and Dropbox accounts to log into apps that demand such information yet do not ask for SMS validation. We were also careful to execute the exact same crawling scenario under both the T-BD and H-BD configurations. We comment, from our experience, that most data leaks happen when an app launches, and initializes advertising/analytics functionality, and so for apps for which deep crawling was not possible the results are still largely meaningful.

For comparability between the H-BD and T-BD configurations, we counted different dynamic reports involving the same pair of source/sink APIs as a single leakage instance. We manually classified the findings into true positives and false positives. For this classification, we scrutinized the reports by the two configurations, and also — in cases of uncertainty — decompiled and/or reran the app to examine its behavior more closely. As in the experiment described in Section 5.3, we then calculated the precision, recall and F-measure for each of the tools.

	TPs	FPs	FNs	Precision	Recall	F-measure	Crashes
H-BD	27	1	0	0.96	1.00	0.98	12
T-BD	14	0	10	1.00	0.58	0.73	22

Table 2: Accuracy of H-BD and T-BD BAYESDROID configurations

Results The results obtained for H-BD and T-BD are summarized in Table 2. Table 3 summarizes the findings reported by both H-BD and T-BD at the granularity of privacy items: the device number, identifier and location, while Table 5 provides a detailed description of the results across all benchmarks including those on which no leakages were detected. The warnings reported by the H-BD configuration are also publicly available for review.[5]

As Table 2 indicates, the H-BD variant is more accurate than the T-BD variant overall (F-measure of 0.98 vs. 0.73). As in the experiment described in Section 5.3, we further performed a two-tail McNemar test, considering 67 observations for each tool: 27 that correspond to true positives, 1 to the false positive due to H-BD and 39 to cases where no leakages were found.

We found that H-BD was accurate in 66 out of 67 cases, and T-DB was accurate in 54 out of 67 cases. Building the 2×2 contingency table and applying the two-tail McNemar test showed that the difference between the tools in accuracy is significant (with a p-value of 0.001 to reject the null hypothesis that the accuracy observations for both tools come from the same Bernoulli distribution). Moreover, H-BD has a lower number of crashes and lower runtime overhead, which confirms H2.

Discussion To give the reader a taste of the findings, we present in Figures 7–8 two examples of potential leakages that BAYESDROID (both the H-BD and the T-BD configurations) deemed legitimate. The instance in Figure 7 reflects the common scenario of obtaining the current (or last known) location, converting it into one or more addresses, and then releasing only the country or zip code. In the second instance, in Figure 8, the 64-bit Android ID — generated when the user first sets up the device — is read via a call to `Settings$Secure.getString(ANDROID_ID)`. At the release point, into the file system, only a prefix of the Android ID consisting of the first 12 digits is published.

As Table 3 makes apparent, the findings by H-BD are more complete: It detects 18 leakages (versus 8 reports by T-BD), with no false negative results and only one false positive. We attribute that to (i) the intrusive instru-

mentation required for tag propagation, which can cause instabilities, and (ii) inability to track tags through native code, as discussed below.

The T-BD variant introduces significantly more instability than the H-BD variant, causing illegal application behaviors in 21 cases compared to only 12 under H-BD. We have investigated this large gap between the H-BD and T-BD configurations, including by decompiling the subject apps. Our analysis links the vast majority of illegal behaviors to limitations that TaintDroid casts on loading of third-party libraries. For this reason, certain functionality is not executed, also leading to exceptional app states, which both inhibit certain data leaks.[6]

A secondary reason why H-BD is able to detect more leakages, e.g. in the lockscreen app, is that this benchmark makes use of the `mobileCore` module,[7] which is a highly optimized and obfuscated library. We suspect that data-flow tracking breaks within this library, though we could not fully confirm this.

At the same time, the loss in accuracy due to heuristic identification of relevant values is negligible, as suggested by the discussion in Section 4.2. H-BD triggers only one false alarm, on ios7lockscreen, which is due to overlap between irrelevant values: extra information on the `Location` object returned by a call to `LocationManager.getLastKnownLocation(...)` and unrelated metadata passed into a `ContextWrapper.startService(...)` request. Finally, as expected, H-BD does not incur false negatives.

6 Related Work

As most of the research on privacy monitoring builds on the tainting approach, we survey related research mainly in this space. We also mention several specific studies in other areas.

[6] For a technical explanation, see forum comment by William Enck, the TaintDroid moderator, at https://groups.google.com/forum/#!topic/android-security-discuss/U1fteEX26bk.

[7] https://www.mobilecore.com/sdk/

Realtime Techniques The state-of-the-art system for realtime privacy monitoring is TaintDroid [4]. TaintDroid features tolerable runtime overhead of about 10%, and can track taint flow not only through variables and methods but also through files and messages passed between apps. TaintDroid has been used, extended and customized by several follow-up research projects. Jung et al. [10] enhance TaintDroid to track additional sources (including contacts, camera, microphone, etc). They used the enhanced version in a field study, which revealed 129 of the 223 apps they studied as vulnerable. 30 out of 257 alarms were judged as false positives. The Kynoid system [20] extends TaintDroid with user-defined security policies, which include e.g. temporal constraints on data processing as well as restrictions on destinations to which data is released.

The main difference between BAYESDROID and the approaches above, which all apply information-flow tracking, is that BAYESDROID exercises "fuzzy" reasoning, in the form of statistical classification, rather than enforcing a clear-cut criterion. As part of this, BAYESDROID factors into the privacy judgment the data values flowing into the sink statement, which provides additional evidence beyond data flow.

Quantitative Approaches Different approaches have been proposed for quantitative information-flow analysis, all unified by the observation that data leakage is a quantitative rather than boolean judgment. McCamant and Ernst [13] present an offline dynamic analysis that measures the amount of secret information that can be inferred from a program's outputs, where the text of the program is considered public. Their approach relies on taint analysis at the bit level. Newsome et al. [14] develop complementary techniques to bound a program's *channel capacity* using decision procedures (SAT and #SAT solvers). They apply these techniques to the problem of false positives in dynamic taint analysis. Backes et al. [1] measure leakage in terms of indistinguishability, or equivalence, between outputs due to different secret artifacts. Their characterization of equivalence relations builds on the information-theoretic notion of entropy. Budi et al. [2] propose *kb*-anonymity, a model inspired by *k*-anonymity that replaces certain information in the original data for privacy preservation, but beyond that also ensures that the replaced data does not lead to divergent program behaviors.

While these proposals have all been shown useful, none of these approaches has been shown to be efficient enough to meet realtime constraints. The algorithmic complexity of computing the information-theoretic measures introduced by these works seriously limits their applicability in a realtime setting. Our approach, instead, enables a quantitative/probabilistic mode of reasoning that is simultaneously lightweight, and therefore acceptable for online monitoring, by focusing on relevant features that are efficiently computable.

Techniques for Protecting Web Applications There exist numerous static and dynamic approaches for preventing attacks on web applications, e.g., [23, 22, 7]. Most relevant to our work are Sekar's taint-inference technique for deducing taint propagation by comparing inputs and outputs of a protected server-side application [21] and a similar browser-resident technique developed in a subsequent study [16]. While BAYESDROID shares ideas with these approaches, it is explicitly designed for mobile devices and applications. Curtsinger et al. [3] apply a Bayesian classifier to identify JavaScript syntax elements that are highly predictive of malware. The proposed system, ZOZZLE, analyzes the application's code statically, while BAYESDROID operates dynamically and focuses on data values.

7 Conclusion and Future Work

In this paper, we articulated the problem of privacy enforcement in mobile systems as a classification problem. We explored an alternative to the traditional approach of information-flow tracking, based on statistical reasoning, which addresses more effectively the inherent fuzziness in leakage judgements. We have instantiated our approach as the BAYESDROID system. Our experimental data establishes the high accuracy of BAYESDROID as well as its applicability to real-world mobile apps.

Moving forward, we have two main objectives. The first is to extend BAYESDROID with additional feature types. Specifically, we would like to account for (i) sink properties, such as file access modes (private vs public), the target URL of HTTP communication (same domain or third party), etc; as well as (ii) the history of privacy-relevant API invocations up to the release point (checking e.g. if/which declassification operations were invoked). Our second objective is to optimize our flow-based method for detecting relevant values (see Section 3.1) by applying (offline) static taint analysis to the subject program, e.g. using the FlowDroid tool [6].

Table 4: Detailed summary of the results of the H1 experiment described in Section 5.3

A Overhead Measurement: Methodology

To complete the description in Section 5.4, we now detail the methodology governing our overhead measurements. The behavior of the benchmark app is governed by two user-controlled values: (i) the length ℓ of the source/sink data-flow path (which is proportional to the number of loop iterations) and (ii) the number m of values reachable from sink arguments.

Based on our actual benchmarks, as well as data reported in past studies [23], we defined the ranges $1 \leq \ell \leq 19$ and $1 \leq m \leq 13 = \Sigma_{n=0}^{2} 3^n$. We then ran the parametric app atop a "hybrid" configuration of BAYESDROID that simultaneously propagates tags and treats all the values flowing into a sink as relevant. For each value of ℓ, we executed the app 51 times, picking a value from the range $[0,2]$ for n uniformly at random in each of the 51 runs. We then computed the average overhead over the runs, excluding the first (cold) run to remove unrelated initialization costs. The stacked columns in Figure 6 each correspond to a unique value of ℓ.

B Detailed Results

Table 4 summarizes the results of the H1 experiment described in Section 5.3. For each of the benchmarks, it specifies the number of true-positive, false-positive and false-negative findings for the compared tools, BAYESDROID and TaintDroid. The benchmarks on which the tools differ are highlighted for convenience.

Similarly, Table 5 summarizes the results of the H2 experiment described in Section 5.4. The first two columns of Table 5 list the applications and their respective domain, and the third column denotes whether crawling was exhaustive. Then, the number of crashes, true-positive, false-positive and false-negative findings are reported for both the H-BD and the T-BD variants of BAYESDROID.

In Section 5.4, we describe an experiment designed to evaluate our Bayesian analysis in "pure" form, i.e. without the support of information-flow tracking to detect relevant values. To make our description of this experiment complete, we include Table 5, which provides a detailed summary of the results of this experiment across all benchmarks (including ones on which no leakages were detected). For comparability between the H-BD and T-BD configurations, we count different dynamic reports involving the same pair of source/sink APIs as a single leakage instance.

Abstract

Typosquatting is a speculative behavior that leverages Internet naming and governance practices to extract profit from users' misspellings and typing errors. Simple and inexpensive domain registration motivates speculators to register domain names in bulk to profit from display advertisements, to redirect traffic to third party pages, to deploy phishing sites, or to serve malware. While previous research has focused on typosquatting domains which target popular websites, speculators also appear to be typosquatting on the "long tail" of the popularity distribution: millions of registered domain names appear to be potential typos of other site names, and only 6.8% target the 10,000 most popular `.com` domains.

Investigating the entire distribution can give a more complete understanding of the typosquatting phenomenon. In this paper, we perform a comprehensive study of typosquatting domain registrations within the `.com` TLD. Our methodology helps us to significantly improve upon existing solutions in identifying typosquatting domains and their monetization strategies, especially for less popular targets. We find that about half of the possible typo domains identified by lexical analysis are truly typo domains. From our zone file analysis, we estimate that 20% of the total number of `.com` domain registrations are true typo domains and their number is increasing with the expansion of the `.com` domain space. This large number of typo registrations motivates us to review intervention attempts and implement efficient user-side mitigation tools to diminish the financial benefit of typosquatting to miscreants.

1 Introduction

Thousands of new domain names are registered daily that at first glance do not have completely legitimate uses: some contain random characters (possibly used by miscreants [23]), are a composite of two completely unrelated words (possibly used in spam [17]), contain keywords of highly-visible recent events (ex. `hillaryclingon.com` for political phishing in 2008 [28]) or are similar to other, typically well-known, domain names (ex. `twtter.com` [27, 32]). Domain purchasers use this final technique, often called "typosquatting," to capitalize on other domain names' popularity and user mistakes to drive traffic to their websites.

Many old and new domain names alike do not ever show up in search engines, spam traps, or malicious URL blacklists, yet still maintain a web server hosting some form of content. However, maintaining the domain registration, DNS, and web server expends resources, even if these domain registrations do not serve an obvious purpose. Investigating the purpose of domain registrations in the "long tail" of the popularity distribution can help us better understand these enterprises and their relationship to speculative and malicious online activities. In this paper, we specifically consider the hypothesis that typosquatting is a reason for many of these registrations, and scrutinize different methods for committing malice or monetizing this behavior.

In the Internet economy, monetizing on user intent has been a very profitable business strategy: search display advertising is effective because relevant ads can be shown based on user search queries. DNS is similar, as domain registrations provide ample opportunities for monetization through direct user navigation rather than search. Domain name front running, domain tasting and typosquatting domain names can all monetize this phenomenon. [1] [12] According to [22], domain tasting was nearly eliminated in the generic TLDs by the 2009 policy changes by ICANN. In addition, [12] reports that the

[1] *Domain name front running* is when registrars register domains that users have been looking for in order to monetize on their registration potential. *Domain tasting* is speculative behavior abusing the five-day grace period after domain registrations in some TLDs. This liberal registration policy gave refunds within a few days if the registrant wanted, however this policy resulted in short domain registrations en masse. ICANN has since changed policy, limiting the behavior [12, 22].

anecdotes about domain name front running by major registrars do not seem to hold. But typosquatting, the most prevalent speculative domain name registration behavior to date, continues apace.

Typosquatting wastes users' time and no doubt annoys them as well. As we show in Section 4.5, less than two percent of all domains we identify as "typo domains" redirect the user to the targeted domain, and the lion's share instead serve advertisements which previous research has shown to be profitable. [16, 26] These ad-filled pages give no clear indication to the user that they have typed the domain incorrectly; without a descriptive error, the user may abandon their task rather than double check their spelling. By monetizing these pages with advertisements, the typosquatter does a disservice both to the user and the victim web site. Protecting users from typosquatters can lessen the damage as well as disincentivize typosquatting by decreasing the squatters' profits.

If a typosquatter hosts a site that impersonates the legitimate brandholder it is certainly malicious and in some jurisdictions illegal. Such overt violations have been mitigated via legislation in the US and policy by ICANN [15, 21, 30]. For example, Facebook recently extracted a $2.8 million judgement against typosquatters impersonating their website; this successful litigation should serve as a strong deterrent against this form of malicious typosquatting against entities with the resources to litigate [18]. Several reports by commercial security teams have cited typosquatting domains' use in malicious campaigns for quiz scams [8], spam survey sites [37], in an SMS micro-payment scam [14], offering deceptive downloads or serving adult content [25], or in a bait-and-switch scam offering illegal music downloads [29]. However, until this paper, evidence regarding the extent of malicious typosquatting problems has not been available.

Typosquatting has been studied in depth in related work. In his first paper, Edelman points to the typosquatting phenomenon and discusses possible incentives for both squatters and defenders [15]. Wang *et al.* include a typopatrol service in their Strider security framework that focuses on generating typo domains for popular domains and protect visitors from offending content [35]. Moore and Edelman revisit the problem in [26] pursuing a more thorough study of the original thesis of Edelman. They explore various monetization methods and suggest intervention options. They pessimistically conclude that the best intervention options are hampered by misaligned incentives of the participants. Banerjee *et al.* [10] make another attempt to design a typosquatting categorization tool. Their method works well for a small set of sample domain names. These analyses have focused on active measurement of typosquatting sites which target the most popular domains – considering no more than 3,264 unique `.com` domain names. However, we find that no more than 4.9% of all lexicographically similar name registrations target these popular domains. While typos for the most popular domains likely account for a significant amount of typo traffic, it is unclear whether the long tail also supports a significant amount of typo traffic.

Here we present a systematic study of domain name registrations focusing on typosquatting perpetrated against the long tail of the popularity distribution. We design a set of algorithms that can effectively identify typosquatting domains and categorize the monetization method of its owner. We also design and implement tools to improve user experience by allowing them to reach their intended destination. Although various user tools exist in the wild, most are inaccurate and focus only on a limited set of targeted domains. Our typo identification algorithms combined with the user protection tools provide improved protection against being misled by typosquatting, even when it is perpetrated against less popular sites.

Section 2 provides background on typosquatting and the most common tricks used by typosquatters. Section 3 presents our data collection methodology and describes our typo categorization framework. Section 4 presents a characterization of the extent, purpose, trends, and malice involved in the perpetration of typosquatting. We present mitigation tools and intervention options in Section 5. Section 6 concludes.

2 Background

Popularity attracts speculation, and typosquatting is a showcase of this observation in the Internet ecosystem. Typosquatting maintains its popularity even in the face of the continuous effort to diminish its impact. In this section, we present a general overview of typosquatting and discuss efforts to protect legitimate domain owners from speculation.

2.1 Typo techniques and monetization

Typosquatters register domain names that are similar to those used by other websites in hope of attracting traffic due to user mistakes. The most frequent occurrences of mistyping are those that involve a one-character distance, also called the Damerau-Levenshtein (DL) distance one, from the correct spelling both in free text [13] and in case of domain names [10][2]. In this paper, we focus on typosquatting domains of Damerau-Levenshtein distance one (DL-1) that are generated using the most common operations: addition, deletion, substitution of one character, transposition of neighboring characters [13]. We extend this to include deletion of the period before the "www"

[2] Although some researchers have found that for longer original domains a small number of typosquatting domain names with larger DL distances exist [26].

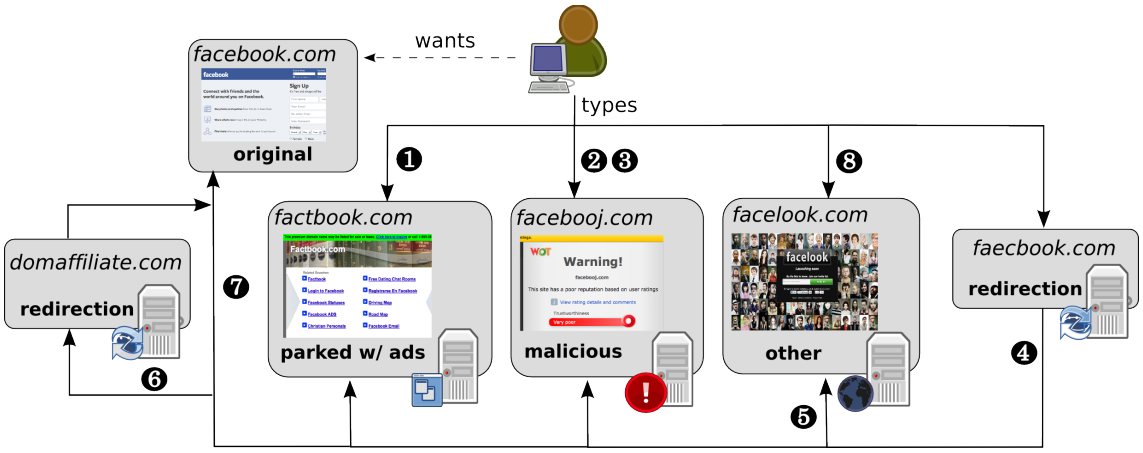

Figure 1: The typosquatting ecosystem with various monetization techniques.

commonly prepended to web server domain names [26]. We note that a special case of DL-1, called fat finger distance (FF distance), is considered when the mistyping occurs with letters that are adjacent on a US English keyboard. The rationale of this metric is that users are more likely to mistype letters in close proximity.

Typosquatters use various techniques to monetize their domain name registrations. The typosquatting domain can be *parked* and serve third-party advertisements to monetize the incoming traffic (❶ on Figure 1). The domain can also be set up to impersonate the intended domain for instance to host a phishing page [33] (❷), serve malware (❸), or perpetrate some other scam on the user [14, 37]. Many monetization techniques can also involve redirection to another domain (❹), the *landing domain*, that might employ the previously mentioned techniques. Speculators can also redirect visitors to *competitor domains* (❺) causing a direct loss to the owner of the original domain. Conversely, the typodomain owner can redirect traffic to the intended site, and monetize this traffic via *affiliate marketing* (❻). The original domain owner can also perform *defensive registrations* of typos for their main domain name and set up the redirections themselves (❼). Finally, in some cases, the typo domain owner can serve content that is unrelated to the original domain (❽).

2.2 Intervention attempts

Typosquatting exists within a legal and moral gray area; consequently, intervention has traditionally been weak to reduce the effect of typosquatting. ICANN provides the Uniform Domain-Name Dispute-Resolution Policy (UDRP) to mediate domain registration disputes for a relatively small filing fee. Unfortunately, cheap domain registration allows for mass typo-domain registrations and this gives a significant advantage to speculators. Against mass registrations of typo-domains UDRP mitigation becomes infeasible. Companies have initiated legal procedures in cases where cybersquatting and trademark infringement was applicable (see for example [32] on a recent court order against `twtter.com` and `wikapedia.com`, and a more recent court order against typosquatters of `facebook.com` [31]). The Anti-cybersquatting Consumer Protection Act (ACPA) (15 USC §1125(d)) offers legal protection to push such cases to court.

Policy intervention is more effective when targeting the registration process either at a national scale for specific TLDs or on a registrar level [24]. One can also mount an effective defense by targeting the monetization infrastructure [23, 24]. Unfortunately, the agility of domain speculators in registering new domains and the difficulty of determining their ill intent makes this a difficult prospect.

There have been some efforts to provide technical tools to mitigate typosquatting, notably the Microsoft Strider Typopatrol system which protects trademarks and childrens' sites [35]. At the user level, the OpenDNS has a typo correction feature which corrects major TLD misspellings [27] and the Mozilla URLFixer Firefox plugin [6] can suggest corrections to typed URLs. A common property of these solutions is that they only cover a relatively small set of typos, typically those that target the most popular domain names. As we show in Section 5.3, our mitigation solution is based on an extensive set of investigated domain names and hence provides significantly better coverage to detect typosquatting. Moreover, our extended set of detection features allows for more accurate detection of typosquatting than solutions in previous work.

3 Methodology

This section presents our data collection and domain categorization framework in detail as illustrated it in Figure 2.

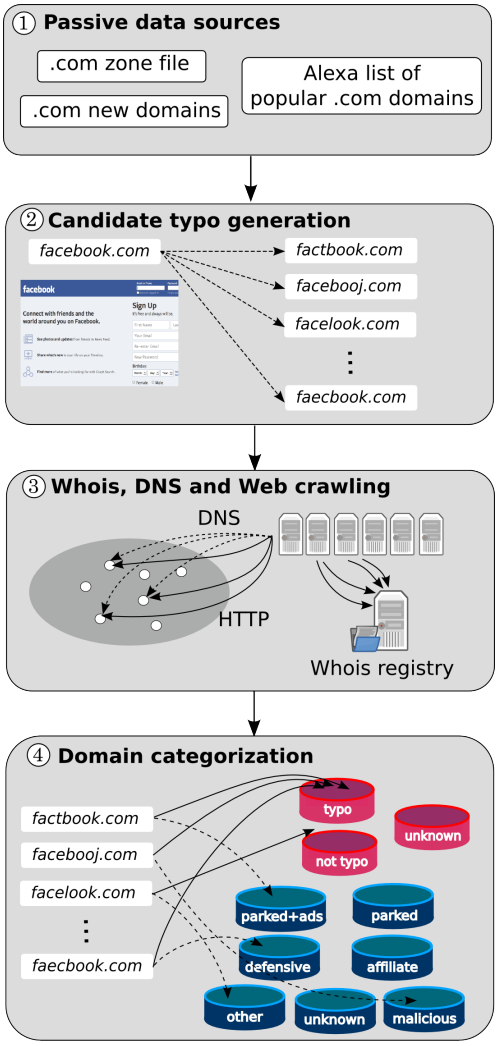

Figure 2: The data collection and typo categorization framework. The framework uses (①) large domain lists (zone file, Alexa popular domains list), (②) derives candidate typos based on lexical features and registration data in the zone file, (③) acquires additional information using active crawlers (Whois, DNS, Web), and finally (④) decides about typo domains and assigns them into typosquatting categories.

Terminology. Throughout this paper, we will refer to domains available for direct registration under a public suffix as *registered domains*, for instance *example.com* or *example.co.uk*. Generated typo domains, or *gtypos*, are domain names which are lexically similar (e.g. at DL-1) to some set of target domains. Candidate typo domains, or *ctypos*, are the subset of registered domains within the *gtypo* set which have been registered. Below we describe both how we select the target set and how we generate the gtypo set.

3.1 Data sources and scope

`.com` zone file. We leverage a variety of data sources to infer the prevalence of typosquatting in domain registrations. Our primary source is the `.com` zone file, which contains records of every domain registered within that TLD. As a popular generic domain name, the `.com` zone file contains millions of registered domain names `.com` and is available to researchers making it an ideal candidate for a representative investigation of typosquatting. Our comprehensive study is based on the March 15, 2013 version of the zone file provided by Verisign Inc containing approximately 106 million domain names. For trend analysis we collected the daily newly added and deleted domains from the zone file from October 01, 2012 to February 20, 2014.

Alexa list. The Alexa list of the top 1 million sites from March 15, 2013 serves as a benchmark for popularity [1], out of which 523,960 domains belong to the `.com` TLD, with 488,113 unique registered domains five characters long or more. For our study, we split the Alexa list into three categories: *Alexa top* containing domains ranked higher than 10,000, *Alexa mid* containing domains ranked 10,000-250,000, and *Alexa tail* containing the remaining `.com` domains ranked below 250,000. While Alexa cautions that rankings below 100,000 are not statistically significant, we are not concerned with exact comparative ranking or traffic counts for these domains but consider the Alexa list rather as a rough indicator of popularity. We also collected the Alexa top 1 million for the October 01, 2012 to February 20, 2014 period for trend analysis.

Domain blacklists. To shed light on the malicious use of typo domains, we check the typo domains from the `.com` zone file against twelve different domain name blacklists. The black lists come from abuse.ch's list of Zeus and SpyEye servers, malwaredomainlist.com, malwaredomains.com, malwarepatrol.com, Google Safe Browsing, and a commonly used commercial list. We also derive lists of malicious domains from recorded requests to DNS-based black lists (DNSBL). This method does not capture the complete list, but rather only includes domains actively marked as malicious and looked up by users during the collection time frame.

3.2 Generating candidate typos

We generated a list of all possible typo domains using the most common typo operations: addition (*add*), deletion (*del*), substitution of one character (*sub*), transposition of neighboring characters (*tra*), and supplement this set with a "." deletion operation specific to "www." domain names (e.g. a user typed (*wwwexample.com*). We define this list as the "generated typo" or *gtypo* list. The subset of the gtypo list which was registered within the `.com` TLD

includes approximately 4.7 million domains, which we refer to as "candidate typos" or *ctypos*.

3.3 Typosquatting definitions

To define the scope of our work, we provide a concise definition of typosquatting.

Definition 1 *A candidate typo domain is called a* typosquatting domain *if (i) it was registered to benefit from traffic intended for a target domain (ii) that is the property of a different entity.*

It is important that both conditions have to be met simultaneously. Typosquatting domain names are registered with the parasitic intent to reap the mistyped traffic of popular domains belonging to someone else. This includes parked domains serving ads, phishing domains, known malicious domains, typo domains redirecting to unrelated content and affiliate marketing. Arguably, these conditions cannot always be checked with confidence, for example ownership information could be disguised[3].

According to our definition, parked domains that do not serve ads are excluded from our definition of typosquatting, because they are not making any visible profit from parking. We still consider them as typos until it becomes clear if they are performing typosquatting on the target or serving unrelated content. Candidate typo domains that are defensively registered by the original domain owner are also excluded from typosquatting, because the owner of the typo domain and the original domain are the same. Although defensive typo registrations cannot be considered as typosquatting, they are born as an unwanted consequence of typosquatting.

We define *true typo* domains as follows.

Definition 2 *We call the union of typosquatting domains, parked domains not serving ads and defensive registrations the* true typo *domain set.*

Finally, all candidate typos that are at DL-1 from an original domain yet have unrelated content are considered as incidental registrations, although they can surely benefit from the lexical proximity[4].

3.4 Active crawling

We developed a set of active crawlers to collect additional information about the ctypo domains.

[3]For example, the name servers `*.aexp.com` of `americanexpressl.com` belong to American Express Inc., but that is the only indicator of ownership. This can only be marked using manual inspection.

[4]Here we face another uncertainty presented by scam pages that generate legitimately looking random content. We observed several such cases for suspiciously looking webshops. We make a conservative assessment and categorize them as other (O) in spite of their questionable content

Whois crawler. First, we collect registration data from the WHOIS global database. We restrict our crawler to the thin whois information as provided by Verisign Inc. for the `.com` domains. From the thin whois record, we use the registrar and registration date information.

DNS crawler. We collect DNS data to explore the background infrastructure serving these domains. Our crawler queries separately for A, AAAA, NS, MX, TXT, CNAME, and SOA records for each domain. The crawler then tests for random strings under the registered domain to infer whether wildcarding is present. Wildcarding is the practice when a name server resolves any subdomain under the domain belonging to its authority in the DNS hierarchy.

Web crawler. We use a web crawler to obtain the rendered DOM of each page, along with any automatic redirections that take place during the page load. This crawler uses the PhantomJS WebKit automation framework to provide high volume, full fidelity web crawling with javascript execution, cookie storage, and page rendering capabilities [20]. The crawler follows JavaScript redirections even when they may be obfuscated or contained in child iframes; it then reports the method of redirection and the destination for intermediate and final redirections. We also collect rendered screenshots of a subset of pages for manual inspection.

3.5 Clustering and categorization

Clustering. We group domains together according to various attributes obtained from available datasets and active analysis. Our goal with this clustering is twofold: to identify typo domains that might have been registered for the same purpose and to point to infrastructure elements that host a large number of typo domains. First, we identify domain sets that are at DL-1 distance from each other, forming a cluster of *typo neighbors*.

Understanding the infrastructure support and the content of the typo domains is required to make an informed decision about their real purpose. To characterize the infrastructure support for typosquatting, we cluster the candidate typo domains based on their registration and hosting information. In particular, we identify the major registrars and name servers (NSs) that host candidate typo domains.

Domain features. We derive a feature set including lexical, infrastructure and content features of the candidate typos as shown in Table 5 in Appendix A. We selected the features after carefully considering related work, collecting 40+ features in various attribute categories, and focusing only on relevant ones. To assess the efficiency of the selected feature set, we perform a systematic evaluation based on manual sampling in Section 4.1

and we use the results of this evaluation as a benchmark.[5]

Among the chosen features, domain length is a key indicator for typosquatting behavior as longer ctypo domains are more likely to indeed typosquat on the original domain they are close to [26]. Intuitively, the Alexa rank of the original domain indicates that more popular domains are more likely a target of typosquatting. Based on the zone file, we are able to observe the ratio of ctypo domains versus all domain names on a given NS and we deem hosting a large of proportion of potential typo domains suspicious for an NS. Similarly, if the registered domain of the NS contains keywords indicating parking behavior, then ctypo domains hosted on this NS are more likely to belong to typosquatting domains. NXDOMAIN wildcarding is used by major parking service providers to serve ads for web requests regardless of the subdomain. It has been shown that NXDOMAIN wildcarding is a precursor of suspicious behavior and quite often indicates parked typosquatting domains [7, 36]. Thus, we also consider it an indicator for typosquatting when the page content matches some collected parking keywords[6]. Finally, several redirections usually imply suspicious behavior, and we deem them important if the redirection targets a registered domain different from the typo domain and the target domain. The features we selected resulted in a significant improvement over existing methods in identifying typosquatting domains across the whole range of `.com` domains. We leave a more complex feature set selection and parameter calibration using machine learning techniques as future work.

Categorization. Using these features, we attribute typosquatting to candidate typo (ctypo) domains by assigning the tag *typosquatting (T)*, *not typosquatting (NT)* or *unknown (U)*. Unknown is typically used when the domain returns an HTTP or DNS error which prevents successfully downloading the page. We also tag the usage type of the typosquatting domains according to the monetization categories presented in Figure 1. We also present the novel approach of categorizing domains based on their monetization strategy. Hence, we tag ctypo domains which do not redirect the user to the target site as *parked (P)* without ads (not on Figure 1), *parked serving ads (PA)* (❶ on Figure 1), employing a *phishing (PH)* scam (❷), or serving *malware (M)* (❸). When redirection is used, then the ctypo domain can be tagged as *defensive (D)* registration (❼), defensive registration using *affiliate (A)* marketing (❻) in addition to the previously mentioned categories. When a ctypo domain redirects to another domain, then we tag it as *other (O)* (❹, ❺) no matter if it is a competitor or a completely unrelated site[7]. Finally, we mark all uncategorized domains as *unknown (U)*, a set that typically contains unreachable domains.

3.6 Checking Maliciousness

To analyze how the typo domains are used, 12 black lists are checked for an indication that the domains are malicious. To check a black list, we look for anything that was on that list during the first quarter of 2013. A "match" is a second-level domain match, since this is the relevant typo label.

To perform a check, a superset of all the domains for Q1 2013 per list was made, and the typo and Alexa domains were compared against that superset. For Google Safe Browsing, due to Google's technical constraints, the each set of domains was checked using the provided python client against data for May 1, 2011 to July 31, 2013. The results are presented in subsection 4.6.

4 Analysis

In this section, our goal is to characterize the current state of typosquatting. For this purpose, we use the `.com` zone file as the most popular and versatile TLD for domain registrations.

4.1 Typosquatting distribution

Experts believe that most newly registered domains are speculative or malicious. Paul Vixie posits that "most new domain names are malicious" [34]. The subset of registered typo domains from the generated typo domains is widely accepted as true typo domains ([26, 35]), and [26] has shown that this assertion mostly holds for the top 3,264 `.com` domains in the Alexa ranking.

We believe, however, that this assertion does not necessarily hold if we extend our scope to less popular domains. In order to investigate this possibility, we first perform a manual sampling from various sets of the `.com` zone file to systematically control the accuracy of typosquatting identification and also to provide a credible ground truth for investigation. We conduct a manual inspection of four thousand domain names because the typosquatting definitions in the academic literature [26, 35] are very crude. Moreover, we present our mitigation tool analysis in Section 5, and in so doing also discuss the limitations of existing defense tools that typically only focus on correcting typos for a limited set of popular domain names.

[5] Manually generated datasets are widely used as indicators for malicious behavior; for example, the PhishTank phishing list is a major component of SURBL, the leading domain blacklist. [2].

[6] Here, we improve on the techniques used by [7] and [19] to find parking services and parked domains

[7] Determining domain competitors is beyond the scope of this work; we summarized redirections to third-party domains independently of the typosquatter's intent. While these redirections might simply be to other parked sites, any redirection away from the original site is a traffic loss for the original domain owner.

We first take a sample of 1000 ctypo domains randomly with uniform distribution from the Alexa top domain list to match the sampling methodology of [26]. We then complete this with three additional samples of 1000 ctypo domains each derived from the `.com` zone and the Alexa domain list. Our four sample sets are thus the following: ctypos of the the Alexa top/mid/tail domains (recall their description from Section 3.1) and ctypos of a random sample taken over the whole `.com` zone file. With these multiple sets, our goal is to check whether the conclusions from prior work regarding the frequency of typosquatting hold for less popular domains.

Typosquatting domains are notoriously difficult to identify. In several cases, only a careful investigation shows the potentially speculative behavior. We performed manual verification to establish a ground truth for identifying typosquatting domains. Clearly, manual classification is not perfect, but it allowed us to go in depth at domains that were ambiguous. In manual classification, we go beyond simple rules, like identifying simple one-hop defensive redirections and consider the environment, like the owner of name servers (`ns*.aexp.com` indeed belongs to American Express Inc) or potential relation between brands (Oldnavy is a subsidiary of GAP and thus `oldnavy.com` redirects to `oldnavy.gap.com`). We could further establish a ground truth based on crowdsourcing typosquatting identification. This would remove the bias introduced by the mindset of the authors, yet it could introduce significant inaccuracies due to the lack of experience and understanding of typosquatting by the crowd.

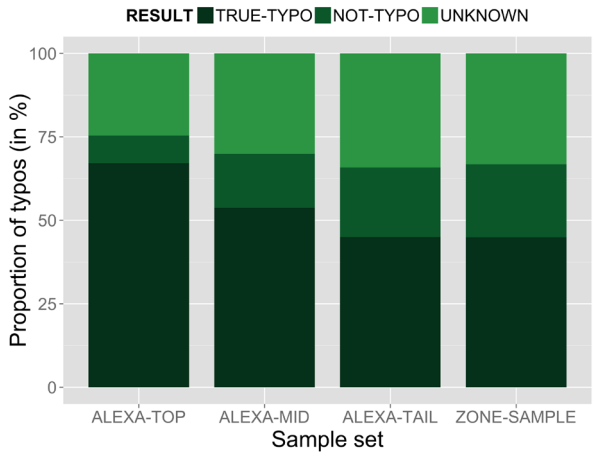

Figure 3: The prevalence of true typo domains in the four sample sets drawn popular and less popular `.com` domain names. The domain sets are ctypo samples of the Alexa top/mid/tail domains and the domains in the `.com` zone file. The number of true typo domains decreases with the Alexa rank of original domains, yet their ratio in the whole population remains high.

According to our manual inspection, a majority of the ctypo domains registered against the Alexa top domains are true typo domains (as shown in Figure 3). This result confirms the finding of [26]. We note here that there is a significant number of ctypo domains for which we cannot reliably decide if they are typo domains or not (U). This is mostly due to the fact that domains return "not accessible" responses for DNS or HTTP queries. The number of true typo domains steadily decreases when we perform the same experiment for the Alexa mid and tail domains, yet it remains high (around 50% within the set of all ctypo domains). While this indicates that thousands of domains are indeed typosquatting on less popular domains, to present defenses we need to develop a more reliable strategy to predict whether a domain is involved in typosquatting.

4.2 Accuracy of identification

We developed an automatic categorization tool based on the domain features presented in Section 3.5 called *Yet Another Typosquatting Tool (YATT)*. YATT has three modes. In the *passive mode, YATT-P* uses the information readily available from static files, such as lexical features, zone information and Alexa information. In the *DNS mode, YATT-PD* includes Whois and DNS features collected from the active crawler infrastructure, and finally in the *content mode, YATT-PDC* content features obtained via crawling are added to the categorization. The complexity of the algorithms increases from YATT-P to YATT-PDC. We expect that YATT-PDC will show the best performance in categorizing typo domains, but the other variants can still provide useful information if one wants to avoid the tedious work of collecting content features.

As presented before, we fine-tuned the parameters of YATT, but further improvement might be possible with additional features and a more complex feature selection process. At the moment, this optimization is left as future work.

In addition to YATT, we tested notable typosquatting identification methods from related work. First, we consider the method in [26], which showed that most ctypo domains of DL-1 are indeed true typos. Their primary feature is the domain length so we repeat their experiment for DL-1 and we name their method *AllTypo*. Then, we implemented the most important features of the *SUT-net* algorithm in [10] and compared it to various modes of YATT.

In Figure 4, we compare the accuracy of the typo identification methods in related work and the three modes of YATT to the established benchmark of manual evaluation. We perform this accuracy evaluation on the four ctypo domain samples described in Section 4.1. In Figure 4, we see that all five algorithms mark ctypo domains

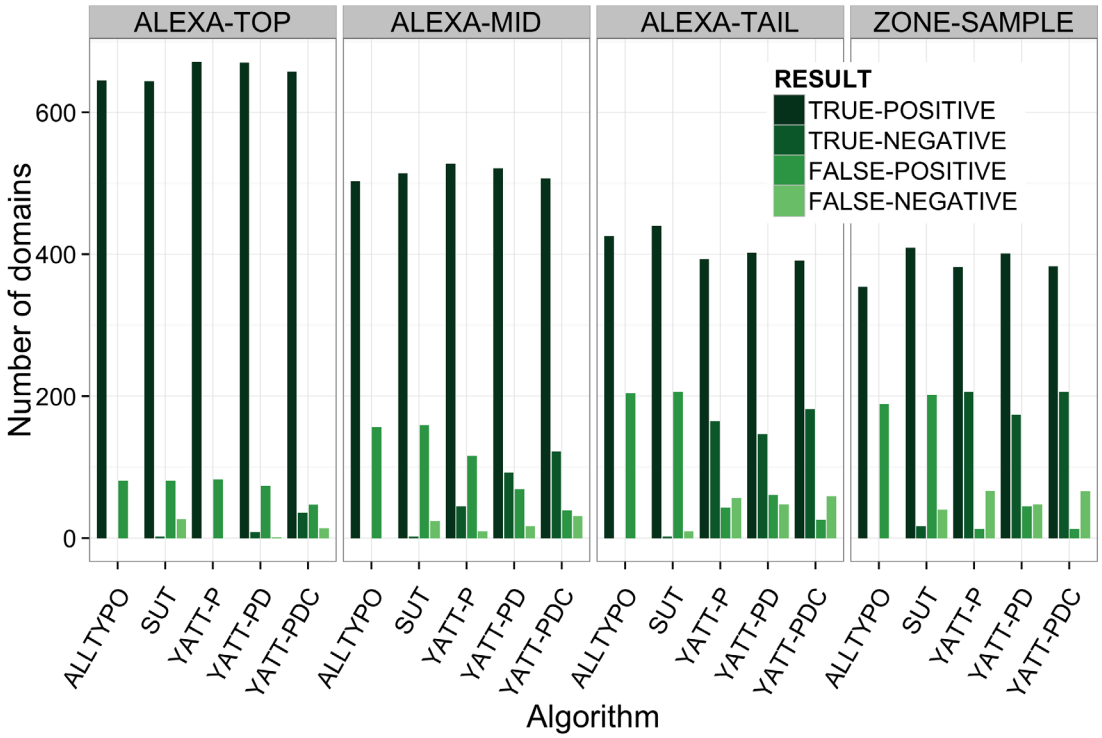

Figure 4: Accuracy of four typosquatting prediction tools. We tested (a) AllTypos, (b) SUT-net-based content features, (c) YATT-P, (d) YATT-PD, and (e) YATT-PDC for the four ctypo domain sample sets of (1/2/3) the Alexa top/mid/tail domains and (4) the domains in the `.com` zone file.

as positives in the Alexa top dataset. This assertive categorization results in a good true positive (TP) rate, a reasonably small number of false positives (FP) and with almost no false negatives (FN). Only the full YATT-PDC can identify a small set of true negatives (TN) in the population. In the Alexa mid, the agressive typo identification of AllTypo and SUT results in a high FP number whereas YATT keeps the FPs low while correctly identifying TNs (with YATT-PDC being the most accurate as expected). For the Alexa tail and zone datasets, the number of true typos further decreases and both AllTypo and SUT overwhelmingly categorize these domains as typos resulting in a very large false positive rate. All versions of YATT keep the FPs low and correctly categorize TNs at the expense of a small number of FNs. It is clear that perfect categorization is difficult to do, but YATT does not sacrifice much precision as the number of non-typo domains get introduced.

Next, we study the accuracy of the YATT-PDC to identify parked domains and other typosquatting indicators based on our manual sampling in Table 1. Note that related work on typosquatting identification usually focuses on typo identification and leaves the categorization aside. Only the active mode of the algorithm can perform this categorization, because it requires content features. YATT-PDC uses regular expression-based matching for the identification of parking domains. It matches these domains with about 85% precision, the error stemming from the incompleteness of the set of regular expressions we use. YATT-PDC still finds the majority of the parking sites and lists a significantly larger number of parking sites than methods in related work [7, 19]. For the defenisve domain registrations, YATT-PDC fares worse. It only finds 60-85% of the defensive registrations. This is due to the complexity of defensive registration patterns that can mostly be caught by a human eye. Finally, for affiliate registrations, YATT-PDC performs quite well, correctly categorizing almost all domains. We also checked the existence of malicious and phishing domains in our sample dataset, but we could not find any in such a small sample. Our results from more rigorously checking for maliciousness in typo domains is described in subsection 4.6, however maliciousness was not used to classify typo domains as typos.

YATT results in an accurate prediction of true typo domains and domain categories for the whole range of the domain population and hence its results can be used as a basis for intervention attempts and tools. Using YATT, we compile a typosquatting blacklist and use it in a set of mitigation tools (see Section 5).

	PARKED			DEFENSIVE			AFFILIATE		
	False Positive	True Positive	False Negative	False Positive	True Positive	False Negative	False Positive	True Positive	False Negative
Alexa top	3	402	76	0	39	15	0	27	1
Alexa mid	3	358	50	0	18	3	0	15	0
Alexa tail	1	295	59	0	9	3	0	0	0
Zone	0	265	43	1	7	4	0	0	0

Table 1: The accuracy of YATT to identify parked, defensive and affiliate registrations across the sample datasets.

4.3 Presence of typosquatting registrations

Having designed an accurate typosquatting identification tool, we now study the existence of typosquatting in current domains registrations. We first obtained 4.7 million ctypos targeting the `.com` domains in the Alexa top 1m domain list and existing in the `.com` zone file using the methodology described in Section 3. Recall, that we split the original domains according to their Alexa rank into the Alexa top/mid/tail categories.

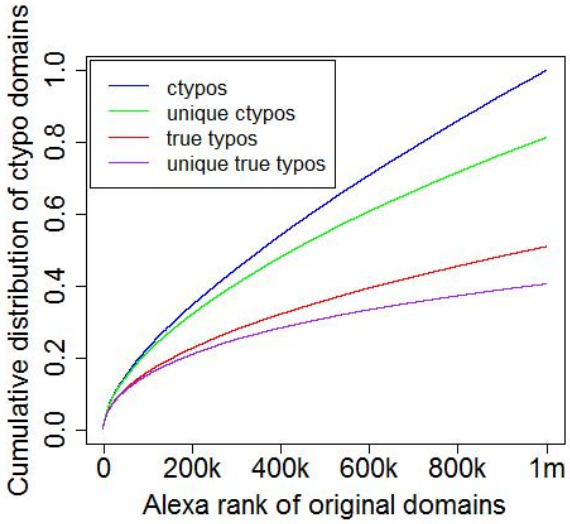

Figure 5: The cumulative distribution of true typo domains in ctypos and unique ctypos as a function of the Alexa rank of the original domains.

The first and foremost question is the extent of typosquatting targeting the Alexa domain set. We use YATT to determine typosquatting behavior and partition ctypo domains into the categories described in Section 3.5. In Figure 5, we plot the cumulative distribution of ctypo domains as a function of the originals' Alexa rank, and we also plot the cumulative distribution of true typo domains. We see that the number of true typos steadily increases as the Alexa rank decreases, although at a slower pace than the number of ctypos. In addition, we also plot the cumulative distribution of unique ctypos and true typo domains.

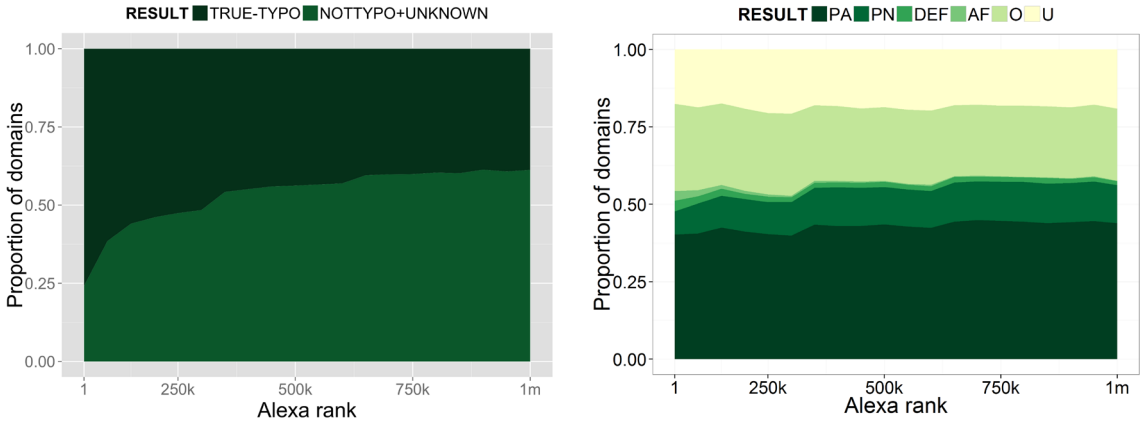
We then show the fraction of true typos in the population of ctypos in Figure 6(a). We calibrated YATT to make a decision about each ctypo and thus it conservatively categorizes the majority of unknown domains as not typos. For Alexa top sites, the fraction of true typos is higher, but for lower Alexa ranks the number of not-typo and unknown domains increases. This is consistent with our benchmarking results in Figure 3. Finally, in Figure 6(b), we present the typosquatting categories as a function of the original domains' Alexa rank. We observe that the bulk of the true typo registrations profits from parked domains with advertisements. The number of defensive and affiliate registrations is higher for the Alexa top sites, but then then the affiliate registrations disappear as we head to the Alexa tail while the defensive registrations persist. Finally, there is a significant number of non-typo domains incidentally close to the domains in the Alexa domain list.

Projecting our results to the total number of `.com` domains in the zone file, we estimate that about 53% of them are candidate typo domains and hence 20% of the total domain set are true typo domains. Based on our results, we estimate that about 21.2m domains are true typo domains in the `.com` zone file.

4.4 Trend analysis

We analyzed trends in typo domain registrations for a period of approximately one year (from 2012-10-01 to 2013-10-15). We considered domains from four datasets: domains from the `.com` zone file, ctypos from the `.com` zone file, ctypos targeting the whole Alexa list and ctypos targeting the Alexa top list.

For the purposes of our analysis, we use visibility into the `.com` zone file as a proxy for domain registration. Because the actual registration and registration lapse events are not visible to us, we use presence in the zone file as a proxy for registration events. We define a registration



(a) (b)

Figure 6: The existence of typosquatting domains targeting the Alexa domain set. The fraction of (a) true typo domains and (b) various typo categories in the true typo population.

event as one where a domain was not in a daily zone dump, and was present in the subsequent day's zone file, and vice-versa for a registration lapse, or deregistration.

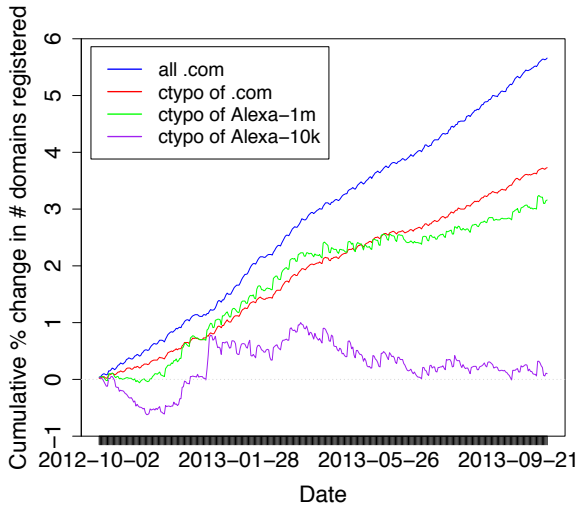


Figure 7: Cumulative change in the total number of domains registered over time.

We looked at the change in domain registrations over time. Figure 7 plots the cumulative changes in the number of domains registered in the above mentioned domain sets. While the overall registration rate is steady, the difference between the rate of Alexa-10k targeted and Alexa-1m targeted typos suggests that, through enforcement or typosquatter preference, the overall increase in registrations targeting popular domain typos is far smaller even though

	Stable	Mean uptime	Reregs
Alexa-1m ctypo	72.3%	458 days	49.5%
Alexa-10k ctypo	71.0%	454 days	49.5%
Alexa-1m	93.3%	501 days	67.1%
Alexa-10k	99.0%	506 days	86.8%
Random sample	70.4%	440 days	28.5%

Table 2: Speculation trend analysis between 2012-10-01 and 2014-02-20. Alexa list and zone file used was from 2012-10-01. The "stable" column indicates what proportion were registered throughout the dataset. "Reregs" indicates how many domains experienced at least one lapse in visibility at the zone file, indicating that the domain was decommissioned and then reactivated. "Random sample" is a selection of 2 million random domain names from the `.com` zone file of 2012-10-01.

many DL-1 typos of popular domains are still available. It is also interesting to note that the spike centered on January 1 2013 is due to four organizations (sedoparking, 1and1.com, dsredirection, and graceperioddomain.com) registering a large number of domains: these four account for 87% of all domains registered at that time.

Our next analysis focuses on the amount of speculation present within the market for typosquatting domains between 2012-10-01 and 2014-02-20. Table 2 shows the percentage of stable domains, the average uptime, and the percent of domains experiencing at least one reregistration event during our measurement time period. As might be expected, random domains are purchased and left to lapse very often, with less than one third being reregistered after being abandoned. Domains which are a typo of a popular domain, however, experience almost

twice as much interest, although they are not active for significantly more time. This trend suggests that the information asymmetry of the typosquatting marketplace is such that new speculators register old typos at a much higher rate than random domains.

4.5 Typosquatting redirections

Now, we scrutinize the affiliate redirections via third-parties. This third-parties can be legitimate brand protection companies, but more frequently they are typosquatting affiliates collecting type-in traffic from a large number of typo domains.

Domain redirections that lead back to the targeted original domains without intermediate domains are considered defensive registrations, as explained in Section 2.1. If the redirection leads back to the target domain via a third-party, then we call it an affiliate defensive registration. In Figure 8 the first graph shows that in the cumulative distribution of third party landing pages, eleven domains (less then 0.1 percent of all of these landing pages) get redirections from more than 50 percent of ctypos redirecting to a third party domain. The second graph in Figure 8 shows defensive affiliate domains, where the landing pages is the original domain, but the traffic goes through an intermediate affiliate domain. 18 such intermediate domains (1.3 percent of all domains) are responsible for more than 80 percent of defensive affiliate marketing. Even though this set has a very small overlap with the non-defensive affiliate domains, a small fraction of affiliate domains are controlling 80 percent of the affiliate market.

Finally, if the redirection leads to a third-party domain, that is away from the original target, then this is considered truly speculative. The third graph in Figure 8 shows redirections to third-party pages with only one redirection. Here the domains are more widely distributed: there is only one big landing domain hugedomains.com which receives traffic from more than 21 percent of this type of redirection. The last graph shows the cumulative distribution of all affiliate domains participating in third-party redirections with a non-defensive purpose. That means that these affiliate domains lead away the users from the targeted original sites. 41 of these non-defensive affiliate domains (0.4 percent of all such domains) control the traffic originating from more than 80 percent of candidate typo domains. This means that, here too, a relatively small set of domains control the majority of such traffic going to a few landing pages.

4.6 Maliciousness of Typo Domains

In order to test the assertion that typo domains are more malicious than other domains, the candidate typo (ctypo) and true typo (ttypo) domains extracted from the `.com` were checked against a variety of available black lists. These results are compared against the same test on the Alexa domains. By using 12 available black lists from various sources fluctuations due to the idiosyncrasies of any individual list can be controlled.

	# Malware Hits	% of List Marked Malware	# Phish Hits	% of List Marked Phish
Alexa	9990	1.907%	27	0.005153%
ctypos	17485	0.3716%	272	0.005781%
ttypos	3720	0.1585%	125	0.005329%

Table 3: Google Safe Browsing results for domains in Alexa, *ttypos*, and *ctypos*.

The Alexa top 488,133 `.com` domains (all the `.com` domains in the top 1m) are more likely to appear on black lists than the typos of them, either *ctypos* or *ttypos*. This result is consistent across all 12 black lists investigated. In each case, the Alexa domains are more likely to host malicious activity. The percentage of .com domains from the Alexa list on each black list is always higher than the percentage of *ttypo* domains on the same list.

Google's Safe Browsing list requires a different checking method, due to their storage method. The list also distinguishes between a match due to malicious content or attempts at phishing. However, the results show a similar trend. The Alexa domains are more likely to be purveyors of malicious software. Table 3 shows the results for Google Safe Browsing checking for any listing from May 1, 2011 – July 31 2013.

There are several possible causes for this pattern, and several of them would be uninteresting. A possibility is that there is a pocket of malicious activity using typos, but that most of it is benign. The first place to look for this would be the name servers hosting predominantly typo domains. There are 10 name servers for which most of the domains they host are typos of other domains—for these name servers, between 20-80% of their domains are typos.

The typo domains hosted on these 10 name servers seem to be even less likely to appear on a black list. The average percentage of these name servers' domains on any of the black lists is 0.051%, and the maximum percentage of typo domains hosted by one of these name servers on any one list is 0.27%. Both of these numbers are below those both for typos generally as well as the results for the Alexa domains.

5 Intervention options

Just as defining typosquatting remains one of the grey areas of domain name security, developing effective in-

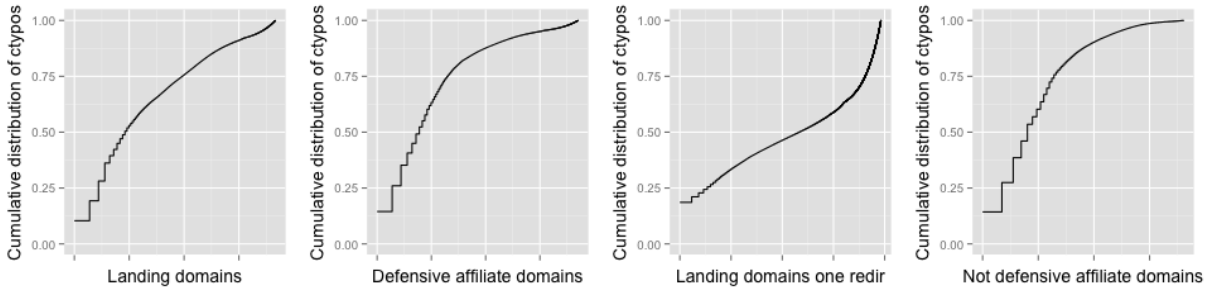

Figure 8: The leftmost figure shows the cumulative distribution of landing pages targeted from ctypo domains. The second figure shows the cumulative distribution of intermediate domains in case of defensive redirections. The third figure is when the length of the domain redirection chain is one. Finally, the rightmost figure shows the cumulative distribution of intermediate domains in case of redirections targeting a third party.

tervention techniques is similarly difficult. So far, most intervention attempts remain ineffective. In the following, we present viable typosquatting mitigation options and present a set of practical tools to prevent typosquatting from negatively effecting users.

5.1 Policy intervention

Much of the effort to crack down on typosquatting focuses on policy options. Two major tools exist for policy intervention. The first is the UDRP arbitration framework provided by ICANN [21]. Unfortunately, only a small fraction of typosquatting domains enters the UDRP procedure [26], although domains are claimed by their trademark holders very often.

The Anti-cybersquatting Consumer Protection Act (ACPA) (15 USC §1125(d)) offers an alternative to the UDRP through legal action. The act "was designed to thwart cybersquatters who register Internet domain names containing trademarks with no intention of creating a legitimate web site, but instead plan to sell the domain name to the trademark owner or a third party." While originally aimed at preventing cybersquatting, in May 2013 Facebook successfully litigated a case including typosquatting domains, earning a US $2.8 million judgement [18]. As with any legal action, the enforcement of this act is costly and only major trademark holders have exercised their legal rights [25, 31, 32]. Additionally, the bad faith of typosquatting registrations is difficult to prove and hence the legal action might not always be efficient [30]. Unfortunately, even vigilant companies seem overwhelmed by the number of typosquatting domains targeting their brands, motivating them to litigate; even so, many of their domains are still controlled by typosquatters.

5.2 Infrastructure support

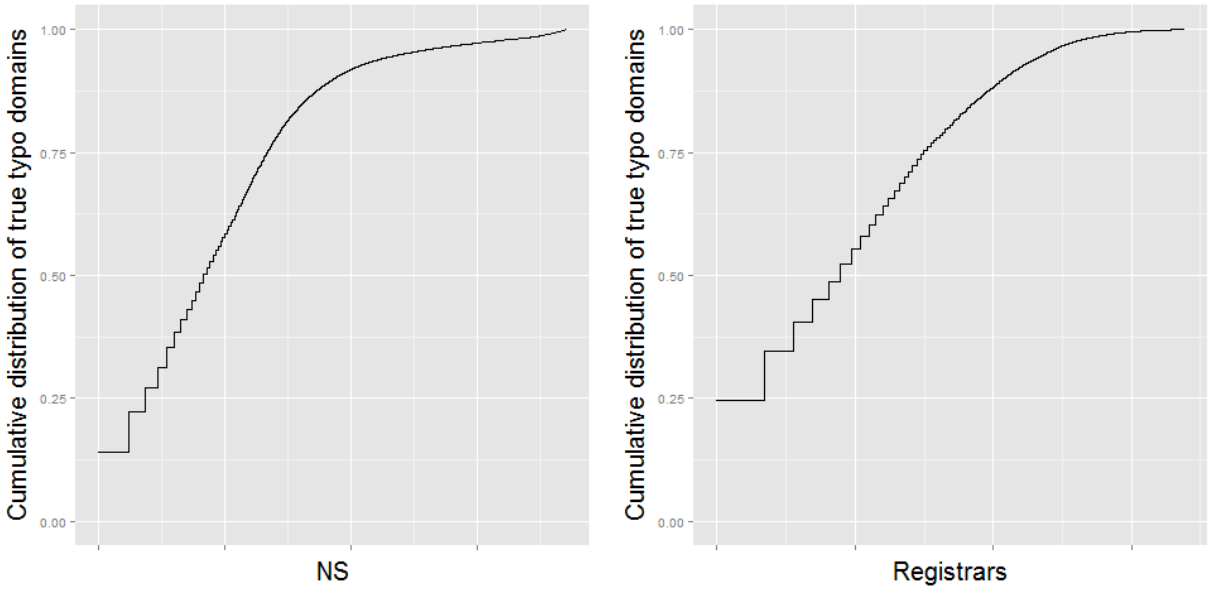
Another option for intervention is to motivate registrars and hosting providers to scrutinize domain name registrations when they happen (with a mandatory light-weight UDRP procedure for example). Let us now look at the potential of registration intervention at the infrastructure side. Figure 9 shows the distribution of typosquatting domains (a) as a function of the registrars and (b) as a function of the supporting NSs (setting the x axis to a log scale to improve visibility). We observe that most true typo domains cluster at major registrars and are hosted at a few NSs. In particular, 12 NSs and 5 major registrars are responsible for hosting 50% of the true typo domains. Forcing these major registrars to enforce prudent registration practices with respect to typosquatting may be a viable policy option.

NS	True typos	All domains	Typo ratio
`a0f.net`	5221	6332	82%
`citizenhawk.net`	8819	12004	73%
`easily.net`	18281	36890	50%
`domainingdepot.com`	51854	132864	39%
`next.org`	9426	30252	31%
`domainmanager.com`	23493	90929	26%

Table 4: Worst offender NSs in true typo hosting with at least 5000 true typo domains. All NSs in the top list have higher than 25% of true typo / all domain ratio.

Based on the `.com` zone file, we are also able to collect the ratio of true typo domains to the total number of domains. Table 4 presents the top offenders with at least 5000 true typo domains hosted. Interestingly, there are only 65 NSs with such a high number of true typo domains. We see that the worst offenders almost exclusively host true typo domains, and none of them belong to the major hosting companies[8]. Further investigating

[8] An interesting case might be `citizenhawk.net`, a brand protec-



(a) (b)

Figure 9: Intervention potential at domain registrars and hosting companies. We present the distribution of typosquatting domains (a) as a funtion of the registrars and (b) as a function of the supporting NSs (while setting the x axis to a log scale for better visibility)

these typo domains we found two interesting results. First, out of the 6 name servers with the highest true typo ratio, 5 have domains that are privately registered and only `citizenhawk.net` is not, showing that the others are aware that their monetization strategy is questionable. Second, we found that on the average 24.5 percent of the domains hosted by these NSs is in the top Alexa, which is 2.5 time higher number than for the rest of the name servers. This indicates that these name servers are more effectively targeting popular typo domains than major hosting services who are not focusing on typosquatting. These hosting companies with an unusually high number of true typo domains could be regulated to effectively decrease the effect of speculative typosquatting.

Infrastructure intervention is promising if it can be enforced globally by ICANN on the supporting providers. Unfortunately, it is unlikely that such a global action will emerge as this is counterproductive for the domain registrars, and thus miscreants can always shift their businesses to negligent or accomplice providers who are financially motivated to assist their businesses. Registrar- and hosting-level intervention remains ineffective against spammers [23, 24] and it is unlikely that it will be effective against typosquatting. Registrars and hosting companies do not suffer from typosquatting, thus there is little economic incentive for them expend resources to defend against it.

tion company who probably registered a large number of domain names for protecting their customers.

5.3 Mitigation tools

The last option to counter typosquatting is the application of technical tools to reduce the impact of typosquatting. There exist mitigation tools to this end, but most tools suffer from either trivial errors or from small coverage of typosquatting domains.

Related work. Wang et al. developed *Strider Typopatrol*, a tool to automatically discover typo domains of popular domains [35]. They focus on a small subset of the Alexa top domain list [1], phishing targets, and childrens' websites. OpenDNS [27] provides typosquatting correction in their DNS services, but only for major TLDs. A similar tool called *URLFixer* [6] was introduced in the Adblock Plus advertisement blocking tool. The URLFixer tool includes misspellings of top Alexa domains, but fails to correct less popular domain names and includes some short domain names leading to false corrections. Chen et al. [11] develop a browser plugin to check typo domains based on a user-customized local repository. Banerjee et al. [9, 10] propose *SUT*, a method to identify typosquatting domains mostly based on HTML properties. Finally, the autocomplete feature of most major browsers can also decrease the instance of typos, albeit only for previously visited sites.

Initial tests show that most existing solutions are lim-

ited in scope (the most popular domains or most frequent typos), in features (only TLD correction or HTML features) or in the information used (search typing or local browser history) and consequently these tools are missing a large set of typosquatting domains.

The YATT framework. We developed a typosquatting categorization tool, YATT, that uses an extended domain feature set to provide accurate typosquatting identification. Based on the output provided by YATT, we implemented three typosquatting detection and protection services. The first service is a typosquatting blacklist (YATT-BL) compiled from the output of one of the versions of the YATT tool. As a DNS based blacklist, this access method is quick and lightweight. The tool works similarly to major domain blacklists such as URIBL [5], SURBL [4] or the Spamhaus DBL [3] and it can be used to filter out typo domains from live traffic. The DNS server uses RPZ [34] to efficiently distribute the typo list.

Second, we implemented a Firefox browser plugin and a corresponding typo protection server to protect users from typosquatting domains. Our plugin contacts the typo protection server each time a user types in a domain and raises a warning if the domain typed by the user is found on the typosquatting domain list. The user is provided with the option of accepting the automatic correction or rewriting it to her needs. The typo protection server uses YATT-BL DNS blacklist described above.

Third, we are in the process of implementing a YATT DNS server for organizations that want to avoid typosquatting yet do not want to expose their DNS traffic to a third party server. Using this tool, a company could periodically download an updated typosquatting blacklist and query it locally.

6 Conclusion

Typosquatting has caused annoyances for Internet users for a long time. Since users lack effective countermeasures, speculators keep registering domain names to target domains and exploit the traffic arriving from mistyping those domain names. Existing studies of typosquatting focused on popular domain names and thus have only shown the tip of the iceberg. Similar to traditional cybercrimes like spamming or financial credential fraud, typosquatting has minimal transparency, allowing what may be an unprofitable activity to continue because new entrants see its effects and attempt to become profitable typosquatters themselves. Investigating such speculative, "gray area" behavior longitudinally can give us insights which might generalize to traditional cybercrime and cybercriminals.

In this paper, we performed a thorough study for an extensive set of potential target domains. We found that 95% of typo domains are targeting less popular domains. We designed an accurate typo categorization framework and find that typosquatting using parked ads and similar monetization techniques not only exists for popular domains, but a whole range of domain names in the Alexa domain list. We showed that a large number of incidental domain registrations exist with close lexical distance to the target domains. Our conservative estimates indicate that as much as 21.2 million `.com` domain registrations are confirmed true typo domains, which accounts for about 20% of all `.com` domain registrations. Additionally, we found that the typosquatting phenomenon is only continuing to thrive and expand.

The difficulty of categorizing typosquatting domains partially explains the inefficiency of existing mitigation techniques. Much like typosquatting itself, mitigation is a gray area: one cannot easily classify a new registration as an example of typosquatting based on the name alone. As such, typo domains rarely appear on blacklists. To counter this problem, we designed several defense tools that rely on a broad range of features. We provide a typosquatting blacklist and a corresponding browser plugin to prevent mistyping at the user side. While typosquatting will likely continue to exist, these analyses and tools may improve user experience and further decrease the profit available to typosquatters.

Abstract

Domain parking is a booming business with millions of dollars in revenues. However, it is also among the least regulated: parked domains have been routinely found to connect to illicit online activities even though the roles they play there have never been clarified. In this paper, we report the first systematic study on this "dark side" of domain parking based upon a novel infiltration analysis on domains hosted by major parking services. The idea here is to control the traffic sources (crawlers) of the domain parking ecosystem, some of its start nodes (parked domains) and its end nodes (advertisers and traffic buyers) and then "connect the dots", delivering our own traffic to our end nodes across our own start nodes with other monetization entities (parking services, ad networks, etc) in-between. This provided us a unique observation of the whole monetization process and over one thousand *seed* redirection chains where some ends were under our control. From those chains, we were able to confirm the presence of click fraud, traffic spam and traffic stealing. To further understand the scope and magnitude of this threat, we extracted a set of salient features from those seed chains and utilized them to detect illicit activities on 24 million monetization chains we collected from leading parking services over 5.5 months. This study reveals the pervasiveness of those illicit monetization activities, parties responsible for them and the revenues they generate which approaches 40% of the total revenue for some parking services. Our findings point to an urgent need for a better regulation of domain parking.

1 Introduction

Consider that you are a domain owner, holding a few domain names that you do not have a better use of. Then one thing you could do is to "park" them with a domain parking service to earn some extra cash: whenever web users type in those domain names (probably accidentally) in the browser's address bar, the parking service resolves the domains to advertisement laden pages, the revenue generated in this way is then split between the parking service and the domain owner. Such *domain parking monetization* is a million-dollar business [29], offering a unique marketing channel through newly acquired, underdeveloped domains, or those reserved for future use. However, with a large number of parked domains being monetized through those services (`Sedo` reported to have 4.4M parked domains in 2013 [29]), what becomes less clear is the security implications of such activities, particularly whether they involve any illicit operations, a question we attempt to answer.

Dark side of domain parking. Prior research shows that once malicious domains (e.g., those hosting a Traffic Distribution System, TDS) have been discovered, they often end up being parked [17], i.e. temporarily hosted by some domain parking services. Those domains come with a large number of backlinks through which they can still be visited by the victims of the malicious activities they were once involved in, such as compromised websites. Web traffic from those backlinks is clearly of low quality but apparently still used by the parking services to make money [17]. More problematically, a recent study reveals suspicious redirections performed by some parking services could be related to click spam [10], though this could not be confirmed. This finding echoes what we observed from the redirection chains collected by crawling parked domains, some of the URLs on the chains carried URL patterns related to ad click delivery even though our crawler did not click on any link at all (Section 2.3). Also malicious web content has long been known to propagate through parked domains [14, 20].

With all such suspicions raised, it is still challenging to determine whether some parking services are indeed involved in illicit activities, and if so the types of roles they play there. The problem is that parking services' monetization decisions and strategies cannot be directly observed from the outside. Therefore, in the absence of information about the nature of input traffic to those services and the actual ways it has been monetized, all we

have is guesswork. For example, even though we did observe redirection chains seemingly related to click delivery, without knowing a parking service's interactions with its ad network, we were still left with little evidence that what we saw was indeed click fraud. Note that parking services do not need to play conventional tricks, such as running click bots [21] or using hidden iframes embedded in a compromised page, to generate fraudulent clicks, and therefore will not be caught by standard ways in click fraud detection. In the presence of such technical challenges, little has been done so far to understand the illicit activities that can happen during the monetization of parked domains.

Our study. In this paper, we report the first attempt to explore the dark side of domain parking and uncover its security implications. This expedition is made possible by an innovative methodology to infiltrate parking services. More specifically, we purchased a set of domains and parked them with those services. Those domains, together with our crawler that continuously explored parked domains, enable us to control some inputs to the parking services. On the receiving end, we launched ad campaigns and made purchases of web traffic through the ad network or the traffic sellers associated with those parking services. By carefully tuning parameters to target web audience we controlled, we were able to connect the dots, receiving the traffic generated by our crawler going through our parked domains and onto our campaign websites. This placed us at a unique vantage point, where we could observe complete monetization chains between the start and the end nodes we controlled.

By analyzing such monetization chains, we were surprised to find that domain parking services, even highly popular ones such as `PS5`[1], shown in Table 1, are indeed involved in less-than-legitimate activities that should never happen: our ad campaigns were charged for the "click" traffic produced by our own crawler that never clicked and the traffic we purchased turned out to have nothing to do with the keywords we specified; also interestingly, we found that for all the visits through our parked domains and hitting our ads, only some of them were reported to our domain-owner's account (i.e. their revenues shared with us), though all of them were billed to our ad account.

To further analyze the scope and magnitude of those problems, which we call *click fraud*, *traffic spam* and *traffic stealing* respectively, we fingerprinted those confirmed illicit monetization chains with a set of salient features called *stamps*, and utilized them to identify monetization activities on 24M visits to parked domains not going through our end nodes (i.e. ad/traffic campaign websites). New findings reveal that even leading domain parking services are involved in illegitimate operations. On the other hand, such operations were present in only about 5% of the traffic we observed, which indicates that those services are largely legitimate. Possible motivations behind their opportunistic attacks could be monetizing less reputable (secondary) domains (e.g., taken-down malicious domains) that are difficult to profit from legitimately, or making up for revenue losses. Furthermore, we conducted an economic study to estimate the revenues of such dark-side activities, which we found to be significant.

Contributions. The contributions of the paper are outlined as follows:

• *New methodologies*. We performed the first systematic study of illicit activities in parked domain monetization. This study was made possible by a suite of new methodologies that allowed us to infiltrate domain parking services and collect a set of complete monetization chains. We further expanded such "seed" chains over a large number of redirection chains collected from parked domains over a 5.5-month period, which laid the foundation for understanding the unique features and the impacts of those activities.

• *New findings*. Our study brought to light a set of interesting and important findings never reported before. Not only did we confirm the presence of illegitimate operations including click fraud, traffic spam and traffic stealing during the monetization of parked domains, but we also reveal the pervasiveness of those activities which affect most leading parking service providers and attribute it to account for up to 40% of their total revenue. Also interesting is the discovery of unique features of those illicit activities and their relations with different monetization strategies and parking service syndicates.

2 Parked Domain Monetization

2.1 Background

Domain parking. As described before, a parked domain is a registered domain name whose owner does not have a better use of it than temporarily running it as an ad portal to profit from the traffic the domain receives. To this end, the owner typically chooses to *park* the domain with a domain parking service, an intermediary between the owner and various monetization options (explained later). This is done by setting up an account with the service, and the owner forwards her domain traffic to the parking service as specified by its regulations. The most common way for doing this is through the Domain Name System (DNS), in which the parked domain's Name Server (NS) or Canonical Name record (CNAME) is set to point to that of the parking service.

[1]Throughout this paper, we anonymize the identities of domain parking services found to be participating in illicit activities due to legal restrictions imposed by Indiana University and RSA.

In this way, the service gains complete control on the parked domain and any traffic it receives. Alternatively, the domain owner can choose to log her domain traffic before redirecting it to the parking service through HTTP redirections.

Parking services provide a domain owner with a platform to manage her parked domains. For example, some parking services let the owner set the keywords to be used for the parked domain monetization. Also, a domain owner can monitor their domain earnings through revenue reports.

Monetization options. A parked domain owner can profit from her domain traffic through a number of monetization options. The most popular ones are search advertising and direct-navigation traffic monetization, as elaborated below:

• *Search advertising*. In search advertising (aka., sponsored search), the advertiser runs a textual ad campaign with a search ad network and selects a set of target keywords for displaying her ads. To serve these ads, the publisher may operate search-related services such as search engines and toolbars, or use in-text advertising techniques (i.e. when the mouse hovers on a target word, the ad is displayed) to identify the right context for advertising: for example, it shows ads associated with the target words that are included in the search terms entered into search engines or the toolbars. Parking services are one of such publishers who provide textual ads relevant to the names of parked domains.

Search advertising is made possible through pay-per-click (PPC) XML feeds as illustrated in Figure 1. A publisher submits a search query for certain keywords (relevant to the domain names, in the case of parked domains) and receives relevant ads in the XML format, which also include the bidding price per ad from the advertisers. The publisher in turn picks up a set of ads to display. Once a user opts to click on an ad, the click traffic is bounced through a number of hosts such as click servers before reaching the advertiser's web page. This click is paid for by the advertiser and the revenue generated in this way is shared between the publisher and the ad networks.

Popular search ad networks such as `Google AdWords` and `BingAds` are considered to be top-tier (premium), while other less reputable ones are 2nd-tier or lower. Compared with other ad networks, top-tier networks offer a higher rate per click (CPC) to the publisher and a better click fraud detection to the advertiser.

• *Direct navigation traffic (PPR)*. Direct navigation traffic (aka., *type-in* traffic) is generated when the web user enters a domain name as a query and expects to be redirected to a related domain. For example, one may type in "findcheaphotels.com" in the address bar and land at `mytravelguide.com`. This is caused by

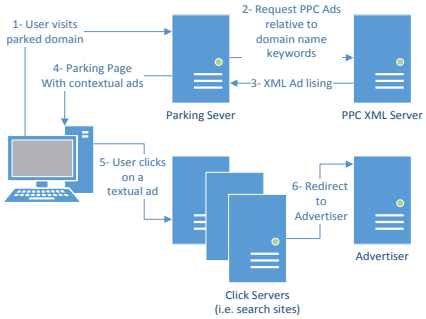

Figure 1: Legitimate PPC XML feed operation.

a direct-navigation-traffic purchase in which the owner of `mytravelguide.com` purchases through a direct navigation system the traffic related to keywords "travel" and/or "hotels", for example. Parked domains can serve such a direct navigation system by redirecting type-in traffic to them who ultimately redirect it to traffic buyers like `mytravelguide.com`. This monetization option is called Pay-Per-Redirect (PPR) or zeroclick.

2.2 Ecosystem and Illicit Monetization

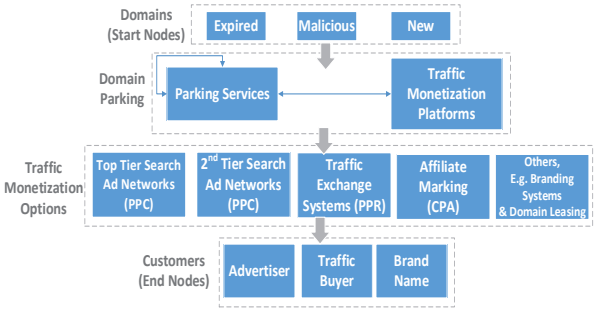

Figure 2: Domain Parking Ecosystem

Domain parking services have a significant hold in the domain industry. Table 1 shows some of the most popular parking services investigated in our study. By looking at the ranks of the domain names associated with the companies running these parking services, we find that many of them are ranked among the top 100k by Alexa [2]. Also shown in the table is the total number of parked domains observed on Feb. 25^{th} according to *DailyChanges* [34]. Note that the list maintained by DailyChanges is not comprehensive. Nevertheless, it is quite clear from Table 1 that parking services indeed cover a large number of domains. Here we describe our understanding of its ecosystem, based on our analysis of a large amount of data collected from the domains under leading parking services. Such an understanding also leads to the suspicion of illicit activities within this ecosystem which motivates this research.

Infrastructure. Figure 2 illustrates the infrastructure of the domain parking ecosystem, as revealed by the redirection chains observed during our crawling of parked domains. Those domains are the *start nodes* for the

#	Parking Service	Alexa [2] Global Rank	DailyChanges [34] # Parked Domains	Our data set # Parked Domains	Our data set # Monetization Chains

Table 1: Top 10 Parking services in our data set. The number of monetization chains is not the same as the number of parked domains since each parked domain was crawled multiple times during our collection period. Note that parking services found in this paper to carryout illicit activities are anonymized as "PS#".

whole ecosystem. They include expired domains with back links, blacklisted domains (e.g., exploit servers or TDSes [17]) seized or taken down then repurchased by domain owners or newly acquired domains. As illustrated in the figure, parked domains forward their traffic to parking services, which in turn select the most profitable monetization option in real time, based upon a set of characteristics of the traffic such as its geolocation, browser type and domain keywords. Occasionally, a parking service chooses to forward the traffic to another parking service when the latter offers a higher return on a specific traffic instance. In addition, a parking service may collaborate with *traffic monetization platforms* (e.g. `Skenzo.com`), which monetize different types of traffic such as parking traffic, error traffic (i.e. `404` not found pages) and non-existent domains. Here, we refer to this type of partnership as parking syndication.

The end targets of any traffic monetization option can be either an advertiser, a traffic buyer or a brand name, which are the *end nodes* of the infrastructure.

Potential illicit monetization activities. In our study, we discovered, during our crawling of parked domains, some suspicious activities that call into question the legitimacy of some monetization operations. Specifically, we found that some URLs on the redirection chains initiated by our crawler contain patterns related to the delivery of clicks, for example, "`http://fastonlinefinder.com/ads-clicktrack/click/newjump1.do?`". The problem is that our crawler never clicked on any URLs. It just visited a parked domain and followed its (automatic) redirection chain (see Section 2.3). Also, we observed a lot of "shady" search websites (e.g., `fastonlinefinder.com`), which look like search engines but return low-quality ad results. Those search sites are also observed in prior research [18, 4] and have been presumed to be related to malicious activities like click fraud and malware delivery.

However, confirming the presence of illicit activities in domain monetization is challenging. Take click fraud as an example. We need to determine whether the crawler traffic has indeed been monetized as clicks, which can only be confirmed at the advertiser end. Further complicating this attempt is the observation that some parking services try to make the click delivery look like zeroclick monetization (PPR) by bouncing the traffic through entities with indications of "zeroclick" in the URL: for example, a visit to a parked domain is initially redirected to `http://bodisparking.com/tracking?method=zeroclickrequest` before moving to the click URL. Also, malware scanning cannot find any malicious payloads from the traffic collected from parked domains. Most importantly, given that the traffic for domain monetization goes down a complicated redirection chain, including ad networks and parking-service syndication, it becomes highly nontrivial to identify the party responsible for a malicious activity, even when its presence has been confirmed.

2.3 Overview of Our Study

Here we describe at a high level what we did in our research to understand the suspicious activities that happen within this domain parking ecosystem.

Data collection. As discussed above, the data used in our study was collected from crawling parked domains. For this purpose, we implemented a dynamic crawler as a Firefox extension and deployed it to 29 Virtual Machines (VMs). The crawler is designed to simulate a user's visit to a URL through a browser by rendering its content and running scripts. All such content and HTTP traffic (such as redirections) generated are collected and dumped into a database. In this way, the crawler is able to gather the information produced by execution of dynamic content.

Those crawlers worked on a list of parked domains, which was updated every 3 days during the past 5.5 months (August 1st, 2013 to January 20th, 2014). Those domains were discovered by reverse-lookup for the NS records of known parking services (a list built manually) using the *PassiveDNS* set (DNS record collection) provided by the Security Information Exchange [30]. In order to investigate the monetization activities through those domains, we constructed a *monetization chain* for each URL visit. A monetization chain is a sequence of URL redirections (e.g. HTTP 302, iFrame tags, etc.) observed during a visit to a parked domain, including ad networks and traffic systems related to monetizing the visit.

During each visit, each crawler randomly picked one of 48 user agent strings covering popular browsers, operating systems and mobile devices. Overall, we made about 24M visits to over 100K parked domains. From all those visits, we identified 1.2M (5%) monetization chains including redirections (not direct display of ads).

The leading parking services involved in those chains are presented in Table 1.

Infiltration and expansion. To identify illicit activities involved in the monetization of parked domains and understand the scope and magnitude of the problem, we performed an infiltration study on the domain parking ecosystem to gain an "insider" view about how those parking systems operate. This is critical for overcoming the barriers mentioned in Section 2.2. More specifically, we ran our crawlers to collect data from parked domains and also parked domains under our control with major parking services. Additionally, we launched a few ad campaigns and also purchased traffic associated with some keywords. By carefully selecting the parameters at our discretion, we were able to "connect the dots", linking the start nodes (domains) or traffic sources (crawlers) under our control to our end nodes (ad or traffic purchase campaigns) on monetization chains. Those chains (called *seeds*), together with the accounting information we received from related parking services and ad networks, reveal the whole monetization process with regard to our inputs. This enables us to identify the presence of click fraud, traffic stealing (failing to report monetized traffic) and traffic spam (low-quality traffic). We elaborate this research in Section 3.

To understand the impacts of those fraudulent activities, we extracted from the seed monetization chains a set of fingerprints, or *stamps*, to identify the monetization method used. Once a monetization chain is identified as either PPC or PPR, we infer the presence of illicit activities. Our research shows that our approach accurately identifies illicit monetizations through known ad networks and traffic systems. Most importantly here, this approach helps us *expand* those seeds to a large number of monetization chains collected by our crawlers. Over those chains, we performed a measurement study, which shows the pervasiveness of the problems, their unique features and the profits the parking services get from the illicit activities. The study and its outcomes is reported in Section 4 and Section 5.

Adversary model. In our research, we consider that the parking service is untrustworthy, capable of manipulating the input traffic it receives and its accounting data to maximize its profits at other parties' cost. It also cloaks frequently to avoid being detected by third parties. On the other hand, the service cannot change its interfaces with legitimate ad networks: it needs to make the right calls to deliver its traffic to the networks. In the meantime, some less reputable ad networks (2nd-tier or lower) may not be trustworthy either, which adds complexity to assigning blame to different parties involved in a known fraudulent activity.

In practice, parking services are actually legitimate companies. What we found is that they apparently behave legitimately most of time but are indeed involved in illicit operations occasionally. This adversary is actually very unique, since they blur the lines between fraudulent and legitimate transactions and conduct operations with highly questionable practices.

3 Dark Side of Domain Parking

In this section, we report on our infiltration of the domain parking ecosystem. As discussed before, what we did is to control traffic sources (crawlers), some start nodes (parked domains) and some end nodes (ad campaigns & traffic purchases) of the ecosystem, to get end-to-end monetization chains going through them, as depicted in Figure 3. The figure shows that the chains are as follows: from our parked domains to our end nodes, that is, advertisers or traffic buyers (in black); from other parked domains to our end nodes (in red); from our parked domains to other end nodes (in green) and from our crawlers but not through our domains or end nodes (in blue). Among those chains, the black and red chains connect our traffic source, crawler, to our end nodes through parked domains, which are used as the ground truth for validating our findings (Section 3.3) and the seeds for detecting illicit activities on other chains (Section 4).

Below we describe how we infiltrated the ad networks and direct traffic navigation systems on the end-node side and the parking services on the start-node side.

3.1 Infiltrating End Nodes

Here we walk through our infiltration of the end nodes of the ecosystem, which includes a few steps: we need to identify the right targets (ad networks or traffic systems), register with them, launch ad campaigns and set the right parameters to maximize the chances of receiving our own crawling traffic.

Target identification and registration. To identify the most popular targets, we inspected a sample dataset, including monetization chains collected during the first two weeks of August 2013, to collect a set of the most prevalent top and 2nd-tier ad networks and direct navigation systems. This turned out to be rather straightforward for some targets (e.g., the `Looksmart` ad network with a domain name `looksmart.com`), but not so for others. For example, for some ad networks (e.g. `Advertise`), only the domains of the "shady" search websites they utilized showed up on their click URLs; the "masters" of those search domains were not revealed from their `whois` records, which indicated either an anonymous registration or missing organization names. To uncover those ad networks, what we did include using a domain's Autonomous System Names (ASN) or other domains sharing its IP addresses to determine its affiliation, as well as comparing an ad network's contact

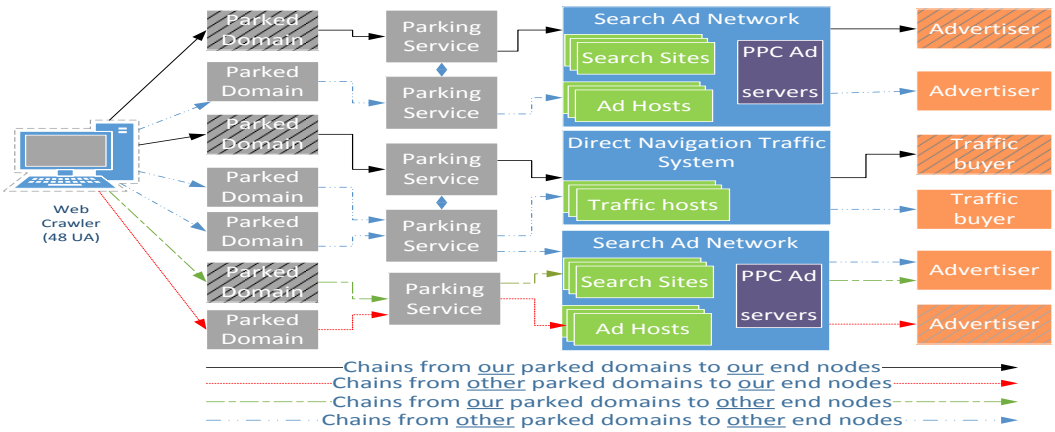

Figure 3: Types of monetization chains captured in our data set where the dashed boxes represent entities under our control.

information with that on the domain's `whois` record.

Once a set of targets (ad networks and traffic systems) were identified, we attempted to register with them as an advertiser or a traffic buyer. This happened with fake identities whenever possible, for the purpose of concealing our true identity to avoid cloaking activities, but we had to use our real information for some of them, which asked for IDs such as driver's license and a credit card. All together, we successfully affiliated ourselves with 15 out of 25 top ad networks and traffic systems identified. For those we failed to do so, the main cause was that they only accepted large-budget customers.

Campaign creation and parameter tuning. We set up a search-like website (Figure 7 in Appendix) and hosted it on three domains, one for traffic purchasing and the other two for advertising. Using those domains, we created both advertising and traffic purchasing campaigns. Specifically, for each of them; we selected 10 keywords related to *our own parked domains*, and also constructed our target URLs, given to the ad networks or traffic systems, to communicate a set of data (e.g., ad network names, publisher IDs, keyword used, etc.) to be used to identify monetization chains that end at our websites through our crawlers. Table 2 summarizes our infiltration meta-data.

For each campaign, we carefully adjusted its parameters to maximize the chances of getting traffic from our own crawlers, which provided us with the end-to-end monetization chains we were looking for. The strategies for such parameter tuning varied across different ad networks and traffic systems. Specifically, some of them offered geo-targeting, which we leveraged to aim at the city our crawlers were located. When this was not available, we tried to take advantage of other features such as browser type and timing when offered. Particularly, for the browser feature, our campaign opted to target the least common browser type, which our crawlers also used for their user agents. Additionally, the timings of some campaigns were tuned in a way that they only ran when traffic from sources other than our crawlers was minimal, for example, from 12AM-6AM and 10PM-12AM. As an example, the direct navigation traffic system `DNTX` provided only country-level geo-location and the platforms (iOS, Android, BlackBerry and others) under its mobile/tablet category. In this case, we targeted our campaigns at the country our crawlers were running from and the Blackberry platforms.

Overall, we ran advertising and traffic campaigns through all 15 ad and traffic networks starting from Nov. 22nd last year, which cost us $2,260 in total. The logistics of our end node infiltration campaigns are summarized in Table 3. Among those campaigns, the two with `Admanage` lasted for only two days before we were locked out from our account for almost a month without giving any explanations. Also, our campaign with `Approved Search` did not receive any traffic that fit our targeting criteria.

3.2 Infiltrating Start Nodes

To infiltrate start nodes, we went through top 10 most popular parking services identified from our sample dataset (Section 3.1), opened accounts with them and carefully chose our monetization options so as to maximize the chance of observing illicit activities.

Parking service registration. Among all the services we tried, `Domain Power` asked for real identity information, which we skipped, and `trafficZ` turned down our application, citing the small volume of traffic our domains received. Other parking services performed some type of authentication, such as sending a PIN number to a valid phone number, and verifying the consistency between the owner information on our domains' `whois` records and that on our application. We passed those checks and used fake identities to register with 7 parking

Note that `7Search` offered both PPC and PPR campaign types and as such, we created two campaigns with it, one for each type.

services as illustrated in Table 4. Most of these services are indeed popular as shown earlier in Table 1.

#	Parking Service	# Parked Domains
1	PS5	9
2	PS2	2
3	PS6	6
4	PS1	4
5	PS4	3
6	Rook Media	2
7	PS7	2

Table 4: Parking Infiltration Logistics. Note that the total number of domains does not add up to 23 which is due to moving some domains between parking services. Note that PS7 is not shown in Table 1 as it is not in the top 10 parking services.

Domain monetization. We purchased 23 domains under a number of top level domains and parked them with the 7 services. The names of those domains were carefully chosen to match the keywords we targeted in our campaigns (see Table 2). We also set their NS records to point to those of their corresponding parking services, with some exceptions discussed later.

Our preliminary analysis on data crawled from parking services showed that suspicious activities were only observed on redirection chains. Therefore, we tried to avoid situations like PPC listings, where a set of PPC ads are displayed on a parking landing page. Instead, we chose not to have such a page (displaying signs like "for sale"), so the parking services can monetize the traffic our domains received through redirections. Actually, one parking service, `Bodis`, allowed us to explicitly set this monetization option by redirecting the traffic instead of setting the NS record to `Bodis`. For example, we parked the domain `news-network.biz` with `Bodis` by using the GoDaddy forwarding service to send our domain traffic to `http://bodisparking.com/news-network.biz`.

3.3 Findings

Through infiltrating the start and end nodes of the ecosystem and crawling domains hosted by popular parking services, we were able to collect 1,015 monetization chains that link our crawlers to our end nodes (our advertising or traffic purchase websites), sometimes through our start nodes (parked domains). Using those chains as the ground truth, we confirmed the presence of illicit activities during parked domain monetization, including click fraud, traffic spam and traffic stealing, as elaborated below.

Click fraud. Out of all the ad clicks delivered to our advertising websites through parking services, 709 were found to come from our own crawlers. They are clearly fraudulent since our crawlers were designed not to click on any ad (Section 2.3). Table 3 details the number of clicks received from our crawler through each ad network.

Traffic spam. The 4 traffic purchasing campaigns we launched received 306 traffic hits from our crawler through domains parked with parking services. Upon examining the parked domains that served as the start nodes on those monetization chains, we found that 83 of them were totally unrelated to the keywords we purchased from the direct traffic systems. Table 5 provides examples of spam and good-quality traffic.

Keyword	Spam	Not Spam
Music	19jj.com, ib2c.com.cn	thepiatebay.org, itunesstore.de

Table 5: "Spam" and "Not Spam" examples of parked domains appearing in traffic purchase monetization chains leading to our traffic buyer website. "Others" represents instances where the purchased keyword was not propagated through to our traffic buyer URL but it is still evident from the spam examples that they are not related to any of the 10 keywords we purchased.

Traffic stealing. Occasionally, parking services were found to be dishonest with domain owners, failing to inform them for part of the revenue they were supposed to share with the owners. Specifically, we cross-examined the revenues of the domains under our control and the billing reports for the ad/traffic campaigns we launched. This revealed that some monetization chains going through our parked domains were not reported to us (domain owners) but charged to our campaign accounts.

For example, we confirmed the existence of traffic stealing from monetization chains captured by our crawler connecting three of our domains (parked with PS5) and our PPR campaign with `7Search`. This was achieved through comparing the billing reports provided by `7Search`, the parked domains' revenue reports provided by the parking service and the related monetization chains with the right combination of time stamp, source IP address, referral domain and keyword. It turns out that we, as a campaign owner, were billed for 23 traffic hits by `7Search` (see Figure 6(b) in Appendix) but nothing was reported by the parking service (see Figure 6(a) in Appendix) in December 2013. We show the breakdown of the crawlers' traffic in Table 6. Clearly, the parking services kept the rightful share away from us as the owners of the parked domains. Note that not all requests from our crawler were billed by `7Search` because they limit the traffic hits by one IP address and a valid visiting period (our campaign was set to run between 12AM-6AM and 10PM-11:59PM). Additionally, we found other monetization chains, captured by our crawler and monetized by the same parking service through other ad networks such as `Advertise` that have not been reported on our parked domains' revenue reports.

4 Fingerprinting Monetization Chains

Through the infiltration study, we confirmed the presence of illicit activities in the monetization of parked domains. What is less clear, however, is the pervasiveness and impact of those activities. Understanding of this issue cannot rely on the 1,015 seed chains (reported in Table 3) whose traffic sources and end nodes were under our control. We need to identify the illicit operations occurring on other monetization chains, particularly those blue and green ones in Figure 3, which do not connect to our ad/traffic campaigns. To this end, we developed a technique that fingerprints the monetization options observed on our seed chains. These fingerprints, which we call *stamps*, were used to "expand" the seed set, capturing the illicit activities on other monetization chains collected by our crawlers over months.

4.1 Methodology

The idea. As discussed above, the problem of detecting illegitimate operations, which we did not have a direct observation of, comes down to identifying the monetization options they involve. More specifically, as soon as we know exactly how a parking service monetizes a visit from our crawler, we can immediately find out whether a fraudulent activity occurred: clearly, the PPC option is a fraudulent click, as our crawler never clicked; when it comes to PPR, we check the consistency between the keywords expected by the end nodes and the names of the parked domains the traffic went through (see Section 5 for details). Therefore, the question here becomes how to determine which options have been used in a given monetization chain.

Actually, even though those options might not be evident on a monetization chain, we know that it must go through a corresponding monetization party (ad networks, traffic systems, etc.) before the traffic gets to the end node. This needs to happen for accounting purposes: for example, if a click has not been sent to a PPC ad network, the ad network never knows about it and therefore will not be able to pay its publisher or bill its advertiser. Also, the last few URLs leading to the end node are clearly related to the monetization party. As an example, let us look at a monetization chain captured by our crawler in Table 7, which was initiated by a visit to a domain parked with `PS1` and ended at our advertiser site. Looking backward from our URL along the chain, we can see two URLs from `fastonlinefinder.com`, a search website. The site turns out to be affiliated with the `Advertise` ad network. Interestingly, once we compare this path with other chains also through the same ad network, it becomes quite clear that they carry a unique pattern: first, right before the end node, the last two URLs are always similar; second, for these two URLs, even though they vary across different chains in terms of search websites, the remaining part mostly stays constant. This observation was further verified by the click URLs for sponsored ads from the same ad network, which we obtained by registering with `Advertise` as a publisher (see Appendix for details on search sites and sponsored click URLs).

The above example shows that we can leverage the ordered sequence of URL patterns to determine the presence of a monetization option. Such a sequence is a "stamp" we utilize to expand our seed set to find other illicit monetization chains within the dataset collected by our crawlers. Following we describe the methodology

#	URL	Description
1,2	http://bastak-taraneh.com/	Parked domain
3	http://otnnetwork.net/?epl=...	Parking service anchor
4,5	http://67.201.62.155/index2.html?q=...&des=	AdLux
6	http://21735.1b2a3r4w5dgp6v.filter.nf.adlux.com/ncp/checkbrowser?key...	ad network (syndicate)
7	**http://fastonlinefinder.com/ads-clicktrack/click/newjump1.do?...&terms=ticketsoftware...**	Search site for
8	**http://fastonlinefinder.com/ads-clicktrack/click/newjump2.do?terms=ticketsoftware&...**	Advertise ad network
9	http://anwers.net/search.php?s=advertise...&kw=software...	Our Advertiser

Table 7: End-to-End monetization chain example of a visit to a parked domain leading to our advertiser page. For clarity sake, we omit parts of the URLs.

for clustering and generalizing URLs from a monetization party, and extracting the stamps from the URL patterns.

URL-IP Cluster (UIC) generation. A specific URL of a monetization party (ad network, traffic systems, etc.) can be too specific for fingerprinting its monetization activity. An ad network can have many affiliated websites and each site may have multiple domains and IP addresses. To utilize such a URL for generating a stamp, we first need to generalize it across those domains, addresses and potential variations in its file path and other parameters. To this end, we clustered related URLs into *URL-IP clusters* (UIC). A UIC includes a set of IP addresses for related hosts and the invariant part of the URL (without the host name) across all members in the cluster. The former describes the ownership of this set of URLs and the latter represents their common functionality, which together fingerprints a monetization option with regard to an ad network or a traffic system.

To cluster a group of URLs into UICs, we first extracted the host part of a URL, replacing it with all IPs of the domain, and then broke the remaining part of the URL into tokens. A token is either the full path of the URL including file name (which is typically very short for a monetization URL) or an argument. The value of the argument was removed, as it can be too specific (e.g. keyword and publisher ID). Over those IP-token sets, we ran a clustering algorithm based upon Jaccard indices for both IPs and tokens, as follows:

1. Each URL (including an IP set and a token set) is first assigned to a unique UIC.

2. Two UICs are merged together when *both* their IP sets and token sets are close enough (Jaccard indices above their corresponding thresholds).

3. Repeat step 2 until no more UICs can be merged.

A pair of thresholds are used here to determine the similarity of two IP sets (T_{ip}) and two token sets (T_{tok}) respectively. In our research, we set T_{ip} to 0.1 and T_{tok} to 0.5, and ran the algorithm to cluster all the URLs on the 1.2M monetization chains collected by our crawlers. By replacing individual URLs with their corresponding UICs, we obtained 429K unique generalized chains, which were further used to detect illicit activities.

Stamp extraction. The stamps for different monetization options were extracted from seed monetization chains, after generalizing them using the aforementioned UICs. Specifically, we utilized 715 UIC chains (generalized from the 1,015 chains reported in Table 3) to fingerprint 11 ad networks and traffic systems, with one stamp created for all the campaigns associated with a given ad network or traffic system. For this purpose, we applied a 2-fold cross-validation approach to generate stamps and assess their effectiveness. Specifically, we randomly split the UIC chains for each campaign into two equal sized sets, one for stamp extraction (training) and the other for stamp evaluation (test). Over the training set, we determined a stamp by traversing each UIC chain backwards and selecting the sequence of UICs shared by *all* the chains involving a certain ad network or traffic system. Typically the longest sequence identified in this way became the stamp for all the chains going through its related monetization organization. However, for a campaign with a small number of UIC chains (e.g. `BingAds`), we only utilized the last common UIC (right before our advertiser's URL) across all the chains as the stamp.

All together, our approach generated stamps for 11 ad networks and traffic systems. Ad network stamps contained on average two UICs while traffic system stamps were mostly one UIC in length.

4.2 Evaluation

False negative. Using all the 11 stamps generated from the training set, we analyzed all the monetization chains within the test set. For each campaign, its stamp was found to match all of its monetization chains in the test set and thus no false negative was observed.

False positives. We further evaluated the false positive rate that could be introduced by the stamps on a dataset containing 768M redirection chains collected by crawling the top 1M Alexa websites [2] Jan 21-31, 2014. The purpose here is to understand whether a redirection chain not involving clicks or traffic selling can be misidentified as a related monetization chain and whether the monetization chains of one ad network or traffic system can be classified as those of another party. By applying our stamps on the dataset, we flagged 12 chains as matches to click stamps and another 19 chains as matches to traf-

fic stamps. Upon manually analyzing the 12 click chains, we found that all of them were actually fraudulent clicks generated by parking services (10 chains) and a traffic/ad network named CPX24 (2 chains). CPX24 in our case generated clicks on its own hosted ads when traffic from publishers flowed in. For the 19 traffic chains, they were indeed PPR monetization chains. Further, by manually searching for a set of ad network specific domain names such as `affinity.com` within the Alexa dataset, we discovered a number of redirection chains going through the same ad networks fingerprinted by our stamps but *not* involving any clicks (e.g. ad display and conversion tracking URLs). None of them were misidentified by our stamps as click-based monetization chains.

Discussion. Our evaluation shows that the stamps generated over UICs accurately capture all monetization chains associated with a specific ad network or traffic system. However, those stamps are designed for analyzing the traffic through individual organizations, which is enough for our purpose of understanding the scope and magnitude of fraudulent activities, not for detecting those operations on any monetization chains, particularly those belonging to other monetization parties. Also note that we cannot use existing ad-blocking lists such as EasyList [26] to serve our goal, due to its limitations: first, EasyList does not distinguish between a click and an impression (ad display); second, search websites used by ad networks to deliver clicks are not covered by the block list; finally, the list fails to include the hosts and URLs of traffic monetization systems.

5 Measurements

In this section, we report our measurement study on illicit parked domain monetization. This study is based upon a dataset of 1.2M monetization chains collected in a 5.5-month span. Such data were first labeled using the "stamps" generated (Section 4.1) from the seed data to identify the monetization options associated with individual chains, and then analyzed to understand the pervasiveness of illicit monetization practices and its financial impact. Here we elaborate on the outcomes of this study.

5.1 Dataset Labeling

Expansion. To perform the measurement study, we labeled the 1.2M monetization chains collected from crawling parked domains by "expanding" the 1,015 seed chains (the ground truth) to this much larger dataset. Specifically, we generated UICs over those 1.2M chains, generalized the seed chains using those UICs, and then extracted click and traffic stamps from the seeds as described in Section 4.1. Matching those stamps to the generalized UIC chains in the larger dataset (429K UIC chains), we were able to label 120,290 (28.03%) UIC chains corresponding to 212,359 (17.1%) URL monetization chains. The labeled set includes two monetization options, PPC (45.7%) and PPR (56.3%) where 2% of them include both PPR and PPC monetizations on the same chain as explained later.

Unknown set. Although many chains were successfully labeled, there are almost 308K UIC chains in the dataset not carrying any stamps, which were marked as "unknown". Looking into this unknown set through random sampling, we found that it exhibited consistent patterns related to click delivery and traffic selling which can be added to the labeled set if we had verified seed chains. For example, we found many other ad-nets such as `Adknowledge` and `Bidvertiser` (2.9%), and other traffic monetization systems such as `Adrenalads` and `ZeroRedirect` (19.5%). Particularly, `Sendori`, a traffic platform, is widely present, covering 5.4% of the chains in the dataset. 2.6% of those chains actually led to domain name marketplaces such as `SnapNames`, and a large portion (over 19.7%) of them stop at some parking services and traffic monetization platforms (e.g. `Skenzo`) with error messages indicating cloaking behavior.

5.2 Monetization Decisions

Over the labeled dataset, we analyzed the parties responsible for such decisions and the way those decisions were made, based on a categorization of the parked domains involved.

Monetization decision maker. Finding the party that chooses a monetization option is important, as it tells us who is the ultimate culprit for an illicit activity. However, this is challenging, due to the syndication of multiple monetization parties, among parking services, ad-nets and traffic systems. Within our dataset, we found that these types of syndications are pervasive (49.5%). As an example, `AdLux` in Table 7 is actually a syndicate of `Advertise`, displaying its ads and sharing its click revenue. In the presence of a syndication, a starting node's parking service may not be responsible for the follow-up illicit monetization, which could actually be performed by one of its syndicates. To this end, we identify the parking service of the starting node to be the responsible party of a monetization chain only when the click or traffic stamp appears right after the starting node (i.e. parked domain). When there are other entities between the parked domain and the stamp, we use a *parking-service anchor* as described below.

Typically, a parking service funnels the traffic from its parked domains to a "controller" domain, which we call a parking service (PS) anchor, for choosing a monetization option. Our idea here is to locate the PS anchor right before a click or traffic stamp. When this happens, the owner of the anchor is clearly responsible for

the monetization decision. To this end, we picked out the most prevalent second UICs down individual monetization chains (which is expected to cover over 50% of all the chains associated with a specific parking service), and identified its ownership using its `whois` records and Name Server. Such a UIC is considered to be an anchor for the parking service.

In our research, we identified anchors for 4 of the most prevalent parking services in our set. Some parking services such as `PS6` and `PS4` launder all the traffic through direct navigation traffic systems (`DNTX` and `ZeroRedirect` respectively) which are owned by the parent companies of the two parking services. Since those traffic systems are used by other clients, we did not consider them to be the anchors of the parking service. Using the heuristic described earlier (i.e. direct link from a parked domain to a stamp) and the list of anchors, we assigned each monetization chain to the parking service responsible for the selection of its monetization option, as illustrated in Table 8. Here the "unknown" category includes the chains we could not determine the parties responsible for their monetizations, due to the disconnection between the parked domain or PS anchor and the click or traffic stamp, with unknown UICs standing in-between. For example, the chain in Table 7 was marked as "unknown", as the known anchor `http://otnnetwork.net/?epl=` is separated from the ad stamp there.

Impacts of domain categorization. As discussed before, our research focuses on the redirection chains generated by 1.2M out of 24M visits to parked domains. The rest of those visits only resulted in a simple display of PPC ads, which were less likely to be used for illicit monetization. The fact that those redirection chains were so rare to see here can be attributed to IP cloaking. In the meantime, we believe that this is also caused by the way that traffic from different domains is monetized. Specifically, a parking service like `Bodis` often classifies domains into "primary" or "secondary". Primary domains are those accepted by top-tier search networks (e.g. `Google AdWords`) to display their ads while secondary ones are less trusted, including those serving malicious content before taken down and the ones related to typos of trade or brand names. The secondary domains here are much more likely to lead to redirection chains, as discovered in our research (illustrated by Figure 4). Among all domains visited by our crawlers, we found (using [6]) that only 2.9% of them were considered to be secondary, which naturally limits the number of the redirection chains we could observe.

5.3 Illicit Monetization

In this section, we report our findings about the prevalence of illicit monetization practices, particularly click

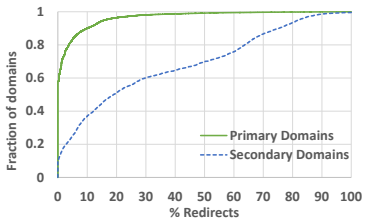

Figure 4: Tendency towards redirect monetization of "secondary" domains. "% Redirects" represents the percentage of redirection chains observed per parked domain.

		PS5	PS6	PS1	PS2	Others	Unknown
PPC Ad-nets	adMarketplace	1		9,526	1670	4	35,704
	Advertise	10,277		2,329		730	3,576

	Trellian - Malware					1	
	AdsPark -Spam		1,755				2,183
	AdsPark - Malware						1
Totals		18,803 (11.02%)	22,425 (13.15%)	13,808 (8.1%)	1,673 (1%)	39,872 (23.4%)	73,949 (43.4%)

Table 8: Illicit activities observed by parking services in the labeled set. "Others" refers to some of the parking services shown in Table 1 not necessarily anonymized.

fraud, traffic spam and the malware distribution discovered during our analysis of the labeled dataset. Note that we did not measure traffic stealing, as this activity could only be observed on the monetization chains whose start and end nodes were under our control.

Traffic spam. Using the traffic stamps, we discovered 119K (56.3%) traffic monetization chains. To identify the presence of traffic spam on each of those chains, we compared the keywords associated with its start node domain with those of its end node (assuming that end nodes purchased keywords related to the contents of their domains). This works as follows:

• *Keyword generation*. To generate keywords for both the start and end nodes, we used a keyword suggestion tool by `BingAds` [1], a tool widely used by advertisers to select keywords for ad targeting. This tool automatically created a list of keywords (including typos) for each domain (start and end nodes).

• *Keyword filtering*. At this step, we cleaned the list of keywords, discarding common ones ("www", "com", etc.). Specifically, we calculated the normalized entropy of each word as the prior work did [31] and then removed the 50 words with the lowest entropy (i.e. highly popular). Also dropped from the keyword list were determiners, pronouns, interjection and "wh"-words ("what", "where", etc.), which are unlikely to be related to specific

domain content. For this purpose, we filtered out the keywords using *Stanford CoreNLP* [35], a natural language processing tool for part-of-speech tagging and stemming.

• *Keyword matching*. Comparing the keywords of the start node (i.e., parked domain) with those of the end node (traffic purchase website) on a monetization chain, we considered the chain to be traffic spam if individual keywords of its parked domain did not match *any* words associated with its end node. In the case that one of these two domains do not have any keywords, we attempted to match the other domain's keywords to its domain name. If this attempt succeeds, the chain would not be considered as spam, otherwise; it would.

As a result, we found that 70.7% of all PPR monetization chains are traffic spam as illustrated in Table 8 and attributed to each parking service and traffic system. Table 9 provides some traffic spam examples received by popular brand names.

End node	Parked domain examples
Amazon.com	craigslits.com, 14.de, audii.de
Apple.com	acgeo.com, backlinkscenter.info
Coupons.com	4google.com,agendo.com
Sears.com	uasairways.com, cursoblogger.com
Expedia.com	pizzahutjobs.com, financetasksforce.com

Table 9: Examples of end nodes receiving spam traffic.

Click fraud. All labeled 97K (45.7%) PPC monetization chains are clearly fraudulent clicks, as our crawlers never clicked on any ads. Table 8 provides a breakdown of fraudulent clicks observed from each parking service through ad-nets for which we have a click stamp. By taking a close look at the ad-nets involved, we found that none of the fraudulent clicks on the top-tier networks (`Google AdWords` & `BingAds`) could be attributed to a parking service, due to ad-net syndications. Parking services avoid clicking on top-tier ad-nets' ads because they have a better click fraud detection system than 2nd-tier networks and as such they only happen through ad-net syndication. Additionally, 2% of the fraudulent clicks could not be attributed to a parking service due to the presence of a traffic stamp between the start node (i.e parked domain) and the click stamp. For example, domains parked with `PS6` resulted in fraudulent clicks through a traffic system (`DNTX`) which is owned by the same parent company of `PS6`, namely `TeamInternet AG`.

Also interesting is the observation that not only were the clicks delivered through those chains completely fraudulent but they often came from parked domains that had nothing to do with the ad campaigns at the end nodes. Specifically, we applied the keyword generation and matching approach described above to analyze the relations between the parked domains on those chains and their corresponding end nodes. This study reveals that 61.3% of the fraudulent clicks were from parked domains completely unrelated to the end nodes on their chains. Also given the fact that the average cost-per-click (CPC), which is $0.28, is twice as much as the average cost-per-redirect (CPR) that we paid, there is no legitimacy whatsoever in such click-faking activities.

(a) Revenue Estimates

	P_{FPPC}	P_{PPR}	P_{TS}	P_{PPC}	P_{PPA}	$\frac{Rev_{Fraud}}{Rev}$
PS5	0.01	0.01	0.78	0.97	0.0057	40.3%
PS1	0.0015	0.0003	0.77	0.998	0.00003	7.4%
PS3	0.0004	0.004	0.71	0.995	0.0001	9.3%
PS2	0.0001	0.0000004	0.7	0.9997	0.00016	0.8%
PS6	0	0.015	0.66	0.983	0.0015	18.5%
PS4	0	0.0073	0.64	0.976	0.017	10%

(b) Description of variables used.

Legitimate	P_{PPC}	Probaility of monetization through the display of Pay-Per-Click (PPC) ads.
	P_{PPR}	Probability of monetization through Pay-Per-Redirect (PPR).
	P_{PPA}	Probaility of monetization through affiliate marketing, Pay-Per-Action (PPA).
Fraudulent	P_{FPPC}	Probability of monetization through a fraudulent click on a Pay-Per-Click (PPC) ad.
	P_{TS}	Probaility of monetization through traffic spam in Pay-Per-Redirect (PPR).

Table 10: Estimates of illicit monetization revenues for selected parking services.

Malware distribution. Also discovered in our research is parking services' involvement (probably unwittingly) in malware distribution. We found that many PPR monetization chains were leading to malicious content, either through drive-by downloads or through social engineering scams such as FakeAV or flash player updates (see Figure 8 in Appendix). This occurred because the traffic systems involved did not do their due diligence in detecting the traffic buyers who actually disseminate malware. Using content structure clustering, a technique applied by prior research [13], we concluded that *at least* 3.7% of the PPR traffic buyers spread malware. This illicit activity not only hurts the victims visiting a parked domain but also affects the parked domain when it gets blacklisted by URL scanners such as SafeBrowsing [12], which reduces the monetary value of the parked domain when its owner decides to sell it.

5.4 Revenue Analysis

Model. As discussed before, parking services are unique in that their monetization operations involve both legitimate and illegitimate activities. To understand the economic motives behind this monetization strategy, we analyzed their revenues with a model derived from that used in prior research [23]:

$$Rev = Visits \cdot (Rev_{Fraud} + Rev_{Legit})$$

where the total revenue Rev is calculated from the total number of visits and the average revenue for each visit. This average revenue is further broken down into two components, the part from illicit monetization (Rev_{Fraud}) and that from legitimate monetization (Rev_{Legit}). These components were further estimated as follows:

$$Rev_{Fraud} = P_{FPPC} \cdot CPC + P_{PPR} \cdot CPR \cdot P_{TS}$$
$$Rev_{Legit} = P_{PPC} \cdot p_{pclk} \cdot CPC + P_{PPR} \cdot CPR \cdot P_{\widetilde{TS}} + P_{PPA} \cdot p_{pact} \cdot CPA$$

Intuitively, the above two equations describe five possible situations when a visit to a parked domain is monetized: illicit activities (click fraud or traffic spam) or legitimate ones (legitimate click, direct traffic or affiliate marking monetization). The revenue component from the illicit activities is estimated using the probability of click fraud P_{FPPC} and that of traffic spam $P_{PPR} \cdot P_{TS}$, where P_{PPR} is the probability of direct traffic monetization (PPR) and P_{TS} is the chance of traffic spam when PPR is chosen, together with the revenues for a click *CPC* and a redirect *CPR*. Similarly, the legitimate revenue component comes from a PPC display (with a probability P_{PPC}) given that a user clicks on one of the ads (with a click-through rate p_{pclk}), type-in traffic (P_{PPR}) when it is *not* subject to traffic spam (with a probability $P_{\widetilde{TS}}$), or affiliate marketing (P_{PPA}) when the user performs the operation expected (with a probability p_{pact}). The revenues for those legitimate activities are *CPC*, *CPR* and *CPA* respectively.

Results. In our analysis, we estimated all the probabilities above (P_{FPPC}, P_{PPR}, P_{TS}, P_{PPC} and P_{PPA}) using the *larger* set of all 24M visits to 100K parked domains in a 5.5-month span (Section 2.3). Also, the click-through rate p_{pclk} and a user's probability of taking an action under PPA were both set to 0.02, and *CPA* to $0.265, all according to the prior work [23], while CPC and CPR were determined as $0.28 and $0.14 respectively, based on the average cost for our ad/traffic campaigns.

In the absence of data about the total number of visits per parking service, all we could do is estimate the portion of its income from the illicit activities to its total revenue, based upon our data. The results are shown in Table 10.

Discussion. From the table, we can see that even reputable parking services like `PS2` have at least 0.8% of its revenue come from illicit monetizations. For others, this revenue source is even more significant (e.g., 40.3% for `PS5` whom we found to be aggressive in its illicit monetizations). Revenue from fraudulent clicks is found to be zero for `PS6` and `PS4` because, as described earlier in Section 5.3, they are bouncing their traffic through their own traffic systems and as such we can not attribute fraudulent clicks to them. Note that our estimates here are very conservative, due to the cloaking those services played to our crawlers (which used a small set of IP addresses) and the limited scope of our study (which only covered 11 ad-nets and traffic systems). We expect that the ratios of illicit revenues are much higher in practice.

6 Discussion

Domain Parking Regulation. Our study uncovers the illicit monetizations by parking services but the underlying problem is even graver. Currently, there is no regulation on the behaviors of parking services, which allows them to set up arbitrary terms of services accommodating their own benefits. It is worth noting that parking services may have started to exhibit illicit monetization activities due to the decline in their revenues [3, 29]. Also, our research shows they have a tendency to profit from secondary domains illicitly (Figure 4), due to the difficulty in monetizing those domains through a legitimate channel. Protecting the advertisers' and traffic buyers' benefits in the existence of dishonest parking services is challenging because incoming traffic can be manipulated. What complicates the situation more is that ad-nets could be owned by the company who also runs parking services and the advertisers have no fair party to talk to. Further, direct navigation traffic (i.e. zeroclick) is being advocated by parking services and there is no guarantee on the quality of the incoming traffic. Our research discloses the dark side of parked domain monetization which calls for serious policy efforts to regulate parking services.

Here, we suggest several practices that could mitigate many types of illicit monetization activities when enforced. First, the advertisers should be provided with a clearer picture of the monetization activities. For example, the types of publishers should be marked out as well to advertisers besides their publishers' IDs, which helps advertisers in auditing and monitoring traffic coming from parking services. In fact, some ad-nets are already moving to such direction: for example, Affinity, a popular ad-net, distinguishes publishers by assigning them types such as "in-text" and "domain zero click". We also suggest providing traffic buyers with a way to check the integrity of incoming traffic such as passing the domain name of each start node in the referral. Enforcement and compliance of such mechanisms requires the presence of a 3rd party service (i.e. policy enforcer) in the ecosystem.

Legal and ethical concerns. There are several ethical concerns raised during our study, and we carefully designed our experiments to address them. First, we crawled our own parked domains which is problematic if we earn profit from it. To address this issue, we avoid cashing in the revenues we earned from the 7 parking services hosting our parked domains ($81.06 in total). Second, we ignore *robots.txt* served by parking services when crawling since we focused on their illicit behaviors. Other studies on malicious activities also ignore the *robots.txt* file [17, 33, 19, 7]. Third, one may question that the artificial traffic generated by our crawler

could affect the advertisers or traffic buyers. In fact, we crawled parked domains in a moderate speed and parking services have deployed mechanisms to discern artificial traffic and stop charging the advertisers when identified [28]. Lastly, we ran campaigns with ad-nets and traffic systems but there was no actual business running. The websites and advertisements we set up were coherent to the policies of ad-nets and traffic systems. There was no damage to visitors and we did not collect any Personally Identifiable Information (PII) from them.

7 Related Work

Parking services. Although domain parking services have been here for years, little has been done to understand their security implications. What comes close are the works on typo-squatting [37, 22, 9], which reveals that domain owners utilize this technique for profit. Also, prior research shows that malicious domains tend to be parked once detected [27, 17]. Most related to our research is the study on click spam [10], which focuses on click-spam detection and also mentions the possible involvement of one parking service (`Sedo`) in such activities based on its JavaScript. Such code was not found in our research. Compared with the prior work, what we did is a systematic study on the illicit activities of parking services, which has never been done before. This is made possible by the new infiltration analysis we performed. Our study not only confirms the presence of illicit operations within parking services but also brings to light their scope and magnitude.

Illicit activities in online advertising. Ad-related illicit activities have been extensively studied. Examples include click-fraud [21, 4, 5, 11, 25], drive-by-download [18], trending-term exploitation [23] and impression fraud [32]. Such prior work all looks at a conventional adversary who performs malicious activities whenever possible. The parking services, however, are very different: they run legitimate business with advertisers and ad networks. However, our study reveals that a significant portion of their revenues actually come from illicit activities, which raises the awareness about this completely unregulated business.

Infiltration into malicious infrastructure. To understand how underground businesses work, a lot of studies attempt to infiltrate their business infrastructure. Examples include the work on Spam [16, 15], CAPTCHA solving [24], blackhat SEO [36] and Pay-per-install networks [8]. Different from such prior research, we need to infiltrate the parking monetization process without disrupting its operations. This was achieved using a new approach through which we controlled some nodes on both ends of the monetization ecosystem and managed to link them together.

8 Conclusion

This paper reports the first systematic study on illicit activities in parked domain monetization. To demystify this "dark side" of parking services, we devised an infiltration analysis to gain control of some start nodes and end nodes of the parking ecosystem, and then connect the dots, sending our crawling traffic across the nodes under our control on the both ends, with the monetization entities (domain parking services, ad networks) in-between. This analysis provided us a unique observation of the whole monetization process, which enabled us to confirm the presence of click fraud, traffic spam and traffic stealing. We further expanded those seed chains to millions of monetization chains collected over 5.5 months, using the stamps of their monetization options. Over such data, our study revealed the pervasiveness of the illicit monetization practices and their revenues, which calls for policy efforts to control those illicit operations.

Appendix

The true operation of the shady search sites. `fastonlinefinder.com` is one of a large number of search sites we refer to as "shady". They are shady in that they rarely display organic results and emphasize on sponsored ads. Moreover, they have been reported in previous works on click fraud [18, 4] and have been presumed malicious to some extent. Additionally, many victims have often complained about a "redirect" malware hijacking their traffic and redirecting to these search sites as shown in Figure 5.

Through our empirical investigations, we discovered the actual role they play. We found their true operation was to act as click servers for search ads (similar to traditional click servers of other none search advertisements) and as such they are owned and operated by ad-nets. Another use of those search sites was to set the click referral and as such, the advertiser will assume their ad was displayed on the referring search site.

It is important to note here, that the use of such search sites is not illegal. It is only misunderstood due to their abuse by ad-net publishers. A fraudulent publisher will use a malware or Trojan to generate clicks on their ads and since the clicks lead to an ad-net's search sites, the

search site become wrongly accused as the malicious party.

Evidence Survey. Along our infiltration we collect a set of evidence to support our findings. We start with Figure 6 which confirms traffic stealing by one parking service that is not reporting traffic, as shown in 6(a), which have been monetized through `7search` and verified by our payment for the traffic as shown in 6(b).

Additionally, We verify the association of search sites to ad-nets by registering with two ad-nets (`Advertise` & `Bidvertiser`) as a publisher interested in displaying their sponsored ads. We set up our website with a search service that pulls organic search results from `Google` and sponsored ads from the two ad-nets we registered with. By pulling sponsored ads from the ad-nets, we verified the use of search sites as the click URLs as shown in Figure 7 which shows one click URL by `Advertise` that has the same URL tokens as the URLs in Table 7. Actually, the same website, `toppagefinder.com`, appeared also in our data set and as such was in the same UIC which was a correct association. Note that the same website used here for our publisher was also used for our advertising and traffic buying campaigns.

Finally, in Figure 8 we show examples of visits to domains parked with `PS5` leading to malware downloads through two traffic systems, namely `DNTX` and `ZeroRedirect`.

Abstract

Users increasingly rely on crowdsourced information, such as reviews on Yelp and Amazon, and liked posts and ads on Facebook. This has led to a market for black-hat promotion techniques via fake (e.g., Sybil) and compromised accounts, and collusion networks. Existing approaches to detect such behavior relies mostly on supervised (or semi-supervised) learning over known (or hypothesized) attacks. They are unable to detect attacks missed by the operator while labeling, or when the attacker changes strategy.

We propose using unsupervised anomaly detection techniques over user behavior to distinguish potentially bad behavior from normal behavior. We present a technique based on Principal Component Analysis (PCA) that models the behavior of normal users accurately and identifies significant deviations from it as anomalous. We experimentally validate that normal user behavior (e.g., categories of Facebook pages liked by a user, rate of like activity, etc.) is contained within a low-dimensional subspace amenable to the PCA technique. We demonstrate the practicality and effectiveness of our approach using extensive ground-truth data from Facebook: we successfully detect diverse attacker strategies—fake, compromised, and colluding Facebook identities—with no *a priori* labeling while maintaining low false-positive rates. Finally, we apply our approach to detect click-spam in Facebook ads and find that a surprisingly large fraction of clicks are from anomalous users.

1 Introduction

The black-market economy for purchasing Facebook likes,[1] Twitter followers, and Yelp and Amazon reviews has been widely acknowledged in both industry and academia [6, 27, 37, 58, 59]. Customers of these black-market services seek to influence the otherwise "organic" user interactions on the service. They do so through a variety of constantly-evolving strategies including fake (e.g., Sybil) accounts, compromised accounts where malware on an unsuspecting user's computer clicks likes or posts reviews without the user's knowledge [35], and incentivized collusion networks where users are paid to post content through their account [7, 8].

When (if) an attack is detected, the affected service usually takes corrective action which may include suspending the identities involved in the attack or nullifying the impact of their attack by removing their activity in the service. One approach for defense used today by sites like Facebook is to raise the barrier for creating fake accounts (by using CAPTCHAs or requiring phone verification). However, attackers try to evade these schemes by using malicious crowdsourcing services that exploit the differences in the value of human time in different countries. Another approach used widely today is to detect misbehaving users after they join the service by analyzing their behavior. Techniques used to address this problem to date have focused primarily on detecting specific attack strategies, for example, detecting Sybil accounts [10, 65, 67], or detecting coordinated posting of content [36]. These methods operate by assuming a particular attacker model (e.g., the attacker is unable to form many social links with normal users) or else they train on known examples of attack traffic, and find other instances of the same attack. Unfortunately, these approaches are not effective against an adaptive attacker. It is known that attackers evolve by changing their strategy, e.g., using compromised accounts with legitimate social links instead of fake accounts [14, 15, 35], to avoid detection.

In this paper we investigate a different approach: detecting *anomalous* user behavior that deviates significantly from that of normal users. Our key insight, which we validate empirically, is that normal user behavior in online social networks can be modeled using

[1] When printed in this font, likes refer to Facebook "Like"s (i.e., the action of clicking on a Like button in Facebook).

only a small number of suitably chosen latent features. Principal Component Analysis (PCA), a technique with well-known applications in uncovering network traffic anomalies [44], can be used to uncover anomalous behavior. Such anomalous behavior may then be subjected to stricter requirements or manual investigations.

We make the following three contributions: First, we introduce the idea of using PCA-based anomaly detection of user behavior in online social networks. PCA-based anomaly detection requires that user behavior be captured in a small number of dimensions. As discussed in more detail in Section 4, using over two years of complete user behavior data from nearly 14K Facebook users, 92K Yelp users, and 100K Twitter users (all sampled uniformly at random), we find that the behavior of normal users on these social networks can be captured in the top three to five principal components. Anomalous behavior, then, is user behavior that cannot be adequately captured by these components. Note that unlike prior proposals, *we do not require labeled data in training the detector*. We train our anomaly detector on a (uniformly) random sampling of Facebook users which contains some (initially unknown) fraction of users with anomalous behavior. Using PCA we are able to distill a detector from this unlabeled data as long as a predominant fraction of users exhibit normal behavior, a property which is known to hold for Facebook.

Second, we evaluate the accuracy of our PCA-based anomaly detection technique on ground-truth data for a diverse set of normal and anomalous user behavior on Facebook. To do so, we acquired traffic from multiple black-market services, identified compromised users, and obtained users who are part of incentivized collusion networks. Our approach detects over 66% of these misbehaving users at less than 0.3% false positive rate. In fact, the detected misbehaving users account for a large fraction, 94% of total misbehavior (number of likes). Section 6 reports on the detailed evaluation.

Lastly, in Section 7 we apply our technique to detect anomalous ad clicks on the Facebook ad platform. Where only 3% of randomly sampled Facebook users had behavior flagged by us as anomalous (consistent with Facebook's claims [32]), a significantly higher fraction of users liking our Facebook ads had behavior flagged as anomalous. Upon further investigation we find that the like activity behavior of these users is indistinguishable from the behavior of black-market users and compromised users we acquired in the earlier experiment. Our data thus suggests that while the fraction of fake, compromised or otherwise suspicious users on Facebook may be low, they may account for a disproportionately high fraction of ad clicks.

2 Overview

Our goal is to detect anomalous user behavior without *a priori* knowledge of the attacker strategy. Our central premise is that attacker behavior should appear anomalous relative to normal user behavior along some (unknown) latent features. Principal Component Analysis (PCA) is a statistical technique to find these latent features. Section 3 describes PCA and our anomaly-detection technique in detail. In this section we first build intuition on why attacker behavior may appear anomalous relative to normal user behavior (regardless of the specific attacker strategy), and overview our approach.

2.1 Illustrative Example and Intuition

Consider a black-market service that has sold a large number of Facebook likes in some time frame to a customer (e.g., the customer's page will receive 10K likes within a week). Since a Facebook user can contribute at most one like to a given page, the black-market service needs to orchestrate likes from a large number of accounts. Given the overhead in acquiring an account—maintaining a fake account or compromising a real account—the service can amortize this overhead by selling to a large number of customers and leveraging each account multiple times, once for each customer. Such behavior may manifest along one of two axes: temporal or spatial (or both). By *temporal* we mean that the timing of the like may be anomalous (e.g., the inter-like delay may be shorter than that of normal users, or the weekday-weekend distribution may differ from normal). By *spatial* anomaly we mean other (non-temporal) characteristics of the like may be anomalous (e.g., the distribution of page categories liked may be different, or combinations of page categories rarely liked together by normal users may be disproportionately more frequent).

A smart attacker would attempt to appear normal along as many features as possible. However, each feature along which he must constrain his behavior reduces the amortization effect, thus limiting the scale at which he can operate. We show in Section 6 that black-market users we purchased have nearly an order of magnitude larger number of likes than normal users, and four times larger number of categories liked. If the attacker constrained himself to match normal users, he would require significantly more accounts to maintain the same level of service, adversely affecting profitability.

In the above illustrative example, it is not clear that the number of likes and categories liked are the best features to use (in fact, in section 6.4 we show that such simple approaches are not very effective in practice). Some other feature (or combination of features) that is even more discriminating between normal and anomalous behavior and more constraining for the attacker may be bet-

ter. Assuming we find such a feature, hard-coding that feature into the anomaly detection algorithm is undesirable in case "normal" user behavior changes. Thus, our approach must automatically find the most discriminating features to use from unlabeled data.

2.2 Approach

At a high level, we build a model for normal user behavior; any users that do not fit the model are flagged as anomalous. We do not make any assumptions about attacker strategy. We use PCA to identify features (dimensions) that best explain the predominant normal user behavior. PCA does so by projecting high-dimensional data into a low-dimensional subspace (called the *normal subspace*) of the top-N principal components that accounts for as much variability in the data as possible. The projection onto the remaining components (called the *residual subspace*) captures anomalies and noise in the data.

To distinguish between anomalies and noise, we compute bounds on the L^2 norm [43] in the residual subspace such that an operator-specified fraction of the *unlabeled* training data (containing predominantly normal user behavior) is within the bound. Note that the normal users do not need to be explicitly identified in the input dataset. When testing for anomalies, any data point whose L^2 norm in the residual subspace exceeds the bound is flagged as anomalous.

2.3 Features

We now discuss the input features to PCA that we use to capture user behavior in online social networks. We focus on modeling Facebook like activity behavior and describe suitable features that capture this behavior.

Temporal Features: We define a temporal feature as a *time-series of observed values*. The granularity of the time-series, and the nature of the observed value, depends on the application. In this paper, we use the number of likes at a per-day granularity. In general, however, the observed value may be the time-series of number of posts, comments, chat messages, or other user behavior that misbehaving users are suspected of engaging in.

Each time-bucket is a separate dimension. Thus, for a month-long trace, the user's like behavior is described by a ∼30-dimensional vector. The principal components chosen by PCA from this input set can model inter-like delay (i.e., periods with no likes), weekday-weekend patterns, the rate of change of like activity, and other latent features that are linear combinations of the input features, without us having to explicitly identify them.

Spatial Features: We define a spatial feature as a *histogram of observed values*. The histogram buckets depend on the application. In this paper, we use the category of Facebook pages (e.g., sports, politics, education) as buckets, and number of likes in each category as the observed value. In general, one might define histogram buckets for any attribute (e.g., the number of words in comments, the number of friends tagged in photos posted, page-rank of websites shared in posts, etc).

As with temporal features, each spatial histogram bucket is a separate dimension. We use the page categories specified by Facebook[2] to build the spatial feature vector describing the user's like behavior, which PCA then reduces into a low-dimensional representation.

Spatio-Temporal Features: Spatio-temporal features combine the above two features into a single feature, which captures the *evolution of the spatial distribution of observed values* over time. In essence, it is a time-series of values, where the value in each time bucket summarizes the spatial distribution of observed values at that time. In this paper, we use *entropy* to summarize the distribution of like categories. Entropy is a measure of information content, computed as $-\sum_i p_i \log_2 p_i$, where bucket i has probability p_i. In general, one might use other metrics depending on the application.

Multiple Features: Finally, we note that temporal, spatial, and spatio-temporal features over multiple kinds of user behavior can be combined by simply adding them as extra dimensions. For instance, like activity described using l_T temporal dimensions, l_S spatial dimensions, and l_{ST} spatio-temporal dimensions, and wall posting activity described similarly (p_T, p_S, p_{ST}), can be aggregated into a vector with $\sum_x l_x + \sum_x p_x$ dimensions passed as input into PCA.

3 Principal Component Analysis (PCA)

Principal component analysis is a tool for finding patterns in high-dimensional data. For a set of m users and n dimensions, we arrange our data in an $m \times n$ matrix $\mathbf{X}$, whose rows correspond to users and whose columns correspond to user behavior features discussed above. PCA then extracts common patterns from the rows of $\mathbf{X}$ in an optimal manner. These common patterns are called *principal components*, and their optimality property is as follows: over the set of all unit vectors having n elements, the first principal component is the one that captures the *maximum variation* contained in the rows of $\mathbf{X}$. More formally, the first principal component v_1 is given by:

$$v_1 = \arg\max_{||v||=1} ||\mathbf{X}v||.$$

The expression $\mathbf{X}v$ yields the inner product (here, equivalent to the correlation) of v with each row of $\mathbf{X}$; so v_1

[2] Facebook associates a topic category to each Facebook page which serves as the category of the like.

maximizes the sum of the squared correlations. Loosely, v_1 can be interpreted as the n-dimensional pattern that is most prevalent in the data. In analogous fashion, for each k, the k^{th} principal component captures the maximum amount of correlation beyond what is captured by the previous $k-1$ principal components.

The principal components $v_1, \ldots, v_n$ are constructed to form a *basis* for the rows of $\mathbf{X}$. That is, each row of $\mathbf{X}$ can be expressed as a linear combination of the set of principal components. For any principal component v_k, the amount of variation in the data it captures is given by the corresponding *singular value* σ_k.

A key property often present in matrices that represent measurement data is that only a small subset of principal components suffice to capture most of the variation in the rows of $\mathbf{X}$. If a small subset of singular values are much larger than the rest, we say that the matrix has *low effective dimension.* Consider the case where r singular values $\sigma_1, \ldots, \sigma_r$ are significantly larger than the rest. Then we know that each row of $\mathbf{X}$ can be approximated as a linear combination of the first r principal components $v_1, \ldots, v_r$; that is, $\mathbf{X}$ has *effective dimension* r.

Low effective dimension frequently occurs in measurement data. It corresponds to the observation that the number of factors that determine or describe measured data is not extremely large. For example, in the case of human-generated data, although data items (users) may be described as points in high-dimensional space (corresponding to the number of time bins or categories), in reality, the set of factors that determine typical human behavior is not nearly so large. A typical example is the user-movie ranking data used in the Netflix prize; while the data matrix of rankings is of size about 550K users $\times$ 18K movies, reasonable results were obtained by treating the matrix as having an effective rank of 20 [41]. In the next section, we demonstrate that this property also holds for user behavior in online social networks.

4 Dimensioning OSN User Behavior

To understand dimensionality of user behavior in online social networks, we analyze a large random sampling of users from three sources: Facebook, Yelp, and Twitter. The Facebook data is new in this study, while the Yelp and Twitter datasets were repurposed for this study from [50] and [4] respectively. We find low-effective dimension in each dataset as discussed below.

4.1 User Behavior Datasets

We use Facebook's people directory [25] to sample Facebook users uniformly at random.[3] The directory summarizes the number of people whose names start with a given character `x`, and allows direct access to the y^{th} user with name starting with `x` at `https://www.facebook.com/directory/people/x-y`. We sample uniformly at random from all possible (1.14B) `x-y` pairs, and follow a series of links to the corresponding user's profile.

We collected the publicly visible like and Timeline [34] activity of 13,991 users over the 26 month period ending in August 2013. For each user, we record three types of features: (i) *temporal*, a time-series of the number of likes at day granularity resulting in 181 dimensions for a 6-month window, (ii) *spatial*, a histogram of the number of likes in the 224 categories defined by Facebook, and (iii) *spatio-temporal*, a time-series of entropy of like categories at day granularity (181 dimensions for 6 months). We compute the entropy H_t on day t as follows: for a user who performs n_t^i likes in category i on day t, and n_t likes in total on day t, we compute $H_t = -\sum_i \frac{n_t^i}{n_t} \log_2 \frac{n_t^i}{n_t}$.

The Yelp dataset consists of all 92,725 Yelp reviewers in the San Francisco area [50] who joined before January 2010 and were active (wrote at least one review) between January 2010 and January 2012. The spatial features are constructed by a histogram of number of reviews posted by the user across 445 random groupings of 22,250 businesses[4] and 8 additional features (related to user reputation provided by Yelp[5]). The dataset also contains temporal features, the time-series of the number of reviews posted by a user at day granularity resulting in 731 dimensions covering the two year period.

The Twitter dataset consists of a random sample of 100K out of the 19M Twitter users who joined before August 2009 [4]. Previous work [4] identified topical experts in Twitter and the topics of interests of users were inferred (e.g., technology, fashion, health, etc) by analyzing the profile of topical experts *followed* by users. In this dataset, each expert's profile is associated with a set of topics of expertise. We construct a spatial histogram by randomly grouping multiple topics (34,334 of them) into 687 topic-groups and counting the number of experts a user is following in a given topic-group. The Twitter dataset does not have temporal features.

4.2 Low-Dimensionality of User Behavior

A key observation in our results from all three online social networks (Facebook, Yelp, Twitter) across the three user behaviors (temporal, spatial, and spatio-temporal)

[3] Users may opt-out of this directory listing. However, our analysis found 1.14 billion users listed in the directory as of April 2013, while Facebook reported a user count of 1.23 billion in December 2013 [31]. We therefore believe the directory to be substantially complete and representative.

[4] Randomly grouping the feature space helps compress the matrix without affecting the dimensionality of the data [13].

[5] Examples of reputation features include features such as number of review endorsements and number of fans.

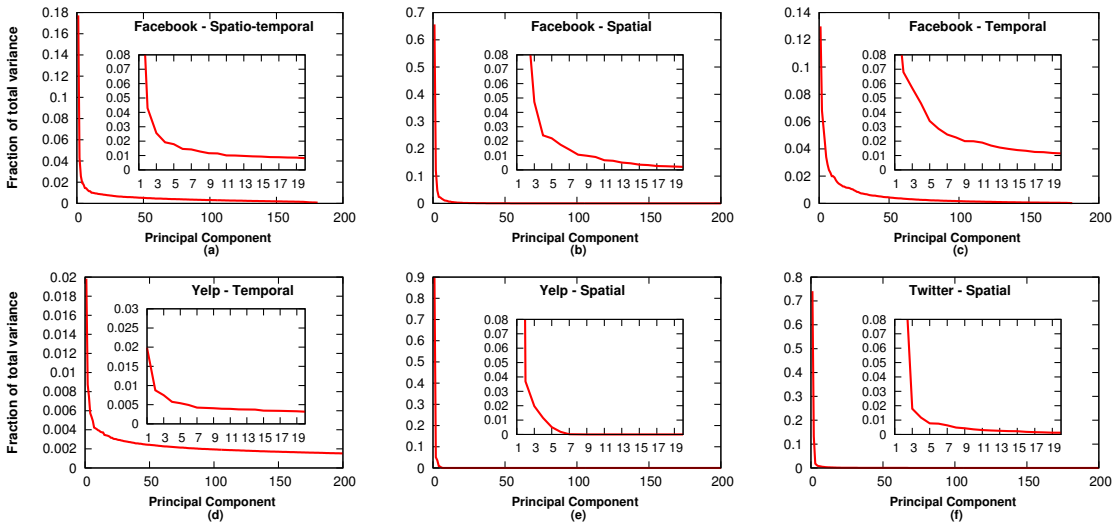

Figure 1: **Scree plots showing low-dimensionality of normal user behavior. A significant part of variations can be captured using the top three to five principal components (the "knee" of the curves).**

is that they all have low effective dimension. Figure 1 presents *scree plots* that show how much each principal component contributes when used to approximate the user behavior matrix $\mathbf{X}$, and so gives an indication of the effective dimension of $\mathbf{X}$. The effective dimension is the x-value at the "knee" of the curve (more clearly visible in the inset plot that zooms into the lower dimensions), and the fraction of the area under the curve left of the knee is the total variance of the data accounted for. In other words, the important components are the ones where the slope of the line is very steep, and the components are less important when the slope becomes flat. This method of visually inspecting the scree plot to infer the effective dimension is known as Cattell's Scree test in the statistics literature [5].

For Facebook like behavior (Figure 1(a)–(c)), the knee is around five principal components. In fact, for spatial features in Facebook like activity (Figure 1(b)), these top five components account for more than 85% of the variance in the data. We perform a parameter sweep in Section 6 and find that our anomaly detector is not overly sensitive (detection rate and false positives do not change drastically) to minor variations in the choice of number of principal components [54]. Yelp and Twitter (Figure 1(d)–(f)) show a knee between three and five dimensions as well. Overall, across all these datasets where the input dimensionality for user behavior were between 181 and 687, we find that the effective dimensionality is around three to five dimensions.

5 Detecting Anomalous User Behavior

In this section, we elaborate on the normal subspace and residual subspace discussed in Section 2, and describe how an operator can use them to detect anomalous behavior.

The operation of separating a user's behavior into principal components can be expressed as a *projection* . Recall that the space spanned by the top k principal components $v_1, \ldots, v_k$ is called the *normal subspace.* The span of the remaining dimensions is referred to as the *residual subspace.* To separate a user's behavior, we project it onto each of these subspaces. Formulating the projection operation computationally is particularly simple since the principal components are unit-norm vectors. We construct the $n \times k$ matrix $\mathbf{P}$ consisting of the (column) vectors $v_1, \ldots, v_k$. For a particular user's behavior vector x, the normal portion is given by $x_n = \mathbf{P}\mathbf{P}^T x$ and the residual portion is given by $x_r = x - x_n$.

The intuition behind the *residual subspace detection* method for detecting anomalies is that if a user's behavior has a large component that cannot be described in terms of *most* user's behavior, it is anomalous. Specifically, if $\|x_r\|_2$ is unusually large where $\|\cdot\|_2$ represents the L^2 norm, then x is likely anomalous. This requires setting thresholds for $\|x_r\|_2^2$ known as the squared prediction error or SPE [44]. We discuss how we choose a threshold in Section 6.

5.1 Deployment

In practice, we envision our scheme being deployed by the social network operator (e.g., Facebook), who has

access to all historical user behavior information. The provider first selects a time window in the past (e.g., $T =$ 6 months) and a large random sample of users active during that time (e.g., 1M) whose behavior will be used to train the detector. As described earlier, training involves extracting the top k principal components that define the normal and residual subspace for these users. This training is repeated periodically (e.g., every six months) to account for changes in normal user behavior.

The service provider detects anomalous users periodically (e.g., daily or weekly) by constructing the vector of user behavior over the previous T months, projecting it onto the residual subspace from the (latest) training phase, and analyzing the L^2 norm as discussed earlier. Since each user is classified independently, classification can be trivially parallelized.

6 Evaluation

We now evaluate the effectiveness of our anomaly detection technique using real-world ground-truth data about normal and anomalous user behavior on Facebook. Our goal with anomaly detection in this section is to detect Facebook like spammers.

6.1 Anomalous User Ground Truth

We collected data for three types of anomalous behaviors: fake (Sybil) accounts that do not have any normal user activity, compromised accounts where the attacker's anomalous activity interleaves with the user's normal activity, and collusion networks where users collectively engage in undesirable behavior. We used the methods described below to collect data for over 6.8K users. We then used Selenium to crawl the publicly visible data for these users, covering 2.16M publicly-visible likes and an additional 1.19M publicly-visible Timeline posts including messages, URLs, and photos. We acquired all activity data for these users from their join date until end of August 2013.

Black-Market Services: We searched on Google for websites offering paid Facebook likes (query: "buy facebook likes"). We signed up with six services among the top search results and purchased the (standard) package for 1,000 likes; we paid on average $27 to each service. We created a separate Facebook page for each service to like so we could track their performance. Four of the services [18–21] delivered on their promise (3,437 total users), while the other two [22, 23] did not result in any likes despite successful payment.

As mentioned, we crawled the publicly-visible user behavior of the black-market users who liked our pages. We discovered 1,555,534 likes (with timestamps at day granularity) by these users. We further crawled the users' publicly visible Timeline for public posts yielding an additional 89,452 Timeline posts.

Collusion Networks: We discovered collaborative services [7, 8] where users can collaborate (or collude) to boost each other's likes. Users on these services earn virtual credits for liking Facebook pages posted by other users. Users can then "encash" these credits for likes on their own Facebook page. Users can also buy credits (using real money) which they can then encash for likes on their page. We obtained 2,259 likes on three Facebook pages we created, obtaining a set of 2,210 users, at an average cost of around $25 for 1,000 likes. The price for each like (in virtual credits) is set by the user requesting likes; the higher the price, the more likely it is that other users will accept the offer. We started getting likes within one minute of posting (as compared to more than a day for black-market services).

As with black-market users, we crawled the user activity of the users we found through collusion networks. We collected 359,848 likes and 186,474 Timeline posts.

Compromised Accounts: We leveraged the browser malware Febipos.A [35] that infects the user's browser and (silently) performs actions on Facebook and Twitter using the credentials/cookies stored in the browser. The malware consists of a browser plugin, written in (obfuscated) Javascript, for all three major browsers: Chrome, Firefox and Internet Explorer [28, 29].

We installed the malware in a sandbox and deobfuscated and analyzed the code. The malware periodically contacts a CnC (command-and-control) server for commands, and executes them. We identified 9 commands supported by the version of the malware we analyzed: (1) like a Facebook page, (2) add comments to a Facebook post, (3) share a wall post or photo album, (4) join a Facebook event or Facebook group, (5) post to the user's wall, (6) add comments to photos, (7) send Facebook chat messages, (8) follow a Twitter user, and (9) inject third-party ads into the user's Facebook page.

We reverse-engineered the application-level protocol between the browser component and the CnC server, which uses HTTP as a transport. We then used `curl` to periodically contact the CnC to fetch the commands the CnC would have sent, logging the commands every 5 minutes. In so doing, we believe we were able to monitor the entire activity of the malware for the time we measured it (August 21–30, 2013).

Identifying which other Facebook users are compromised by Febipos.A requires additional data. Unlike in the black-market services and collusion networks—where we were able to create Facebook pages and give to the service to like— we can only passively monitor the malware and cannot inject our page for the other infected users to like (since we do not control the CnC server).

To identify other Facebook users compromised by

Febipos.A, we identified two commands issued during the week we monitored the malware: one which instructed the malware to like a specific Facebook page, and second, to join a specific Facebook event. We use Facebook's graph search [26] to find other users that liked the specific page and accepted the specific event directed by the CnC. From this list we sampled a total of 4,596 users. Note, however, that simply because a user matched the two filters does not necessarily mean they are compromised by Febipos.A.

To improve our confidence in compromised users, we clustered the posts (based on content similarity) made to these users' walls and manually inspected the top 20 most common posts. Among these 20 posts, two posts looked suspicious. Upon further investigation, we found out that one of the post was also found on pages the malware was directed to like. The other post was present in the CnC logs we collected. The first was posted by 1,173 users while the second was posted by 135 users. We considered users from both these clusters and obtained a set of 1,193 unique users.[6] We collected 247,589 likes and 916,613 Timeline posts from their profile.

6.2 Ethics

We note that all money we paid to acquire anomalous likes were exclusively for pages both controlled by us and setup for the sole purpose of conducting the experiments in this paper. For the malware analysis, we ensured that our sandbox prevented the malware from executing the CnC's instructions. We did not seek or receive any account credentials of any Facebook user. Overall, we ensured that no other Facebook page or user was harmed or benefited as a result of this research experiment.

6.3 Normal User Ground Truth

We collected three datasets to capture normal user behavior. The first dataset is the 719 users that are part of the SIGCOMM [33] and COSN [24] Facebook groups. We picked these technically savvy users, despite the obvious bias, because we presume that these users are less likely to be infected by browser or other malware which we have found to be stealthy enough to avoid detection by non-technically-savvy users. An anomaly detector that has low false-positives on both this dataset as well as a more representative Facebook dataset is more likely to have a range that spans the spectrum of user behavior on Facebook.

[6]The friendship network formed by these users has a very low edge density of 0.00023. Thus, even though they had similar posts on their Timeline, very few of them were friends with each other (further suggesting suspicious behavior).

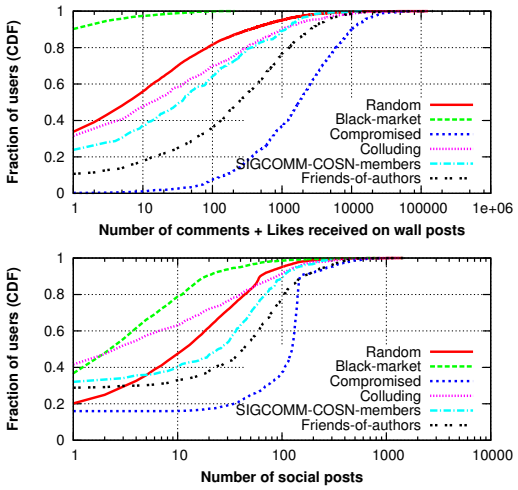

Figure 2: **Characterizing social activity of normal and anomalous users considered in our study based on activity on their Timeline.**

For our second dataset, we use the random sampling of Facebook users described in Section 4.1. Note that this dataset may be biased in the opposite direction: while it is representative of Facebook users, an unknown fraction of them are fake, compromised, or colluding. Public estimates lower-bound the number of fake users at 3% [32], thus we expect some anomalies in this dataset.

A compromise between the two extremes is our third dataset: a 1-hop crawl of the social-neighborhood of the authors (a total of 1,889 users). This dataset is somewhat more representative of Facebook than the first dataset, and somewhat less likely to be fake, compromised, or colluding than the second dataset. Users in these three datasets in total had 932,704 likes and 2,456,864 Timeline posts putting their level of activity somewhere between the black-market service on the low end, and compromised users on the high end. This fact demonstrates the challenges facing anomaly detectors based on simplistic activity thresholds.

For the rest of the analysis in this paper, we use the random sampling dataset for training our anomaly detector, and the other two datasets for testing normal users.

Figure 2 plots the cumulative distribution (CDF) of likes and comments received on wall posts and the number of *social*[7] posts for all of our six datasets. The top figure plots the CDF of likes and comments on a logarithmic x-axis ranging from 1 to 1M, and the bottom figure plots the CDF of social posts (messages, URLs, photos). As is evident from the figure, black-market users are the least active, compromised users are the most active, and all three normal user datasets—as well as the collusion network users—fall in the middle and are hard to distin-

[7]Posts that involve interaction with other users, e.g., photo tagging.

	Random	Normal	Black-market	Compromised	Colluding
#Users (#likes)	11,851 (561,559)	1,274 (73,388)	3,254 (1,544,107)	1,040 (209,591)	902 (277,600)

Table 1: **Statistics of different types of users whose like activity (from June 2011 to August 2013) we analyze.**

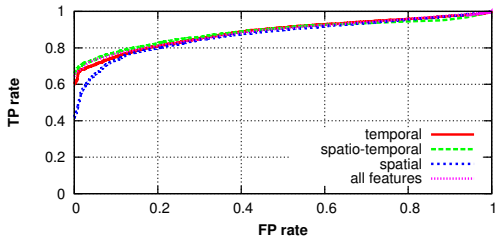

Figure 3: **ROC curve showing the performance of our anomaly detector in distinguishing between normal and misbehaving users.**

guish visually (especially for social post activity).

6.4 Detection Accuracy

Methodology: We analyze Facebook like activity from June 2011 to August 2013. We need to pay special attention to users that joined Facebook in the middle of our analysis period (or stopped being active) to avoid the degenerate case where the anomaly detection flags their lack of activity. We avoid this by considering a six-month sliding window that advances by one month. In each window, we consider users that joined before that window and had at least one like during the window. Unless otherwise mentioned, for the rest of the analysis in the paper, we consider only these users and their likes that fall within our period of analysis—data statistics are shown in Table 1. A user's behavior is flagged as anomalous if they are flagged in any one of the sliding time windows. They are flagged as anomalous in a window if the squared prediction error (SPE) exceeds the threshold parameter.

We set the detection threshold (conservatively) based on Facebook's estimate (from their SEC filings [32]) of users that violate terms of service. Facebook estimates around 3.3% users in 2013 to be undesirable (spam or duplicates). Recall that we train our anomaly detector on the like behavior of random Facebook users during much of the same period. We conservatively pick a training threshold that flags 3% of random accounts, and adjust our false-positive rate downwards by the same amount and further normalize it to lie in the range 0 to 1. We select the top-five components from our PCA output to build the normal subspace.

Results: Figure 3 plots the *receiver operating characteristic* (ROC) curve of our detector when evaluated on all datasets for normal and anomalous user behavior (except random, which was used to train the detector) as we perform a parameter-sweep on the detection threshold. The y-axis plots the true-positive rate ($\frac{TP}{TP+FN}$) and the x-axis plots the false-positive rate ($\frac{FP}{FP+TN}$) where TP, TN, FP, FN are true-positive, true-negative, false-positive, and false-negative, respectively. The area under the ROC curve for an ideal classifier is 1, and that for a random classifier is 0.5. For the mix of misbehaviors represented in our ground-truth dataset, the spatio-temporal features performs best, with an area under the curve of 0.887, followed closely by temporal and spatial features at 0.885 and 0.870, respectively.

By combining the set of users flagged by all three features, our detector is able to flag 66% of all misbehaving users at a false-positive rate of 0.3%. If we compare this with a naïve approach of flagging users based on a simple like volume/day (or like categories/day) cut-off (i.e., by flagging users who exceed a certain number of likes per day or topic categories per day) we can only detect 26% (or 49%) of all misbehaving users at the same false-positive rate. This further suggests that our PCA-based approach is more effective than such naïve approaches at capturing complex normal user behavior patterns to correctly flag misbehaving users.

Figure 4 and Table 2 explore how the set of features performed on the three classes of anomalous behavior. Spatio-temporal features alone flagged 98% of all activity for users acquired through the four black-market services. 61% (939K) of black-market activity was flagged as anomalous by all three sets of features. Due to the dominant nature of the spatio-temporal features on the black-market dataset, there is insufficient data outside the spatio-temporal circle to draw inferences about the other features. The three features performed more evenly on the dataset of compromised and colluding users, with 43.9% and 78.7% of the anomalous user behavior respectively being flagged by all three sets of features, and 64% and 91% respectively being flagged by at least one. Except in the black-market case, no class of features dominates, and combined they flag 94.3% of all anomalous user behavior in our dataset.

6.5 Error Analysis

To better understand our false-negative rate, Figure 5 plots the likelihood of detection as a function of the level of activity (number of likes) for each class of anomalous traffic. Unlike black-market users that are easily detected at any level of activity, the anomaly detector does not flag compromised and colluding users with low activity. This

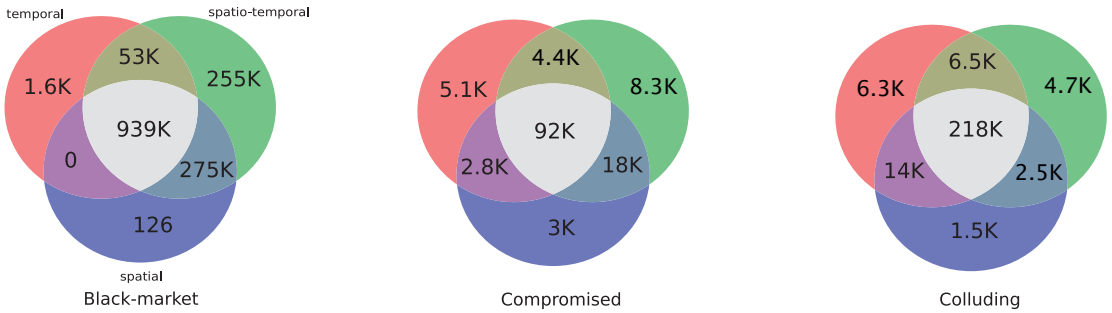

Figure 4: **Venn diagram illustrating performance of different features in detecting different classes of anomalous user behavior. The numbers indicate number of likes flagged.**

Identity type	Identities flagged	Likes flagged			
		Total	Temporal	Spatio-temporal	Spatial
Black-market	2,987/3,254 (91%)	1,526,334/1,544,107 (98%)	994,608 (64%)	1,524,576 (98%)	1,215,396 (78%)
Compromised	171/1,040 (16%)	134,320/209,591 (64%)	104,596 (49%)	123,329 (58%)	116,311 (55%)
Colluding	269/902 (29%)	254,949/277,600 (91%)	246,016 (88%)	232,515 (83%)	237,245 (85%)

Table 2: **Performance of different features in detecting different classes of anomalous user behavior.**

is consistent with compromised and colluding user behavior being a blend of normal user behavior intermixed with attacker behavior. At low levels of activity, the detector lacks data to separate anomalous behavior from noise. However, as the attacker leverages the account for more attacks, the probability of detection increases. It increases faster for colluding users, where the user is choosing to engage in anomalous activity, and more slowly for compromised accounts where the user contributes normal behavior to the blend.

Figure 6 compares anomalous user behavior that was not flagged by our detector to the behavior of normal users. As is evident from the figure, the false-negatives for compromised and colluding users appear indistinguishable from normal user behavior, especially when compared to the behavior of colluding and compromised users that were flagged. Our hypothesis (consistent with the previous paragraph) is that these false-negative users are newly compromised users or users newly recruited to the collusion network, and their overall behavior has not yet diverged significantly enough to be considered an anomaly.

Regarding false-positives, we expect some fraction of users to be flagged, since an unknown fraction of the normal users may be infected by malware. Our false-

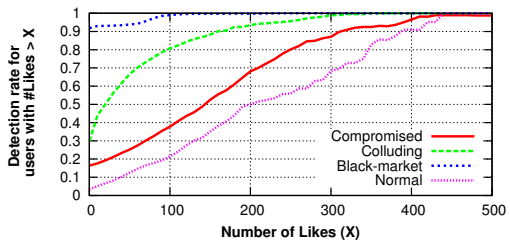

Figure 5: **Higher like activity generally correlates with higher detection rates, however limits for normal user behavior being flagged are 50–100 likes higher than for anomalous user behavior.**

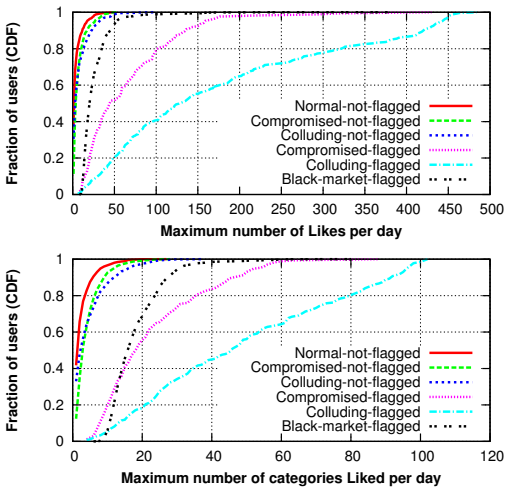

Figure 6: **Characterizing activity of users that are not flagged in the compromised and colluding set and comparing them with normal users who were not flagged.**

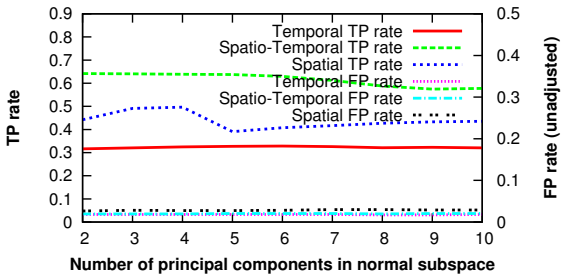

Figure 7: **False-positive rate (unadjusted) and true-positive rate as we vary the number of principal components chosen for the normal subspace. Our detector is stable for small variations in the number of principal components chosen.**

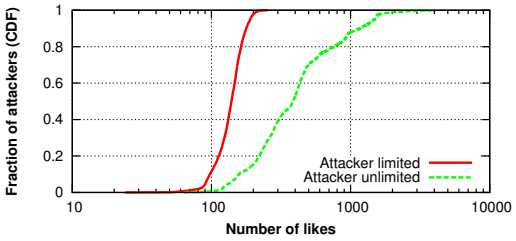

Figure 8: **Distribution of number of anomalous likes before anomalous users are flagged by our approach. For comparison, we show the actual number of anomalous likes we received.**

positive rate is under 3.3%, which when adjusted for the fraction of users Facebook expects to be anomalous [32], suggests a false-positive rate of 0.3%. We specifically note in Figure 5 that the threshold before normal user behavior is flagged is consistently 50–100 likes higher than that for compromised users for the same y-axis value. Thus, our anomaly detection technique accommodates normal users that are naturally prone to clicking on many likes.

6.6 Robustness

Next we evaluate the sensitivity of our detector to small variations in the number of principal components chosen for the normal subspace. Figure 7 plots the true-positive rate and the false-positive rate (unadjusted) as we vary k, the number of principal components used to construct the normal subspace. As is evident from the figure, our detection accuracy does not change appreciably for different choices of k. Thus our detector is quite robust to the number of principal components chosen.

6.7 Adversarial Analysis

In this section, we consider two classes of attackers: first, where the attacker scales back the attack to avoid detection, and second, where the attacker attempts to compromise the training phase.

Scaling Back: Figure 8 explores the scenario where attackers scale back their attacks to avoid detection. Specifically, we simulate the scenario where we subsample likes uniformly at random from our ground-truth attack traffic (black-market, compromised and colluding) until the point a misbehaving user is no longer flagged by the anomaly detector. As users' behavior spans multiple six month time windows, for each user we consider the window in which the user displayed maximum misbehavior (maximum number of likes in this case). In this way, we analyze the extent to which we can constrain attackers during their peak activity period. We find that our current model parameters constrains attackers by a factor of 3 in the median case, and by an order of magnitude at the 95^{th} percentile.

Compromising Training: An attacker that controls a sufficiently large number of users may attempt to compromise the training phase by injecting additional likes, thereby distorting the principal components learned for normal users [39, 55, 56]. The compromised detector would have a higher false-negative rate, since more anomalous behavior would fall within the normal subspace. At a high level, this attack may be mitigated by defense-in-depth, where multiple techniques can be used to filter users selected for the training set.

The first defense-in-depth technique is the attacker's need to control a sufficiently large number of anomalous users. We first note that our training data already contains an estimated 3% anomalous users, and that the trained detector has good performance on the ROC curve. Since users in the training set are sampled uniformly at random from all users, an attacker with equivalent power would need to be in control of over $30M$ users (given Facebook's user base of over $1B$ users). In comparison, one of the largest botnets today is estimated to have fewer than 1 million bots [47]. A related issue is that the quantity of like volume that must be injected to affect the detector depends on the overall volume of likes in the system, which is information that is not likely to be readily available to the attacker.

Assuming the attacker is able to amass this large a number of users, the next defense-in-depth technique is to sanitize training data, where anomalous users discovered in one time window are excluded from being used for training in all subsequent time windows [39]. Thus if an attacker ends up altering like traffic significantly in one time window, it could lead to detection and further

removal of those anomalous users from the training set.

Finally, variants of PCA that are more robust to outliers can be used to further harden the training phase from compromise. Croux et al. [9, 39] proposed the robust PCA-GRID algorithm that reduces the effect of outliers in the training data. Using this approach one can compute principal components that maximize a more robust measure of data dispersion – the *median absolute deviation* without under-estimating the underlying variance in the data. Such an algorithm could yield robust estimates for the normal subspace.

6.8 Scalability

As discussed earlier, classifying users can be trivially parallelized once the training phase is complete. Thus our primary focus in this section is on evaluating the scalability of the training phase.

Space: The total space requirement of the training phase is $O(n \times m)$ where n is the number of input dimensions (typically a few hundred), and m is the number of users in the training set (typically a few million). Thus the space needed to store the matrix is at most a few gigabytes, which can easily fit in a typical server's memory.

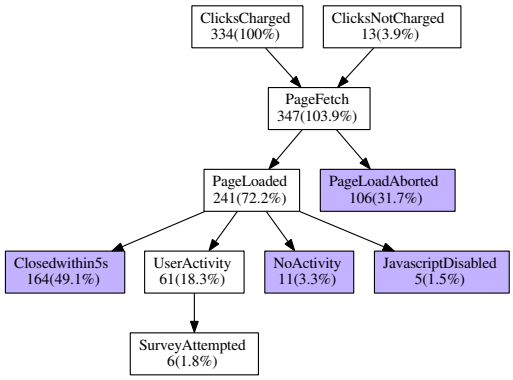
Computation: The primary computation cost in PCA arises from the eigenvalue decomposition of the covariance matrix of the feature vectors, which is a low-order polynomial time algorithm with complexity $O(n^3 + n^2 m)$. Eigenvalue decomposition is at the heart of the PageRank algorithm (used in early search engines) for which efficient systems exist to handle input data several orders of magnitude larger than our need [1]. Furthermore, efficient algorithms for PCA based on approximation and matrix sketching have been designed which have close to $O(mn)$ complexity [46, 57].

7 Detecting Click-Spam on Facebook Ads

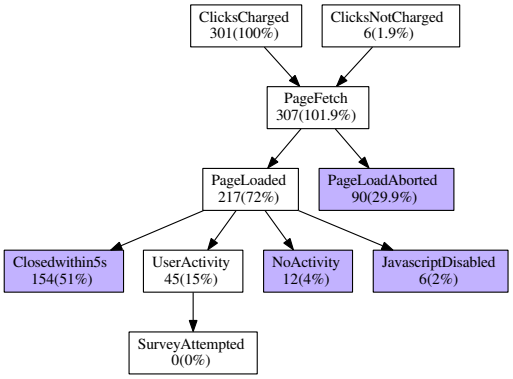
So far, we have discussed the performance of our anomaly detector in detecting diverse attack strategies. Next, we demonstrate another real world application of our technique: detecting click-spam on Facebook ads. Click-spam in online ads—where the advertiser is charged for a click that the user did not intend to make (e.g., accidental clicks, clicks by bots or malware)—is a well-known problem in web search [11, 12], and an emerging problem for Facebook ads [2, 16, 17].

7.1 Click-Spam in Facebook

To gain a preliminary understanding of Facebook click-spam, we signed up as an advertiser on Facebook. We set up an ad campaign targeting users in the USA aged between 15 and 30. The campaign advertised a simple user survey page about Facebook's privacy settings. When clicked, the ad leads to our heavily instrumented landing page to capture any user activity such as mouse clicks, mouse movement, or keyboard strokes. Of the 334 original ad clicks Facebook charged us for, only 61 (18.3%) performed any activity on the landing page (e.g., mouse move). Figure 9(a) shows how users proceeded after clicking the ad. Percentages are relative to the number of ad clicks Facebook charged us for. Shaded boxes are undesirable terminal states that suggest click-spam. For instance, 106 users (31.7%) did not even complete the first HTTP transaction to load the page (e.g., closed the tab, or pressed the back button immediately after clicking the ad).



(a) **Original ad**



(b) **Bluff ad**

Figure 9: **Summary of click statistics for real and bluff ad campaigns on Facebook.**

To distinguish between unintentional clicks and intentional clicks followed by lack of interest in our page, we ran Bluff Ads [11,38] that are ads with identical targeting parameters as the original ad, but nonsensical content. Our bluff ad content was empty. Figure 9(b) shows that our bluff ad performed identically to the original ad, both qualitatively and quantitatively; of 301 clicks in roughly the same time-frame as the original ad, almost 30% did not complete first HTTP, etc. From our data it appears

that the content of the ad has no effect on clicks on Facebook ads that we were charged for, a strong indicator of click-spam.

7.2 Anomalous Clicks in Facebook Ads

In order to analyze anomalous user behavior, our approach requires information from the user's profile. Due to a change in how Facebook redirects users on ad clicks [42], we were unable to identify the users that clicked on our ad in the experiment above. Fortunately, Facebook offers a different type of ad campaign optimization scheme—maximizing likes—where the destination must be a Facebook page as opposed to an arbitrary website. With such ads, it is possible to identify the users that clicked on such an ad, but not possible to instrument the landing page to get rich telemetry as above. We chose this campaign optimization option for maximizing likes to the advertised page.

We set up 10 ad campaigns, listed in Table 3, targeting the 18+ demographic in 7 countries: USA, UK, Australia, Egypt, Philippines, Malaysia and India. Our 10 campaigns were about generic topics such as humor, dogs, trees, and privacy awareness. Our ad contained a like button, a link to the Facebook page, some text, and an image describing the topic of the ad. We ran these ads at different points in time: Campaigns 1 to 4 were run in February 2014, while campaigns 5 to 10 were run in January 2013. In total, we received 3,766 likes for all our pages. For most of the campaigns targeting India (especially #7), we received 80% of the likes within 10 minutes, which is very anomalous.

We first checked whether we obtained most of these likes via social cascades (i.e., a user liking a page because their friend liked it), or from the Facebook ads directly. To do so, we analyzed the edge density of all friendship networks (graph formed by friendship links between users) formed by users of each ad campaign. We find the edge density of friendship networks for all campaigns to be very low (e.g., the friendship network edge density for users in campaign #8 was only 0.000032). This strongly suggests that the Facebook ads, rather than any social cascades, were responsible for the likes.

Out of 3,766 likes, we were able to crawl the identity of the users clicking like for 3,517 likes.[8] Next, we apply our anomaly detection technique from Section 5 with the same training data and model parameters that we used in Section 6 to 2,767 users (out of 3,517) who fall within our 26-month training window. The penultimate column in Table 3 lists the number of users tested in each campaign, and the last column lists the number of users flagged as click-spam.

[8]The Facebook user interface does not always show the identity of all users who like a page.

Of the 2,767 users that clicked our ads in this experiment, 1,867 were flagged as anomalous. Figure 10 plots the like activity of the users we flagged as anomalous relative to our normal user behavior dataset, and the black-market user dataset that serves as our ground-truth for anomalous user activity. The flagged users from our ad dataset have an order of magnitude more like activity than the black-market users, and nearly two orders of magnitude more like activity than normal users; they also like twice as many categories as black-market users and almost an order of magnitude more categories than normal users.

7.3 Anomaly Classification

To better understand the click-spam we observed, we attempt to classify the ad users as one of our three ground-truth anomalous behaviors: black-market, compromised, and collusion. Note that anomaly classification in this section is unrelated to the anomaly detection approach from Section 5.

We use the k-Nearest Neighbor (kNN) algorithm for classification. We train the classifier using ground-truth labels for black-market, compromised, and colluding users. The input feature vectors can be formed in different ways: First, we can capture user behavior by projecting it on to the normal and residual subspace. The normal projection reflects normal behavior and the residual projection captures noisy or deviant behavior of a user. Second, we know that user behavior can also be expressed using temporal, spatio-temporal and spatial features. By leveraging all these different combinations, we built 6 classifiers using 6 different feature vectors (2 projections

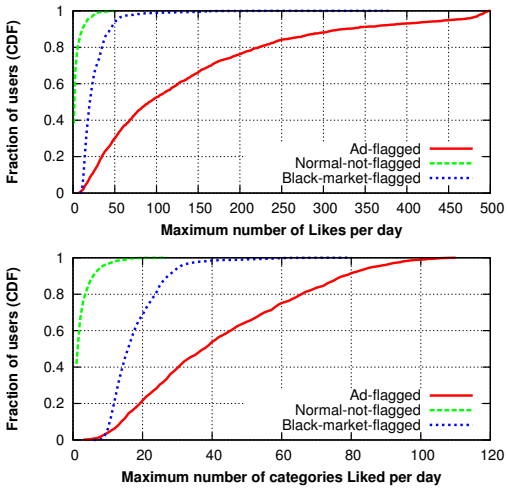


Figure 10: **Characterizing activity of users flagged in the ad set. Note that most flagged ad users like a much larger number of categories/likes per day than normal and black-market users.**

Campaign	Ad target	Cost per like (€)	Total spent (€)	Users		
				Total	Tested	Flagged
1	US	1.62	192.43	119	76	43
2	UK	1.95	230.05	118	69	27
3	AU	0.87	158.89	182	88	38
4	Egypt, Philippines, Malaysia	0.08	47.69	571	261	135
5	India	0.13	30.00	230	199	137
6	India	0.11	22.71	209	169	99
7	India	0.09	22.61	250	199	114
8	India, US, UK	0.22	242.72	1,099	899	791
9	India	0.12	30.00	247	215	143
10	India	0.07	50.00	741	632	372

Table 3: **Anomalies flagged for different ad campaigns. We observe a significant fraction of anomalous clicks for all campaigns.**

$\times$ 3 features). Each classifier, given an unlabeled user from the ad set, predicts a label for the user.

We use a simple ensemble learning technique of *majority voting* to combine the results of all the classifiers; this also means that there could be test instances that may not be labeled due to lack of consensus. We choose the most recent six-month time window (March to August 2013) in our dataset and use all known misbehaving users (black-market, compromised and colluding) in that window for training the classifier and apply this technique to the 1,408 flagged ad users who fall in that window. To balance classes for training, we randomly under-sample larger classes (black-market and colluding) and use 780 users in each of black-market, colluding and compromised set for training. For each classifier, we pick a value of k that gives the lowest misclassification rate for 10-fold cross validation on the training data. We next apply our trained classifier to predict the unlabeled ad users. Results are averaged over 50 different random trials and we observe an average misclassification rate of 31% (standard deviation of 0.5) based on cross-validation in the training phase. Table 4 shows the statistics for the labels predicted for the flagged ad users. We find that the majority of ad users (where we had majority agreement) are classified as black-market or compromised.

Classified As	Number of users
Black-market	470
Compromised	109
Colluding	345
Unclassified (no consensus)	484

Table 4: **Anomaly class predicted for the ad users that are flagged.**

While the level of anomalous click traffic is very surprising, it is still unclear what the incentives are for the attacker. One possibility is that black-market accounts and compromised accounts are clicking (liking) ads to generate cover traffic for their misbehavior. Another possibility is that the attacker is trying to drain the budget of some advertiser by clicking on ads of that advertiser. We plan to explore this further as part of future work.

8 Corroboration by Facebook

We disclosed our findings to Facebook in March 2014, and included a preprint of this paper. Our primary intent in doing so was to follow responsible disclosure procedures, and to allow Facebook to identify any ethical or technical flaws in our measurement methodology. We were informed that Facebook's automated systems detect and remove fake users and fraudulent likes.

Table 5 tabulates the users (flagged by our detector) and likes that were removed between the time we conducted our experiments and June 2014. While very few users were removed by Facebook, a sizable fraction of their likes across all pages were indeed removed confirming the accuracy of our detector. To establish a baseline for the fraction of users and likes removed by Facebook's automated systems we find that from our random user dataset (Section 4) only 2.2% users, and 32% of all their likes were removed over a ten month period. For black-market, compromised, and colluding users (ground-truth anomalous user dataset from Section 6), over 50% of all their likes had been removed over 6–10 months. Over 85% of the all likes of users that clicked our ad were removed within four months. Recall that our ad was targeted to normal Facebook users and we did not use any external services to acquire ad likes; nevertheless, 1,730 of the 3,517 likes we were charged for in February 2014 had been removed by Facebook's fraudulent like detection system by June 2014, corroborating our earlier result that a large fraction of users that clicked on our ad are anomalous both by our definition as well as Facebook's.[9] As of this writing we have not received any

[9] While Facebook allows users to un-like pages, according to Facebook insights [30] we had only 56 un-likes across all our pages, which we exclude from our analysis.

	Removed by Facebook's automated systems			
	Users	**likes on all pages**	**likes on our page**	**Timespan**
Normal User Dataset (Section 4)				
Random users	262/12K	179K/561K	n/a	10 months
Ground-Truth Anomaly Dataset (Section 6)				
Black-market	228/2987	715K/1.5M	2829/3475	10 months
Compromised	3/171	80K/134K	n/a	7 months

credit adjustments for the likes charged to our advertiser account that Facebook's fraudulent like detection system since identified and removed.

9 Related Work

We survey approaches to detecting misbehaving identities along three axes.

Leveraging Hard-to-earn Attributes: Manual verification of users would be ideal to avoiding Sybils in crowdsourcing systems but does not scale for large-scale systems. Additionally, normal users may not join the system for privacy reasons due to the effort required to be verified. Current systems typically employ CAPTCHA or phone verification to raise the barrier by forcing the attacker to expend greater effort. Although pervasive, attackers try to evade these schemes by employing Sybil identities that use sites like Freelancer or Amazon's Mechanical Turk to exploit the differences in value of human time in different countries [51]. However, steps taken by service providers to raise the barrier for fake account creation complements our proposed defense because each account flagged as anomalous raises the cost for the attacker.

In OSNs, where identities are associated with each other through hard-to-earn endorsement and friend edges, several graph-based Sybil detection schemes have been developed over the years [10, 52, 61, 66, 67]. Such schemes make assumptions about the OSN graph growth and structure, for example that creating and maintaining edges to honest identities requires significant effort [48], or that honest OSN regions are fast-mixing [66, 67]. However, recent studies cast doubts on these assumptions and subsequently on the graph-based Sybil defense techniques. Specifically, Yang et al. [65] observe that Sybils blend well into the rest of OSN graphs, while Mohaisen et al. [49] find that most OSN graphs are not fast-mixing, and that detection schemes may end up accepting Sybil identities and/or wrongly expelling honest identities [62].

Supervised Learning: Most existing work on detecting misbehaving identities in social networks leverage supervised learning techniques [14,40,53]. Lee et al. [40] propose a scheme that deploys honeypots in OSNs to attract spam, trains a machine learning (ML) classifier over the captured spam, and then detects new spam using the classifier. Rahman et al. [53] propose a spam and malware detection scheme for Facebook using a Support Vector Machines-based classifier trained using the detected malicious URLs. The COMPA scheme [14] creates statistical behavioral profiles for Twitter users, trains a statistical model with a small manually labeled dataset of both benign and misbehaving users, and then uses it to detect compromised identities in Twitter.

While working with large crowdsourcing systems, supervised learning approaches have inherent limitations. Specifically they are attack-specific and vulnerable to *adaptive* attacker strategies. Given the adaptability of the attacker strategies, to maintain efficacy, supervised learning approaches require labeling, training, and classification to be done periodically. In this cat-and-mouse game, they will always lag behind attackers who keep adapting to make a classification imprecise.

Unsupervised Learning: Unsupervised learning-based anomaly detection has been found to be an effective alternative to non-adaptive supervised learning strategies [12, 45, 60, 63, 64]. For example, Li et al. [45] propose a system to detect volume anomalies in network traffic using unsupervised PCA-based methods. AutoRE [64] automatically extracts spam URL patterns in email spam based on detecting the bursty and decentralized nature of botnet traffic as anomalous.

In crowdsourcing scenarios, Wang et al. [63] proposed a Sybil detection technique using server-side clickstream models (based on user behavior defined by clickthrough events generated by users during their social network browsing sessions). While the bulk of the paper presents supervised learning schemes to differentiate between Sybil and non-Sybils based on their clickstream behavior, they also propose an unsupervised approach

that builds clickstream behavioral clusters that capture normal behavior and users that are not part of normal clusters are flagged as Sybil. However, their approach still requires some constant amount of ground-truth information to figure out clusters that represent normal click-stream behavior. Tan et al. [60] use a user-link graph along with the OSN graph to detect some honest users with supervised ML classifier and then perform an unsupervised analysis to detect OSN spam. CopyCatch [3] detects fraudulent likes by looking for a specific attack signature — groups of users liking the same page at around the same time (*lockstep behavior*). CopyCatch is actively used in Facebook to detect fraudulent likes, however as evidenced in Table 5, it is not a silver-bullet.

While we welcome the push towards focusing more on unsupervised learning strategies for misbehavior detection, most of the current techniques are quite ad hoc and complex. Our approach using Principal Component Analysis provides a more systematic and general framework for modeling user behavior in social networks, and in fact, our PCA-based approach could leverage the user behavior features (e.g., user click-stream models [63]) used in existing work for misbehavior detection.

10 Conclusion

We propose using Principal Component Analysis (PCA) to detect anomalous user behavior in online social networks. We use real data from three social networks to demonstrate that normal user behavior is low-dimensional along a set of latent features chosen by PCA. We also evaluate our anomaly detection technique using extensive ground-truth data of anomalous behavior exhibited by fake, compromised, and colluding users. Our approach achieves a detection rate of over 66% (covering more than 94% of misbehavior) with less than 0.3% false positives. Notably we need no *a priori* labeling or tuning knobs other than a configured acceptable false positive rate. Finally, we apply our anomaly detection technique to effectively identify anomalous likes on Facebook ads.

Abstract

Recent work in security and systems has embraced the use of machine learning (ML) techniques for identifying misbehavior, *e.g.* email spam and fake (Sybil) users in social networks. However, ML models are typically derived from *fixed* datasets, and must be periodically retrained. In adversarial environments, attackers can adapt by modifying their behavior or even sabotaging ML models by polluting training data.

In this paper[1], we perform an empirical study of adversarial attacks against machine learning models in the context of detecting malicious crowdsourcing systems, where sites connect paying users with workers willing to carry out malicious campaigns. By using human workers, these systems can easily circumvent deployed security mechanisms, *e.g.* CAPTCHAs. We collect a dataset of malicious workers actively performing tasks on Weibo, China's Twitter, and use it to develop ML-based detectors. We show that traditional ML techniques are accurate (95%–99%) in detection but can be highly vulnerable to adversarial attacks, including simple *evasion attacks* (workers modify their behavior) and powerful *poisoning attacks* (where administrators tamper with the training set). We quantify the robustness of ML classifiers by evaluating them in a range of practical adversarial models using ground truth data. Our analysis provides a detailed look at practical adversarial attacks on ML models, and helps defenders make informed decisions in the design and configuration of ML detectors.

1 Introduction

Today's computing networks and services are extremely complex systems with unpredictable interactions between numerous moving parts. In the absence of accurate deterministic models, applying Machine Learning (ML) techniques such as decision trees and support vector machines (SVMs) produces practical solutions to a variety of problems. In the security context, ML techniques can extract statistical models from large noisy datasets, which have proven accurate in detecting misbehavior and attacks, *e.g.* email spam [35, 36], network intrusion attacks [22, 54], and Internet worms [29]. More recently, researchers have used them to model and detect malicious users in online services, *e.g.* Sybils in social networks [42, 52], scammers in e-commerce sites [53] and fraudulent reviewers on online review sites [31].

Despite a wide range of successful applications, machine learning systems have a weakness: they are vulnerable to adversarial countermeasures by attackers aware of their use. First, through either reading publications or self-experimentation, attackers may become aware of details of the ML detector, *e.g.* choice of classifier and parameters used, and modify their behavior to *evade* detection. Second, more powerful attackers can actively tamper with the ML models by polluting the training set, reducing or eliminating its efficacy. Adversarial machine learning has been studied by prior work from a theoretical perspective [6, 12, 27], using simplistic all-or-nothing assumptions about adversaries' knowledge about the ML system in use. In reality, however, attackers are likely to gain incomplete information or have partial control over the system. An accurate assessment of the robustness of ML techniques requires evaluation under *realistic* threat models.

In this work, we study the robustness of machine learning models against practical adversarial attacks, in the context of detecting malicious crowdsourcing activity. Malicious crowdsourcing, also called crowdturfing, occurs when an attacker pays a group of Internet users to carry out malicious campaigns. Recent crowdturfing attacks ranged from "artificial grassroots" political campaigns [32, 38], product promotions that spread false rumors [10], to spam dissemination [13, 39]. Today, these campaigns are growing in popularity in dedicated

[1]Our work received approval from our local IRB review board.

crowdturfing sites, *e.g.* ZhuBaJie (ZBJ)[2] and SanDaHa (SDH)[3], and generic crowdsourcing sites [26, 48].

The detection of crowdturfing activity is an ideal context to study the impact of adversarial attacks on machine learning tools. First, crowdturfing is a growing threat to today's online services. Because tasks are performed by intelligent individuals, these attacks are undetectable by normal measures such as CAPTCHAs or rate limits. The results of these tasks, fake blogs, slanderous reviews, fake social network accounts, are often indistinguishable from the real thing. Second, centralized crowdturfing sites like ZBJ and SDH profit directly from malicious crowdsourcing campaigns, and therefore have strong monetary incentive and the capability to launch adversarial attacks. These sites have the capability to modify aggregate behavior of their users through interface changes or explicit policies, thereby either helping attackers evade detection or polluting data used as training input to ML models.

Datasets. For our analysis, we focus on Sina Weibo, China's microblogging network with more than 500 million users, and a frequent target of crowdturfing campaigns. Most campaigns involve paying users to retweet spam messages or to follow a specific Weibo account. We extract records of 20,416 crowdturfing campaigns (1,012,923 tasks) published on confirmed crowdturfing sites over the last 3 years. We then extract a 28,947 Weibo accounts belonging to crowdturfing workers. We analyze distinguishing features of these accounts, and build detectors using multiple ML models, including SVMs, Bayesian, Decision Trees and Random Forests.

We seek answers to several key questions. First, can machine learning models detect crowdturfing activity? Second, once detectors are active, what are possible countermeasures available to attackers? Third, can adversaries successfully manipulate ML models by tampering with training data, and if so, can such efforts succeed in practice, and which models are most vulnerable?

Adversarial Attack Models. We consider two types of practical adversarial models against ML systems: those launched by individual *crowd-workers*, and those involving coordinated behavior driven by administrators of centralized *crowdturfing sites*. First, individual workers can perform *evasion* attacks, by adapting behavior based on their knowledge of the target classifier (*e.g.* ML algorithms, feature space, trained models). We identify a range of threat models that vary the amount of knowledge by the adversary. The results should provide a comprehensive view of how vulnerable ML systems to evasion, ranging from the worst case (total knowledge by attacker) to more practically scenarios. Second, more powerful attacks are possible with the help of crowdturfing site administrators, who can manipulate ML detectors by *poisoning* or polluting training data. We study the impact on different ML algorithms from two pollution attacks: injecting false data samples, and altering existing data samples.

Our study makes four key contributions:

- We demonstrate the efficacy of ML models for detecting crowdturfing activity. We find that Random Forests perform best out of multiple classifiers, with 95% detection accuracy overall and 99% for "professional" workers.
- We develop adversarial models for *evasion attacks* ranging from optimal evasion to more practical/limited strategies. We find while such attacks can be very powerful in the optimal scenario (attacker has total knowledge), practical attacks are significantly less effective.
- We evaluate a powerful class of *poison* attacks on ML training data and find that *injecting* carefully crafted data into training data can significantly reduce detection efficacy.
- We observe a consistent tradeoff between fitting accuracy and robustness to adversarial attacks. More accurate fits (especially to smaller, homogeneous populations) make models more vulnerable to deviations introduced by adversaries. The exception is Random Forests, which naturally supports fitting to multiple populations, thus allowing it to maintain both accuracy and robustness in our tests.

To the best of our knowledge, this is the first study to examine automated detection of large-scale crowdturfing activity, and the first to evaluate adversarial attacks against machine learning models in this context. Our results show that accurate models are often vulnerable to adversarial attacks, and that robustness against attacks should be a primary concern when selecting ML models.

2 Datasets and Methodology

In this section, we provide background on crowdturfing, and introduce our datasets and methodology.

2.1 Background: Crowdturfing Systems

Malicious crowdsourcing (crowdturfing) sites are web services where attackers pay groups of human workers to perform questionable (and often malicious) tasks. While these services are growing rapidly world-wide, two of the largest are Chinese sites ZhuBaJie (ZBJ) and SanDaHa (SDH) [48]. Both sites leave records of campaigns publicly visible to recruit new workers, making it possible for us to crawl their data for analysis.

[2] http://www.zhubajie.com/c-tuiguang/
[3] http://www.sandaha.com/

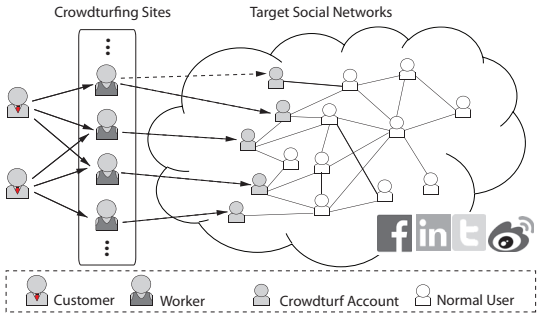

Figure 1: Crowdturfing process.

Figure 1 illustrates how crowdturfing campaigns work. Initially, a *customer* posts a campaign onto the crowdturfing site, and pays the site to carry it out. Each campaign is a collection of small *tasks*, *e.g.* tasks to send or retweet messages advertising a malware site. *Workers* accept the task, and use their fake accounts in the target social network(s) (*e.g.* Twitter) to carry out the tasks. Today, crowdturfing campaigns often spam web services such as social networks, online review sites, and instant-messaging networks [48]. While workers can be any Internet user willing to spam for profit, customers often require workers to use "high quality" accounts (*i.e.* established accounts with real friends) to perform tasks [48]. In the rest of the paper, we refer workers' social network accounts as *crowdturf accounts*.

Crowdturfing on Weibo. Sina Weibo is China's most popular microblogging social network with over 500 million users [30]. Like Twitter, Weibo users post 140-character *tweets*, which can be *retweeted* by other users. Users can also *follow* each other to form asymmetric social relationships. Unlike Twitter, Weibo allows users to have conversations via *comments* on a tweet.

Given its large user population, Weibo is a popular target for crowdturfing systems. There are two major types of crowdturfing campaigns. One type asks workers to follow a customer's Weibo account to boost their perceived popularity and visibility in Weibo's ranked social search. A second type pays crowd-workers to retweet spam messages or URLs to reach a large audience. Both types of campaigns directly violate Weibo's ToS [2]. A recent statement (April 2014) from a Weibo administrator shows that Weibo has already begun to take action against crowdturfing spam [1].

2.2 Ground Truth and Baseline Datasets

Our study utilizes a large *ground-truth* dataset of crowdturfing worker accounts. We extract these accounts by filtering through records of all campaigns and tasks targeting Weibo from ZBJ and SDH, and extracting all Weibo accounts that accepted these tasks. This is possible because ZBJ and SDH keep complete records of campaigns and transaction details (*i.e.* workers who completed tasks, and their Weibo identities) visible.

Category	# Weibo IDs	# (Re) Tweets	# Comments
Turfing	28,947	18,473,903	15,970,215
Authent.	71,890	7,600,715	13,985,118
Active	371,588	34,164,885	75,335,276

Table 1: Dataset summary.

As of March 2013, we collected a total of 20,416 Weibo campaigns (over 3 years for ZBJ and SDH), with a total of 1,012,923 individual tasks. We extracted 34,505 unique Weibo account IDs from these records. 5,558 of which have already been blocked by Weibo. We collected user profiles for the remaining 28,947 active accounts, including social relationships and the latest 2000 tweets from each account. These accounts have performed at least one crowdturfing task. We refer to this as the *Turfing* dataset.

Baseline Datasets for Comparison. We need a baseline dataset of "normal" users for comparison. We start by snowball sampling a large collection of Weibo accounts[4]. We ran breadth-first search (BFS) in November 2012 using 100 Seeds randomly chosen from Weibo's public tweet stream, giving us 723K accounts. Because these crawled accounts can include malicious accounts, we need to do further filtering to obtain a real set of "normal" users.

We extract two different baseline datasets. First, we construct a conservative *Authenticated* dataset, by including only Weibo users who have undergone an optional identity verification by phone number or Chinese national ID (equivalent to US drivers license). A user who has bound her Weibo account to her real-world identity can be held legally liable for her actions, making these authenticated accounts highly unlikely to be used as crowdturfing activity. Our *Authenticated* dataset includes 71,890 accounts from our snowball sample. Second, we construct a larger, more inclusive baseline set of *Active* users. We define this set as users with at least 50 followers and 10 tweets (filtering out dormant accounts[5] and Sybil accounts with no followers). We also cross reference these users against all known crowdturfing sites to remove any worker accounts. The resulting dataset includes 371,588 accounts. While it is not guaranteed to be 100% legitimate users, it provides a broader user sample that is more representative of average user behavior.

[4]Snowball crawls start from an initial set of seed nodes, and runs breadth-first search to find all reachable nodes in the social graph [3].

[5]Dormant accounts are unlikely to be workers. To qualify for jobs, ZBJ/SDH workers must meet minimum number of followers/tweets.

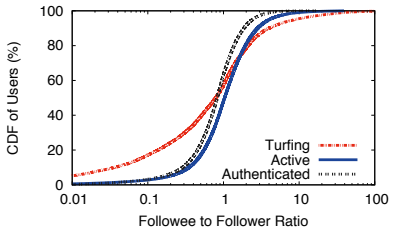

Figure 2: Followee-to-Follower ratio.

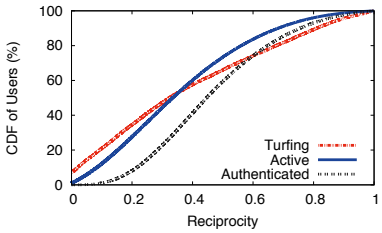

Figure 3: Reciprocity.

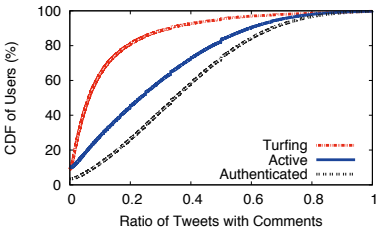

Figure 4: Ratio of commented tweets.

This is likely to provide a lower bound for detector accuracy, since more carefully curated baselines would produce higher detection accuracy. Our datasets are listed in Table 1.

2.3 Our Methodology

We have two goals: evaluating the efficacy of ML classifiers to detect crowdturfing workers, and evaluating the practical impact of adversarial attacks on ML classifiers.

- We analyze ground-truth data to identify key behavioral features that distinguish crowdturfing worker accounts from normal users (§3).
- We use these features to build a number of popular ML models, including Bayesian probabilistic models via Bayes' theorem (*i.e.* conditional probability), Support Vector Machines (SVMs), and algorithms based on single or multiple decision trees (*e.g.* Decision Trees, Random Forests) (§4).
- We evaluate ML models against adversarial attacks ranging from weak to strong based on level of knowledge by attackers (typically evasion attacks), and coordinated attacks potentially guided by centralized administrators (possible poison or pollution of training data).

3 Profiling Crowdturf Workers

We begin our study by searching for behavioral features that distinguish worker accounts from normal users. These features will be used to build ML detectors in §4.

User Profile Fields. We start with user profile features commonly used as indicators of abnormal behavior. These features include followee-to-follower ratio (FFRatio), reciprocity (*i.e.* portion of user's followees who follow back), user tweets per day, account age, and ratio of tweets with URLs and mentions.

Unfortunately, our data shows that most of these features alone cannot effectively distinguish worker accounts from normal users. First, FFRatio and reciprocity are commonly used to identify malicious spammers [4, 43, 50]. Intuitively, spammers follow a large number of random users and hope for them to follow back, thus they have high FFRatio and low reciprocity. However, our analysis shows worker accounts have balanced FFRatios, the majority of them even have more followers than followees (Figure 2), and their reciprocity is very close to those of normal users (Figure 3). Other profile features are also ineffective, including account age, tweets per day, ratio of tweets with URLs and mentions. For example, existing detectors usually assume attackers create many "fresh" accounts to spam [4, 43], thus account age has potential. But we find that more than 75% of worker accounts in our dataset have been active for at least one year.

These results show that crowd-worker accounts in many respects resemble normal users, and are not easily detected by profile features alone [47].

User Interactions. Next, we move on to features related to user interactions. The intuition is that crowdturf workers are task-driven, and log on to work on tasks, but spend minimal time interacting with others. User interactions in Weibo are dominated by comments and retweets. We perform analysis on both of them and find consistent results which show they are good metrics to distinguish workers from non-workers. For brevity, we limit our discussion to results on comment interactions.

Figure 4 shows crowdturf accounts are less likely to receive comments on their tweets. For 80% of crowdturf accounts, less than 20% of their tweets are commented; while for 70% of normal users, their ratio of commented tweets exceeds 20%. This makes sense, as the fake content posted by crowdturf workers may not be interesting enough for others to comment on. We also examine the number of people that each user has bidirectional comments with (bi-commentors). Crowdturf workers rarely interact with other users, with 66% of accounts having at most one bi-commentor.

Tweeting Clients. Next we look at the use of tweeting clients (devices). We can use the "device" field associated with each tweet to infer how tweets are sent. Tweet clients fall into four categories: web-based browsers, apps on mobile devices, third-party account management

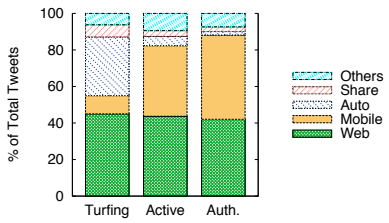

Figure 5: Tweet client usage.

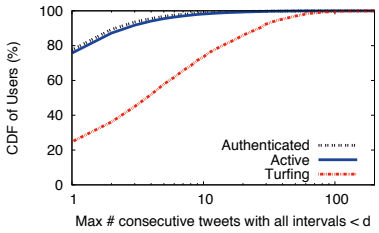

Figure 6: Max size of tweeting burst (threshold $d = 1$ minute).

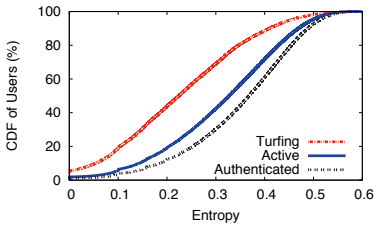

Figure 7: Normalized entropy of tweeting inter-arrival time.

Categ.	Top Tweet Clients
Web	Weibo Web, Weibo PC, 360Browser, Weibo Pro.
Mobile	iPhone, Android, iPad, XiaoMi
Auto	PiPi, Good Nanny, AiTuiBao, Treasure Box
Share	Taobao, Youku, Sina Blog, Baidu

Table 2: High-level categories for tweeting clients.

tools, and third-party websites via "share" buttons (Table 2). Figure 5 shows key differences in how different users use tweet clients. First, crowdturf workers use mobile (10%) much less than normal users (36% – 46%). One reason is that crowdturf workers rely on web browsers to interact with crowdturfing sites to get (submit) tasks and process payment, actions not supported by most mobile platforms.

We also observe that crowdturf workers are more likely to use automated tools. A close inspection shows that workers use these tools to automatically post non-spam tweets retrieved from a central content repository (*e.g.* a collection of hot topics). Essentially, crowdturf accounts use these generic tweets as cover traffic for their crowdturfing content. Third, crowdturf accounts "share" from third-party websites more often, since that is a common request in crowdturfing tasks [48].

Temporal Behavior. Finally, we look at temporal characteristics of tweeting behavior: tweet burstiness and periodicity. First, we expect task-driven workers to send many tweets in a short time period. We look for potential bursts, where each burst is defined as m consecutive tweets with inter-arrival times $< d$. We examine each user's maximum burst size (m) with different time thresholds d, *e.g.* Figure 6 depicts the result for d is set to 1 minute. We find that crowdturf accounts are more likely to post consecutive tweets within one-minute, something rarely seen from normal users. In addition, crowdturf workers are more likely to produce big bursts (*e.g.* 10 consecutive tweets with less than one-minute interval).

Second, workers accept tasks periodically, which can leave regular patterns in the timing of their tweets. We use *entropy* to characterize this regularity [16], where low entropy indicates a regular process while high entropy indicates randomness of tweeting. We treat each user's tweeting inter-arrival time as a random variable, and compute the first-order entropy [16]. Figure 7 plots user's entropy, normalized by the largest entropy in our dataset. Compared to normal users, crowdturf accounts in general have lower entropy, indicating their tweeting behaviors have stronger periodic patterns.

4 Detecting Crowdturfing Workers

We now use the features we identified to build a number of crowdturfing detectors using machine learning models. Here, we summarize the set of features we use for detection, and then build and evaluate a number of machine-learning detectors using our ground-truth data.

4.1 Key Features

We chose for our ML detectors a set of 35 features across five categories shown below.

- *Profile Fields (9).* We use 9 user profile fields[6] as features: follower count, followee count, followee-to-follower ratio, reciprocity, total tweet count, tweets per day, mentions per tweet, percent of tweets with mentions, and percent of tweets with embedded URLs.
- *User Interactions (8).* We use 8 features based on user interactions, *i.e.* comments and retweets. 4 features are based on user comments: percent of tweets with comments, percent of all comments that are outgoing, number of bi-commentors, and comment h-index (a user with h-index of h has at least h tweets each with at least h comments). We include 4 analogous retweet features.
- *Tweet Clients (5).* We compute and use the % of tweets sent from each tweet client type (web, mobile, automated tools, third-party shares and others) as a feature.

[6] Although profile fields *alone* cannot effectively detect crowdturf accounts (§3), they are still useful when combined with other features.

Alg.	Settings
NB	Default
BN	Default, K2 function
SVMr	Kernel γ =1, Cost parameter C =100
SVMp	Kernel degree d =3, Cost parameter C =50
J48	Confidence factor C =0.25, Instance/leaf M =2
RF	20 trees, 30 features/tree

Table 3: Classifier configurations.

- *Tweet Burstiness (12).* These 12 features capture the size and number of tweet bursts. A burst is m consecutive tweets where gaps between consecutive tweets are at most d minutes. For each user, we first compute the maximum burst size (m) while varying threshold d from 0.5 to 1, 30, 60, 120, 1440. Then we set d to 1 minute, and compute the number of bursts while varying size m over 2, 5, 10, 50, 100, and 500.
- *Tweeting Regularity (1).* This is the entropy value computed from each user's tweeting time-intervals.

4.2 Classification Algorithms

With these features, we now build classifiers to detect crowdturf accounts. We utilize a number of popular algorithms widely used in security contexts, including two Bayesian methods: Naive Bayesian (NB) [20] and BayesNet (BN) [18]; two Support Vector Machine methods [33]: SVM with radial basis function kernel (SVMr) and SVM with polynomial kernel (SVMp); and two Tree-based methods: C4.5 Decision Tree (J48[7]) [34] and Random Forests (RF) [7]. We leverage existing implementations of these algorithms in WEKA [17] toolkits.

Classifier and Experimental Setup. We start by constructing two experimental datasets, each containing all 28K turfing accounts, plus 28K randomly sampled baseline users from the "authenticated" and "active" sets. We refer to them as *Authenticated+Turfing* and *Active+Turfing*.

We use a small sample of ground-truth data to tune the parameters of different classifiers. At a high-level, we use grid search to locate the optimized parameters based on cross-validation accuracy. For brevity, we omit the details of the parameter tuning process and give the final configurations in Table 3. Note that features are normalized for SVM algorithms (we tested unnormalized approach which produced higher errors). We use this configuration for the rest of our experiments.

Basic Classification Performance. We run each classification algorithm on both experimental datasets with 10-fold cross-validation.[8] Figure 8 presents their classification error rates, including false positives (classifying normal users as crowdturf workers) and false negatives (classifying crowdturf accounts as normal users).

[7] J48 is WEKA's C4.5 implementation.

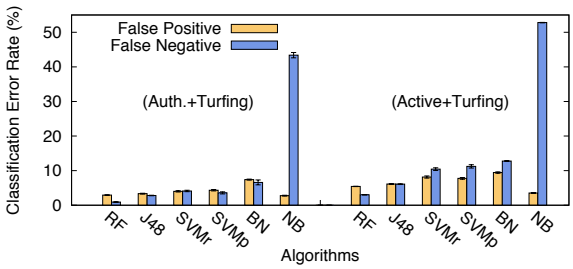

Figure 8: Classification error rates. Tree-based algorithms and SVMs outperform Bayesian methods.

We make four key observations. First, the two simple Bayesian methods generally perform worse than other algorithms. Second, Decision Tree (J48) and Random Forests (RF) are more accurate than SVMs. This is consistent with prior results that show SVMs excel in addressing high-dimension problems, while Tree algorithms usually perform better when feature dimensionality is low (35 in our case) [8]. Third, Random Forests outperform Decision Tree. Intuitively, Random Forests construct multiple decision trees from training data, which can more accurately model the behaviors of multiple types of crowdturf workers [7]. In contrast, decision tree would have trouble fitting distinct types of worker behaviors into a single tree. Finally, we observe that the two experiment datasets show consistent results in terms of relative accuracy across classifiers.

Comparing the two datasets, it is harder to differentiate crowdturf workers from *active* users than from *authenticated* users. This is unsurprising, since *authenticated* accounts often represent accounts of public figures, while *active* users are more likely to be representative of the normal user population. In the rest of the experiments, wherever the two datasets show consistent results, we only present the results on *Active+Turfing* for brevity, which captures the worse case accuracy for detectors.

4.3 Detecting Professional Workers

Our machine learning detectors are generally effective in identifying worker accounts. However, the contribution of tasks per worker is quite skewed, *i.e.* 90% of all tasks are completed by the top 10% most active "professional" workers (Figure 9). Intuitively, these "professional workers" are easier to detect than one-time workers. By focus-

[8] Cross-validation is used to compare the performance of different algorithms. We will split the data for training and testing the detectors later.

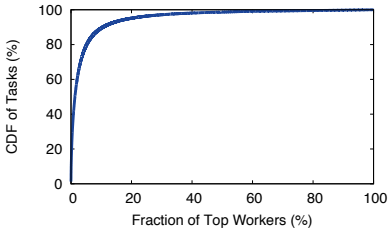

Figure 9: % of Tasks finished by top % of workers. The majority of spams were produced by top active workers.

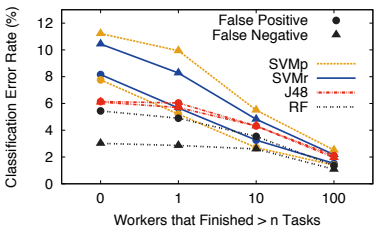

Figure 10: Classifying different levels of workers. Workers are filtered by # of crowdturfing tasks finished.

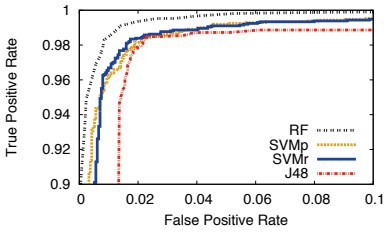

Figure 11: ROC curves of classifying professional workers (workers who finished more than 100 tasks).

ing on them, we can potentially improve detection accuracy while still effectively eliminate the largest majority of crowdturf output.

We evaluate classifier accuracy in detecting professional workers, by setting up a series of datasets each consisting of workers who performed more than n tasks (with n set to 1, 10, and 100). Each dataset also contains an equal number of randomly sampled normal users. We focus on the most accurate algorithms: Random Forests (RF), Decision Tree (J48) and SVM (SVMr and SVMp), and run 10-fold cross-validation on each of the datasets.

Figure 10 shows the classification results on *Active+Turfing*. As expected, our classifiers are more accurate in identifying "professional" workers. Different algorithms converge in accuracy as we raise the minimum productivity of professional workers. Accuracy is high for crowdturf workers who performed >100 tasks: Random Forests only produce 1.2% false positive rate and 1.1% false negative rate (99% accuracy). Note that while these top workers are only 8.9% of the worker population, they are responsible for completing 90% of all tasks. In the rest of the paper, we use "professional workers" to refer to workers who have completed >100 tasks.

False Positives vs. False Negatives. In practice, different application scenarios will seek different tradeoffs between false positives (FP) and false negatives (FN). For example, a system used as a pre-filter before more sophisticated tools (*e.g.* manual examination) will want to minimize FN, while an independent system without additional checks will want to minimize false positives to avoid hurting good users.

Figure 11 shows the ROC[9] curves of the four algorithms on the dataset of professional workers. Again, Random Forests perform best: they achieve extremely low false positive rate of <0.1% with only 8% false negative rate, or <0.1% false negative rate with only 7% false positive rate. We note that SVMs provide better false positive and false negative tradeoffs than J48, even though they have similar accuracy rates.

Imbalanced Data. We check our results on imbalanced data, since in practice there are more normal users than crowdturf workers. More specifically, we run our classifier (RF, professional) on imbalanced *testing* data with turfing-to-normal ratio ranging from 0.1 to 1. Note that we can still train our classifiers on balanced *training* data since we use supervised learning (we make sure training and testing data have no overlap). We find all the classifiers have accuracy above 98% (maximum FP 1.5%, FN 1.3%) against imbalanced testing data. We omit the plot for brevity.

Summary. Our results show that current ML systems can be used to effectively detect crowdturf workers. While this is a positive result, it assumes no adversarial response from the crowdturfing system. The following sections will examine detection efficacy under different levels of adversarial attacks.

5 Adversarial Attack: Evasion

We show that ML detectors can effectively identify "passive" crowdturf accounts in Weibo. In practice, however, crowdturfing adversaries can be highly adaptive: they will change their behaviors over time or can even intentionally attack the ML detectors to escape detection. We now re-evaluate the robustness of ML detectors under different adversarial environments, focusing on two types of adversaries:

1. *Evasion Attack:* individual crowd-workers adjust their behavior patterns to evade detection by trained ML detectors.
2. *Poisoning Attack:* administrators of crowdturfing sites participate, manipulating the ML detector training process by poisoning the training data.

We focus on evasion attacks in this section, and delay the study of poisoning attacks to §6. First, we define the evasion attack model. We then implement evasion attacks of different strengths, and study the performance

[9]ROC (receiver operating characteristic) is a plot that illustrates classifier's false positives and true positives versus detection threshold.

of ML detectors accordingly. Specifically, we consider "optimal evasion" attacks, where adversaries have full knowledge about the ML detectors and the Weibo system, and more "practical" evasion attacks, where adversaries have limited knowledge about the detectors and the Weibo system.

5.1 Basic Evasion Attack Model

Evasion attacks refer to individual crowdturfing workers seeking to escape detection by altering their own behavior to mimic normal users. For example, given knowledge of a deployed machine learning classifier, a worker may attempt to evade detection by selecting a subset of user features, and replacing their values with the *median* of the observed normal user values. Since mimicking normal users reduces crowdturfing efficiency, workers are motivated to minimize the number of features they modify. This means they need to identify a minimal core set of features enabling their detection.[10]

This attack makes two assumptions. *First*, it assumes that adversaries, *i.e.* workers, know the list of features used by the classifiers. Technical publications, *e.g.* on spam detection [4, 43, 50], make it possible for adversaries to make reasonable guesses on the feature space. *Second*, it assumes that adversaries understand the characteristics of normal users in terms of these features. In practice, this knowledge can be obtained by crawling a significant portion of Weibo accounts.

Depending on their knowledge of the ML features and of normal user behavior, adversaries can launch evasion attacks of different strengths. We implement and evaluate ML models on a range of threat models with varying levels of adversary knowledge and computational capabilities. We start from the *optimal evasion* scenario, where adversaries have *complete* knowledge of the feature set. The corresponding ML detector results represent worst-case performance (or lower bound) under evasion attacks. We also study a set of *practical evasion* models where adversaries have limited (and often noisy) knowledge, and constrained resources.

5.2 Optimal Evasion Attack

In this *ideal* case, adversaries have perfect knowledge about the set of features they need to modify. To understand the impact of the feature choices, we look at multiple variants of the optimal evasion models. These include the *per-worker optimal evasion model*, where each worker finds her own optimal set of features to alter, the *global optimal evasion* where all workers follow the same optimal set of features to alter, and *feature-aware evasion* where workers alter the most important features.

[10] For simplicity, we consider features to be independent.

We implement these evasion models on our ground-truth dataset, and evaluate ML detector accuracy. Note that these attacks we identify are not necessarily practical, but are designed to explore worse-case scenarios for ML models.

Per-worker Optimal Evasion. Intuitively, each worker should have her own optimal strategy to alter features, *e.g.* some workers need to add followers first, while others need to reduce tweeting burstiness. Doing so is hard in practice: each worker has to apply exhaustive search to identify its optimal strategy that minimizes the set of features to modify.

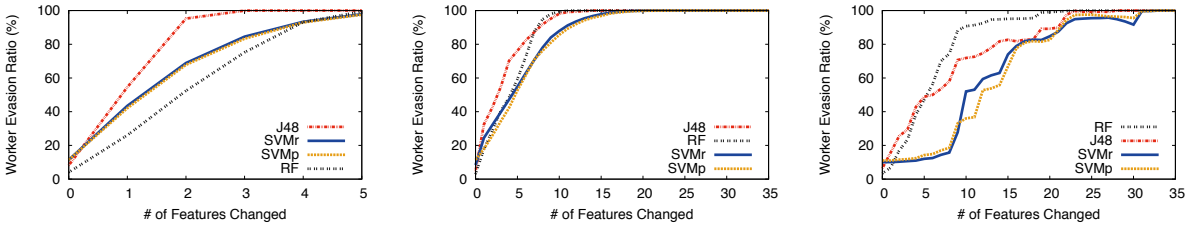
We implement this scenario on our *Active+Turfing* dataset. We first split the data into equal-sized training and testing datasets, and use the top-4 most accurate algorithms to build classifiers with authentic training data. We then run detection on worker accounts in the testing dataset. Here for each worker, we exhaustively test all combinatorial combinations of possible features to modify until the classifier classifies this worker as normal. In this way, we find the minimal set of features each user must modify to avoid detection.

Figure 12(a) plots the evasion rate for the four ML algorithms. Clearly, this optimal evasion model is highly effective. By simply altering one feature, 20-50% of workers can evade detection (different workers can choose to alter different features). And by altering five features, 99% of workers can evade all four classifiers. We also observe that the Random Forests (RF) algorithm achieves the best robustness, since it requires the most number of features to be altered.

Global Optimal Evasion. The per-worker model makes a strong assumption that each worker can identify her own optimal feature set. Next, we loosen this assumption and only assume that all workers exercise a uniform strategy. This is possible if a third-party (*e.g.* site admin) guides workers in altering their features.

To identify the global optimal strategy, we search exhaustively through all possible feature combinations, and locate the feature set (for a given size) that allows the majority of workers to achieve evasion. The corresponding evasion rate result is in Figure 12(b). 99% of workers can successfully evade all four detectors by altering 15 features, which is much larger than the per-worker case (5 features). This is because any one-size-fits-all strategy is unlikely to be ideal for individual workers, thus the feature set must be large enough to cover all workers.

Feature-aware Evasion. Achieving optimal evasion is difficult, since it requires adversaries to have knowledge of the trained classifiers. Instead, this model assumes that adversaries can accurately identify the relatively "importance" of the features. Thus workers alter the most important features to try to avoid detection.



(a) Per-worker Optimal Evasion (b) Global Optimal Evasion (c) Feature Importance Aware Evasion

Figure 12: Evasion rate of optimal evasion strategies (all workers).

We implement this attack by building the classifiers and then computing the feature importance. For this we use the χ^2 (Chi Squared) statistic [51], a classic metric to measure feature's discriminative power in separating data instances of different classes[11]. During detection, workers alter features based on their rank.

Figure 12(c) plots evasion results for the four classifiers. We make two key observations. First, this feature-aware strategy is still far away from the per-worker optimal case (Figure 12(a)), mostly because it is trying to approximate global optimal evasion. Second, performance depends heavily on the underlying classifier. For RF and J48, performance is already very close to that of the global optimal case, while the two SVM algorithms are more resilient. A possible explanation is that the χ^2 statistic failed to catch the true feature importance for SVM, since SVM normalizes feature values before training the classifier. These results suggest that without knowing the specific ML algorithm used by the defenders, it is hard to avoid detection even knowing the importance of features.

5.3 Evasion under Practical Constraints

Our results show workers can evade detection given complete knowledge of the feature set and ML classifiers. However, obtaining complete knowledge is very difficult in practice. Thus we examine *practical* evasion threat models to understand their efficacy compared to optimal evasion models. We identify practical constraints facing adversaries, present several practical threat models and evaluate their impact on our detectors.

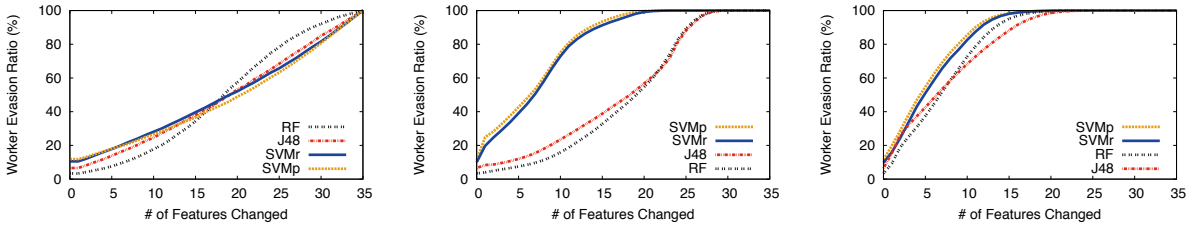
Practical Constraints. In practice, adversaries face two key resource constraints. First, they cannot reverse-engineer the trained classifier (*i.e.* the ML algorithm used or its model parameters) by querying the classifier and analyzing the output – it is too costly to establish millions of profiles with controlled features and wait for some of them to get banned. Thus workers cannot perform exhaustive search to launch optimal evasion attacks, but have to reply on their partial knowledge for evasion. Second, it is difficult for adversaries to obtain *complete* statistics of normal users. They can estimate normal user statistics via a (small) sampling of user profiles, but estimation errors are likely to reduce their ability to precisely mimic normal users.

Next, we will examine each constraint separately, and evaluate the likely effectiveness of attacks under the more realistic conditions.

Distance-aware Evasion. We consider the first constraint which forces workers to rely on *partial* knowledge to guide their evasion efforts. In this case, individual workers are only aware of their own accounts and normal user statistics. When choosing features to alter, they can prioritize features with the largest differential between them and normal users. They must quantify the "distance" between each crowdturf account and normal users on a given feature. Here, we pick two very intuitive distance metrics and examine the effectiveness of the corresponding evasion attacks. For now, we ignore the second constraint by assuming workers have perfect knowledge of average user behaviors.

- *Value Distance (VD):* Given a feature k, this captures the distance between a crowd-worker i and normal user statistics by $VD(i,k) = \frac{|F_k(i) - Median(N_k)|}{Max(N_k) - Min(N_k)}$ where $F_k(i)$ is the value of feature k in worker i, and N_k is normal user statistical distribution on feature k. When altering feature k, worker i replaces $F_k(i)$ with $Median(N_k)$.
- *Distribution Distance (DD):* Here the distance depends on where $F_k(i)$ is positioned within N_k. For example, if $F_k(i)$ is around 50%-tile of N_k, then worker i is similar to a normal user. Therefore, we define the distance by $DD(i,k) = |Percentile(N_k, F_k(i)) - 50|/100$ where $Percentile(N_k, F_k(i))$ is the percentile of $F_k(i)$ in the normal user CDF N_k. Note that when $F_k(i)$ exceeds the range of N_k, this distance metric becomes invalid. However, our data suggests that this rarely happens ($<1\%$).

[11] We also tested information gain to rank features, which produced similar ranking results (*i.e.* the same top-10 as using χ^2).



(a) Random Evasion Strategy (Random) (b) Value Distance Aware Strategy (VD) (c) Distribution Distance Aware Strategy (DD)

Figure 13: Evasion rate of practical evasion strategies (all workers).

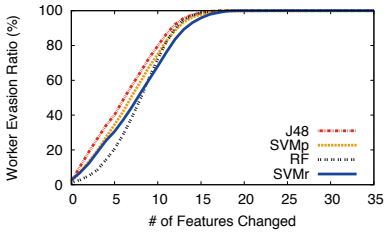


Figure 14: Evasion rate using distribution distance aware strategy (DD) for professional workers.

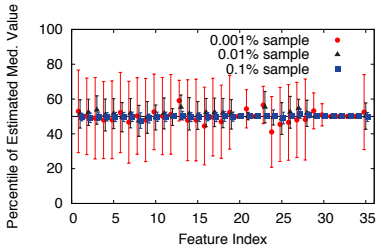

Figure 15: The percentile of *estimated* median value in the true normal user CDF.

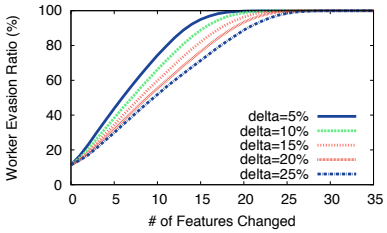

Figure 16: Impact of median value estimation error on evasion rate, using DD evasion on SVMp.

To evaluate the impact of practical evasion attacks, we split the *Active+Turfing* data into equal-sized training and testing sets. After classifier training, we simulate the distance-aware evasion attacks on the testing data. Figure 13(b) and 13(c) show evasion rates based on VD and DD respectively. As a baseline, we also show Figure 13(a) where adversaries *randomly* select features to alter. Compared to random evasion, distance-based approaches require much less feature altering. For example, when altering 15 features, random approach only saves <40% of workers, while distance strategies provide as high as 91% (VD-SVMp) and 98% (DD-SVMp).

The four classifiers perform very differently. RF and J48 classifiers are much more vulnerable to DD based evasion than to VD based evasion. While SVMs perform similarly in both strategies. In general, Tree-based algorithms are more robust than SVM classifiers against distance-aware evasions. This is very different to what we observed in the optimal evasion cases (Figure 12(a)–12(b)), where SVMs are generally more robust. This suggests that theoretical bounds on ML algorithms may not truly reflect their performance in practice.

Consistently, the impact of practical evasion attacks is much weaker than that of optimal evasion (*i.e.* per-worker optimal). Adversaries are severely constrained by lack of knowledge of detection boundaries of the classifiers, and have to guess based on "distance" information. The implication is that the less adversaries know about classifiers, the harder it is for them to evade detection.

We also evaluate the attack impact on classifiers to detect professional workers. We find the general trends are similar and only show the results of DD-based attack in Figure 14. We note that it is easier to evade classifiers dedicated to detect professionals (compared with Figure 13(c)). This is because when trained to a smaller, more homogeneous worker population, classifiers expect strong malicious behaviors from crowd-workers. Thus even a small deviation away from the model towards normal users will help achieve evasion.

Impact of Normal User Estimation Errors. We extend the above model by accounting for possible errors in estimating normal user behaviors (the second constraint). These errors exist because adversaries can only sample a limited number of users, leading to noisy estimations. Here, we investigate the impact of sampling strategies on the attack efficacy.

For all 35 features, we vary the sampling rate, *i.e.* the ratio of normal users sampled by adversaries, by taking random samples of 0.001%, 0.01% to 0.1% of the *Active* dataset. We repeat each instance 100 times, and compute the mean and standard deviation of the estimated median feature values (Figure 15). We show each feature's *percentile* in the true CDF of the *Active* dataset. In this case, the optimal value is 50%. Clearly sampling rate does impact feature estimation. With the 0.001% sampling rate, the estimated value varies significantly across instances. Raising the sample rate to 0.1% means attackers can accurately estimate the median value using only

a few instances. Furthermore, we see that burstiness features (*e.g.* features 30-34) are easy to sample, since normal user values are highly skewed to zero.

Finally, we evaluate the impact of estimation errors on practical evasion attacks. This time we run distance-aware evasions based on the *estimated* median feature values. For each worker's feature k, we estimate the median value $M'(k)$ with a given bound of error Δ. That is, $M'(k)$ is randomly picked from the percentiles within $[50\% - \Delta, 50\% + \Delta]$ on the true CDF of normal user behaviors. By iterating through different Δ (from 5% to 25%), our results show that Δ only has a minor impact. The most noticeable impact is on SVMp using DD distance (Figure 16). Overall, we conclude that as long as adversaries can get a decent guess on normal user behaviors, the residual noise in the estimation Δ should not affect the efficacy of evasion attacks.

Summary. Our work produces two key observations.

- Given complete knowledge, evasion attacks are very effective. However, adversaries under more realistic constraints are significantly less effective.
- While no classifier is robust against all attack scenarios, there is a consistent inverse relationship between single model fitting accuracy and robustness to adversarial evasion. Highly accurate fit to a smaller, more homogeneous population (*e.g.* professionals) makes models more vulnerable to evasion attacks.

6 Adversarial Attack: Poisoning

After examining evasion attacks, we now look at how centralized crowdturfing sites can launch more powerful attacks to manipulate machine learning models. Specifically, we consider the poisoning attack where administrators of crowdturfing sites intentionally pollute the training dataset used to build ML classifiers, forcing defenders to produce inaccurate classifiers. Since the training data (*i.e.* crowdturfing accounts) actually comes from these crowdturfing sites, administrators are indeed capable of launching these attacks.

In the following, we examine the impact of poisoning attacks on ML detection accuracy. We consider two mechanisms for polluting training data. The first method directly adds misleading/synthetic samples to the training set. Adversaries in the second method simply alter data records, or modify operational policies to alter the composition of the training data used by ML models.

6.1 Injecting Misleading Samples

Perhaps the simplest way to pollute any training data is to add misleading or false samples. In our case, since the training data has two classes (groups) of accounts, this can be done by mixing normal user samples into the "turfing" class, *i.e.* poisoning the turfing class, or mixing crowdturf samples into the "normal" user class, *i.e.* poisoning the normal class. Both introduce incorrectly labeled training data to mislead the classifier.

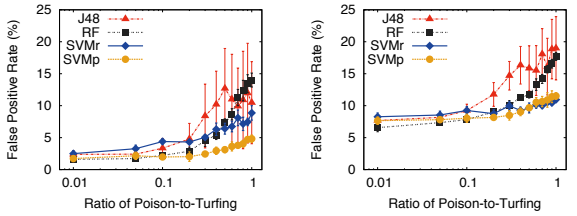
Poisoning Turfing Class. To poison the turfing class, adversaries (*e.g.* ZBJ and SDH administrators) add normal Weibo accounts to the public submission records in their own systems. Since ML classifiers take ground-truth crowdturf accounts from those public records, these benign accounts will then be mixed into the training data and labeled as "turfing." The result is a model that marks some characteristics of normal users as crowdturfing behavior, likely increasing false positive rate in detection.

We simulate the attack with our ground-truth dataset. At a high level, we train the classifiers on "polluted" training data, and then examine changes in classifiers' detection accuracy. Here we experiment with two strategies to pollute the turfing class. First, as a baseline strategy, adversaries *randomly* select normal users as poison samples to inject into the turfing class. Second, adversaries can inject *specific* types of normal users, causing the classifiers to produce *targeted* mistakes.

Random Poisoning: We simulate this poisoning attack with *Active+Turfing* dataset, where adversaries inject random normal accounts to the turfing class. Specifically, for training, the turfing class (14K accounts) is a mixture of crowdturf accounts and poison samples randomly selected from *Active*, with a mixing ratio of p. The normal class is another 14K normal accounts from *Active*. Then we use 28K of the rest accounts (14K turfing and 14K normal users) for testing. For any given p, we repeat the experiment 10 times with different random poison samples and training-testing partitions to compute average detection rates.

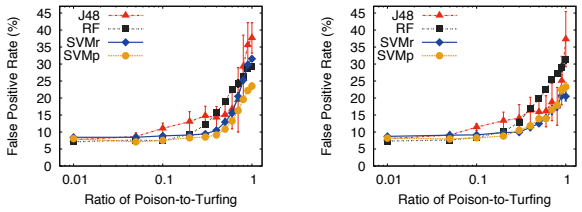
Results are shown in Figure 17(b). As a baseline comparison, we also present the results of the classifiers for professional workers in Figure 17(a). We have three observations. First, as poison-to-turfing ratio p increases, false positive rates go up for all four algorithms. False negative rates are not much affected by this attack, thus are omitted from the plot.[12] Second, we find that the SVM classifiers are more resilient: SVMp's false positive rate increases <5% as p approaching 1.0, while the analogous increases exceed 10% for Random Forests and J48. Particularly, J48 experiences more drastic fluctuations around average, indicating it is very sensitive to the choice of poison samples. This is consistent with our prior observation that more accurate single model fitting (*i.e.* J48 is more accurate than SVM) is more vulnerable to adversarial attacks. Similarly, highly accurate detec-

[12] False negative rates increase $< 2\%$ when p approaches 1.0.



(a) Professional Workers (b) All Workers

Figure 17: Poisoning training dataset by injecting random normal user samples to the turfing class.



(a) Injecting Accounts with $>50\%$ tweets commented (b) Injecting Accounts with <150 followers

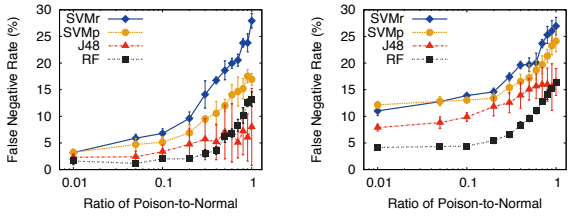
Figure 18: Targeted poisoning. Adversaries inject specific type of normal users to the turfing class (all workers).

tion of the more homogeneous population of professional workers (§4) means the models experience larger relative impacts from attacks compared to classifiers over all workers.

Note that we limited the poison-to-turfing ratio <1, since in practice adversaries cannot inject unlimited poison samples to defender's training data. First, injecting noise causes inconvenience to their own customers in locating qualified workers. Second, defenders may collect ground-truth records from multiple crowdturfing sites.

Targeted Poisoning: Next, we explore *targeted* poisoning to the turfing class. Here the adversaries want to carefully inject selected poison samples so classifiers make targeted mistakes. For example, our classifier uses "ratio of commented tweets" as a feature with the intuition that worker's tweets rarely receive comments (§3). Once adversaries gain this knowledge, they can intentionally select accounts whose tweets often receive comments as the poison samples. As a result, the trained classifier will mistakenly learn that users with high comment ratio can be malicious, thus are likely to misclassify this kind of normal users as crowd-workers.

To evaluate the impact of targeted poisoning, we perform similar experiments, except that we select poison samples based on specific feature. Figure 18 shows the attacking results on two example features: ratio of tweets with comments and follower count. Compared with Figure 17, targeted poisoning can trigger higher false positives than randomly selecting poison samples. Also, the previous observations still hold with SVM being more robust and J48 experiencing unstable performance (large deviation from average).



(a) Professional Workers (b) All Workers

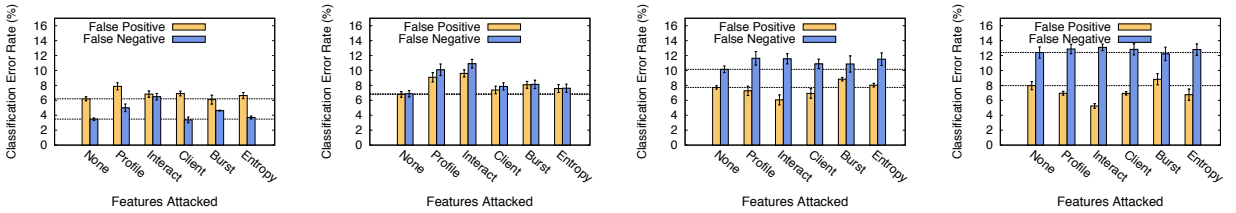
Figure 19: Poisoning training dataset by adding turfing samples to normal class.

Poisoning Normal User Class. Next, we analyze the other direction where adversaries inject turfing samples into the "normal" class to boost the *false negative rate* of classifiers. This may be challenging in practice since the normal user pool – Weibo's whole user population – is extremely large. Hence it requires injecting a significant amount of misleading samples in order to make an impact. Here from defender's perspective, we aim to understand how well different classifiers cope with "noisy" normal user data.

We repeat the previous "Random Poisoning" attack on the normal class. Figure 19(a) and Figure 19(b) show the attack results on classifiers for professional workers and all workers respectively. As we increase the ratio of poison samples, the false negatives of all four classifiers increase. This is expected as the classifiers will mistakenly learn crowdturf characteristics when modeling normal users, thus are likely to misclassify turfing accounts as benign later. In addition, we find the robustness of different classifiers varies, with Random Forests algorithm producing the lowest overall false negatives. Finally, we again observe that the more accurate classifier for professional workers suffers larger relative impacts from adversaries than classifiers for all-workers.

6.2 Altering Training Data

The above poisoning attacks focus on misleading classifiers to catch the wrong target. However, it does not fundamentally prevent crowd-workers from detection, since workers' behavior patterns are still very differently from normal users. To this end, we explore a second poisoning attack, where adversaries directly *alter* the training data by tuning crowd-workers' behavior to mimic normal users. The goal is to make it difficult (or even impossible) to train an accurate classifier that isolates crowdturf accounts with normal accounts.



(a) Random Forests (b) J48 (c) SVMr (d) SVMp

Figure 20: Performance of different classifiers when adversaries alter crowd-workers' features to mimic normal users. The horizontal lines represent the baseline false positive (false negative) rates when no feature is altered.

To carry out this attack, adversaries (*e.g.* administrators of ZBJ and SDH) need to modify the behaviors of numerous crowdturf workers. This can be done by centrally enforcing operational policies to their own system. For example, enforcing minimal time interval between taking tasks to reduce the tweeting burstiness or enforcing screening mechanisms to reject worker accounts with "malicious" profile features. In the following, we evaluate the attack impact using simulations, followed by the discussion of practical costs.

Feature Altering Attack. To simulate this attack, we let adversaries select a set of features F of crowdturf accounts and alter F to mimic the corresponding features of normal users. Unlike evasion attacks that can simply mimic normal users' median values, here we need to mimic the whole distribution in order to make the two classes indistinguishable on these features. Since the feature altering is for all workers in the crowdturfing system, thus it actually applies to crowdturf accounts in both training and testing datasets. Finally, note that features are not completely independent, *i.e.* changing one feature may cause changes in others. To mitigate this, we tune features under the same category simultaneously.

Figure 20 shows the attack results on *Turfing+Active* dataset. We attack each feature category and repeat the experiment for 10 times. Here we simulate attacking one category at a time, and will discuss attacking category combinations later. In general, the attack makes all classifiers produce higher error rates compared with baseline where no feature is altered (the horizontal lines). However the impact is mild compared to injection-based poisoning attacks. For example, the most effective attack is on J48 when altering interaction features, which causes error rate increased by 4%, while injection-based attack can boost error rate by more than 20% (Figure 18). One possible reason is that unlike injection-based poisoning, altering-based poisoning does not cause inconsistencies in training and testing data, but only make the two classes harder to separate.

Costs of Altering. In practice, feature altering comes with costs, and some features may be impossible to manipulate even by crowdturfing administrators. For instance, *Tweeting Regularity* (Entropy) and *Burstiness* features are easier to alter. Recall that crowdturfing systems can enforce minimal (random) time delay between workers taking on new tasks, or use delays to increase entropy. Changing the *Tweet Client* feature is also possible, since crowdturfing systems can develop mobile client software for their workers, or simply release tools for workers to fake their tweeting clients.

Features Attacked	Error Rate (FP %, FN %)			
	RF	**J48**	**SVMr**	**SVMp**
None	(6.2, 3.4)	(6.7, 6.8)	(7.7, 10.1)	(7.9, 12.1)
C+B	(5.7, 4.4)	(7.9, 8.7)	(8.7, 12.2)	(8.0, 14.0)
B+E	(6.5, 3.9)	(7.1, 7.8)	(8.7, 12.5)	(7.3, 13.1)
C+E	(6.4, 4.5)	(7.9, 8.2)	(7.5, 11.8)	(6.3, 13.8)
C+B+E	(5.8, 4.2)	(8.3, 8.5)	(8.6, 13.2)	(7.7, 15.2)

Table 4: Error rates when features are altered in combinations. We focus on attacking low-cost features: Tweet Client (C), Burstiness (B) and Entropy (E).

Profile and *Interaction* features are more difficult to alter. Some features are mandatory for common tasks. For example, workers need to maintain a certain number of followers in order to spread spam to reach large enough audiences. In addition, some features are rooted in the fact that crowd-workers don't use their accounts organically, which, making it hard to generate normal user interactions. Although, crowdturfing systems could potentially use screening mechanisms to reject obviously-malicious crowdturf accounts from their system. However, this high bar will greatly shrink the potential worker population, and likely harm the system's spam capacity.

Considering practical costs, we consider whether it is more impactful to alter the combinations of features from different categories. Here we focus on altering the low cost features in *Tweet Client* (C), *Burstiness* (B) and *Entropy* (E). As shown in Table 4, attacking feature combinations produces slightly higher error rates than attacking a single feature category, but the overall effect is still small (less than 4% error rate increase).

Summary and Discussion. Through our analysis, we find that injecting misleading samples into training data causes more significant errors than uniformly altering worker behavior. In addition, we again observe the inverse relationship between single model fitting accuracy and robustness.

To protect their workers, crowdturfing sites may also try to apply stronger access control to their public records in order to make training data unavailable for ML detectors[13]. However, this creates obvious inconvenience for crowdturfing sites, since they rely on these records to attract new workers. Moreover, even if records were private, defenders can still obtain training data by joining as "customers," offering tasks, and identifying accounts of participating workers.

7 Related Work

Crowdturfing. Prior works used measurements on crowdturfing sites to understand their operation and economic structure [23, 24, 26, 48]. Some systems have been developed to detect paid human spammers in online review sites [31] and Q&A systems [9, 45]. To the best of our knowledge, our work is the first to explore detection of crowdturfing behaviors in adversarial settings.

OSN Spammer Detection. Researchers have developed mechanisms to detect fake accounts (Sybil) and spam campaigns in online social networks, including Facebook [15, 49], Twitter [43], Renren [52] and LinkedIn [46]. Most prior works develop ML models using features of spammer profiles (*e.g.* FFRatio, blacklisted URLs) or bot-like behaviors [4, 11, 42, 47, 50]. However, a recent study shows dedicated spam bots can still infiltrate social networks without being detected [14]. In our case, crowdturf accounts are carefully maintained by human users, and their questionable activities are camouflaged with synthetic cover traffic. This makes their detection challenging, until we add additional behavioral features (*e.g.* user-interaction, task-driven behavior).

Adversarial Machine Learning. In an early study [19], researchers classify ML adversarial attacks into two high-level categories: *causative* attacks where adversaries alter the training process to damage the classifier performance, and *exploratory* attacks where adversaries try to circumvent an already-trained classifier. Much of existing work focuses on *exploratory* attacks [5, 12, 25, 28] with less focusing on *causative* attacks [6, 37], since it's usually more difficult for adversaries to access training data in practice. In this paper, we studied both angles as both attacks are practically feasible from crowdturfing adversaries.

Several studies have examined attacks on specific ML-based applications, from email spam detection [12] to network intuition detection [37, 40, 44] to malicious (PDF) file classification [5, 25, 41] and malware detection [21]. Our work focuses on crowdturfing and explores a wider range of adversarial attacks, including active evasion and more powerful poison attacks against the model training process.

8 Conclusion and Discussion

We use a large-scale ground truth dataset to develop machine learning models to detect malicious crowdsourcing workers. We show that while crowdturfing workers resemble normal users in their profiles, ML models can effectively detect regular workers (95% accuracy) or "professionals" (99% accuracy) using distinguishing features such as user interactions and tweet dynamics.

More importantly, we use crowdturfing defense as context to explore the robustness of ML algorithms against adversarial attacks. We evaluate multiple adversarial attack models targeting both training and testing phases of ML detectors. We find that these attacks are effective against all machine learning algorithms, and coordinated attacks (such as those possible in crowdturfing sites) are particularly effective. We also note a consistent tradeoff where more accurate fits (especially to a smaller, more homogeneous population) result in higher vulnerability to adversarial attacks. The exception appears to be Random Forests, which often achieves both high accuracy and robustness to adversaries, possibly due to its natural support for multiple populations.

Limitations and Future Work. We note that our study has several limitations. First, our analysis focuses on Weibo, and our adversary scenarios may not generalize fully to other platforms (*e.g.* review sites, instant message networks). However, more work is necessary to validate our findings on other platforms. Second, our adversarial models use simplifying assumptions, *i.e.* features are independent and costs for feature modification are uniform. In addition, attackers may behave differently to disrupt the operation of ML detectors.

Moving forward, one goal is to validate our adversarial models in practice, perhaps by carrying out a user-study on crowdturfing sites where we ask workers to actively evade and disrupt ML detectors. In addition, our results show we must explore approaches to improve the robustness of ML-based systems. Our analysis showed that ML algorithms react differently to different adversarial attacks. Thus one possible direction is to develop hybrid systems that integrate input from multiple classi-

[13] As of late 2013, some crowdturfing sites (*e.g.* ZBJ) have already started to follow this direction, by limiting access to public transaction records to verified active participants.

fiers, ideally without affecting overall accuracy. We also observe that limiting adversaries' knowledge of the target system can greatly reduce their attack abilities. How to effectively prevent adversaries from gaining knowledge or reverse-engineering models is also a topic for future work.

Abstract

State-of-the-art memory forensics involves signature-based scanning of memory images to uncover data structure instances of interest to investigators. A largely unaddressed challenge is that investigators may not be able to *interpret the content of data structure fields*, even with a deep understanding of the data structure's syntax and semantics. This is very common for data structures with application-specific encoding, such as those representing images, figures, passwords, and formatted file contents. For example, an investigator may know that a `buffer` field is holding a photo image, but still cannot display (and hence understand) the image. We call this the *data structure content reverse engineering* challenge. In this paper, we present DSCRETE, a system that enables automatic interpretation and rendering of in-memory data structure contents. DSCRETE is based on the observation that the application in which a data structure is defined usually contains interpretation and rendering logic to generate human-understandable output for that data structure. Hence DSCRETE aims to *identify and reuse* such logic in the program's *binary* and create a "scanner+renderer" tool for scanning and rendering instances of the data structure in a memory image. Different from signature-based approaches, DSCRETE avoids reverse engineering data structure signatures. Our evaluation with a wide range of real-world application binaries shows that DSCRETE is able to recover a variety of application data — e.g., images, figures, screenshots, user accounts, and formatted files and messages — with high accuracy. The raw contents of such data would otherwise be unfathomable to human investigators.

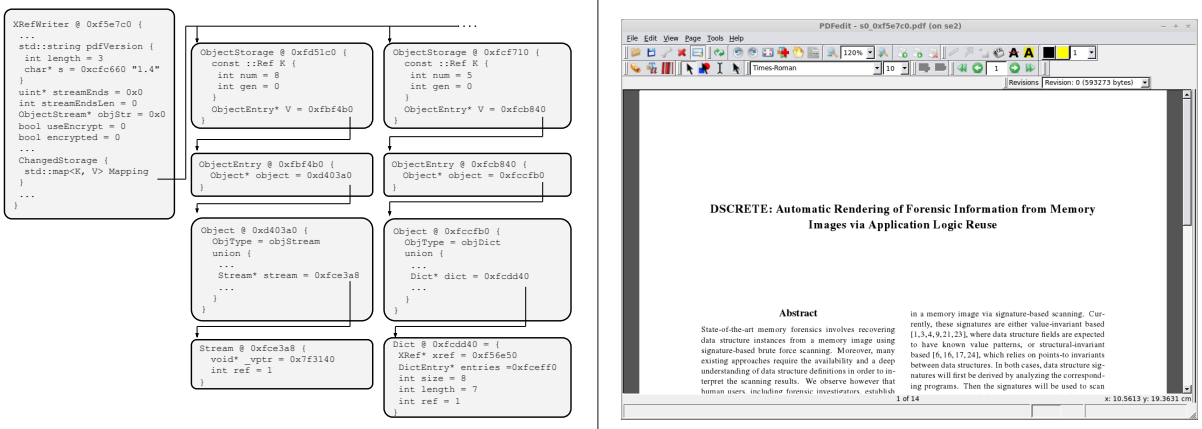
1 Introduction

Traditionally, digital investigations have aimed to recover evidence of a cyber-crime or perform incident response via analysis of non-volatile storage. This routine involves powering down a workstation, preserving images of any storage devices (e.g., hard disks, thumb drive, etc.), and later analyzing those images to recover evidentiary files. However, this procedure results in a significant loss of *live evidence* stored in the system's RAM — executing processes, open network connections, volatile IPC data, and OS and application data structures.

Increasingly, forensic investigators are looking to access the wealth of actionable evidence stored in a system's memory. Typically, this requires that an investigator have access to a suspected machine, prior to it being powered down, to capture an image of its volatile memory. Further, memory acquisition (both hardware [6] and software [25] based) must be as minimally invasive as possible since they operate directly on the machine under investigation. The resulting memory image is then analyzed offline using memory analysis tools. Therefore, the goal of memory analysis tools (like the work presented in this paper) is to recreate, in the forensics lab, the system's previously observable state based on the memory image.

Uncovering evidence from memory images is now an essential capability in modern computer forensics. Most state-of-the-art solutions locate data structure instances in a memory image via signature-based scanning. Currently these signatures are either value-invariant based [2, 3, 9, 21, 23, 26], where data structure fields are expected to have known value patterns, or structural-invariant based [5, 16, 17, 24], which rely on points-to invariants between data structures. In both cases, data structure signatures will first be derived by analyzing the corresponding programs. Then the signatures will be used to scan memory images and identify instances of the data structures. Contents of the identified instances will be presented to forensic investigators as potential evidence.

A significant challenge, not addressed in existing memory forensics techniques, is that investigators may not be able to *interpret the content of data structure fields*, even with the data structure's syntax and seman-



(a) Signature-based scanner output.

(b) DSCRETE-based scanner output.

tics. This is very common for data structures with application-specific encoding, such as those representing images, passwords, messages, or formatted file contents (e.g., PDF), all of which are potential evidence in a forensic investigation. For example, an investigator may know that a `buffer` field is holding a photo image (through existing data structure reverse engineering and scanning techniques [9, 15–17, 24, 26]), but still cannot display (and hence understand) the image. Similarly, a `message_body` field may hold an instant message, but the message is encoded, and hence it cannot be readily interpreted. We call this the *data structure content reverse engineering* challenge.

To enable automatic data structure content reverse engineering, we present DSCRETE[1], a system that automatically *interprets and renders* contents of in-memory data structures. DSCRETE is based on the following observation: The application, in which a data structure is defined, usually contains interpretation and rendering logic to generate human-understandable output for that data structure. Hence the key idea behind DSCRETE is to *identify and reuse* such interpretation and rendering logic in a binary program — without source code — to create a "scanner+renderer" tool. This tool can then identify instances of the data structure in a memory image and, most importantly, render them in the application's *original output format* to facilitate human perception and avoid the overhead of reverse engineering data structure signatures required by signature-based memory image scanners.

To illustrate the challenge of data structure content reverse engineering, we present a concrete example (from Section 4). Figure 1a shows the raw content of an in-memory data structure graph representing a PDF file. This is the output produced by existing signature-based scanners. For comparison, Figure 1b shows the same data structure content *after* applying DSCRETE's scanner with content reverse engineering capability. It is quite obvious that the reverse-engineered content would be far more helpful to investigators than the raw data structure content.

We have performed extensive experimentation with DSCRETE using a wide range of real-world commodity application binaries. Our results show that DSCRETE is able to recover a variety of application data — e.g., images, figures, screenshots, user accounts, and formatted files and messages — with very high accuracy. The raw contents of such data would otherwise be unfathomable to human investigators.

The remainder of this paper is organized as follows: Section 2 presents an overview of DSCRETE. Section 3 details the design of DSCRETE. Section 4 presents our evaluation results. Section 5 discusses some observations from our evaluation, current limitations, and future directions for this research. Section 6 discusses related works and Section 7 concludes the paper.

2 System Overview

2.1 Key Idea: Executable Code Reuse

DSCRETE is based on reusing the existing data structure interpretation and rendering logic in the original application binary. As a simple example, consider the Linux `gnome-paint` application. At the high-level,

[1]DSCRETE stands for "Data Structure Content Reverse Engineering via execuTable rEuse," pronounced as "discrete."

`gnome-paint` works as follows: An input image file is processed into various internal application data structures. The user then performs edits to and saves the image. To save the image, `gnome-paint` will reconstruct a formatted image from its internal data structures and write this image to the output file.

Later, if a forensic investigator wanted to recover the edited image left by `gnome-paint` in a memory snapshot, DSCRETE would be used to identify and automatically reuse `gnome-paint`'s own data structure rendering logic. First, DSCRETE will identify and isolate the corresponding data structure printing functionality within the application binary. For brevity, let us refer to this printing/rendering component as the function *P*. *P* should take as input a data structure instance and produce the human readable application output which is expected for the given data structure. In the case of `gnome-paint`, this component is the `file_save` function. It takes as input a `GdkPixbuf` structure and outputs a formatted image to a file. Note that *P* may not be a function in the programming language sense, but instead a *subsection of the application's code* responsible for converting instances of a certain data structure into some human-understandable form (e.g., output to the screen, file, socket, etc.).

Once *P* is identified, DSCRETE will reuse this function to create a *memory scanner+renderer* (or "scanner" for short) to identify all instances of the subject data structure in a memory image. If *P* is well defined for the input data structure, then one can expect *P* to behave erroneously when given input which is not a valid instance of that data structure. Under this assumption, we can present each possible location in the memory image to *P* and see if *P* renders valid output for the data structure of interest. We note that should an investigator alternatively choose to use a signature-based memory scanner to locate data structure instances, the DSCRETE-generated scanner *is still able to render* any located instances.

2.2 Overview of DSCRETE Workflow

Figure 2 presents the key phases and operations of DSCRETE. The first input is a binary application for which an investigator wishes to recover application data of interest from a memory image. To avoid compatibility issues (such as different data structure field layouts), this binary should be the same as the one that has contributed to the memory image.

The subject binary is then executed under instrumentation to identify the code region responsible for converting a specific data structure into application output (the function *P* defined earlier). We refer to this phase of DSCRETE as "tracing," and the details of this step are presented in Section 3.1. In the next phase, "identification" (Section 3.2), a *graph closure algorithm* is used to formulate a list of possible candidates for *P*. Each candidate is tested, by the "tester" component (Section 3.3), with a ground truth data structure instance to determine if it can serve as a viable memory scanner.

Once the specific application logic (*P*) is identified, DSCRETE packages this logic as a *context-free memory scanner* (Section 3.4), which will be presented to forensic investigators to scan and interpret memory images in this and future investigations involving the same application. We point out that the first three phases (tracing, identification, and tester) are a one-time procedure internal to DSCRETE and do *not* involve field investigators who will be using the DSCRETE scanners in their practice.

It is important to note that, unlike signature-based memory scanning techniques, we do not attempt to find and return the raw contents (bytes) of identified data structure instances in a memory image. Instead, we aim to present the investigator a set of *application-defined outputs* that would naturally be generated by the subject application, had it executed *P* with the data identified in the memory image. We emphasize that DSCRETE does *not* infer data structure definitions (unlike [17, 24]), nor does it derive data structure signatures (unlike [16]).

2.3 Assumptions and Setup

Firstly, we assume that when producing DSCRETE-based memory scanners (which is typically the task of a central lab of a law enforcement agency), the subject binary can be executed. This includes recreating any execution environment (i.e., operating system and application version, required libraries, directory configurations, etc.) which the application requires. We believe that this assumption is not overly difficult to realize. In a real forensic investigation, such runtime configuration information can be collected via preliminary examination of suspect or victim machines. Additionally, our dynamic instrumentation requires that address space layout randomization (ASLR) be turned off during the production of the DSCRETE memory scanners (i.e., only the investigator's personal workstation, *not* the suspect machine under study). The reason for this will become clear in Section 3.3.

Secondly, we assume that the OS kernel's paging data structures in the subject memory image are intact. This is a similar assumption made by many previous memory forensics projects [16, 21, 26]. We require this because DSCRETE takes as input only the subject application's memory session from the suspect machine. For our evaluation, we extracted the memory pages directly from running applications — which is preferred when an investigator has physical access to a suspect's ma-

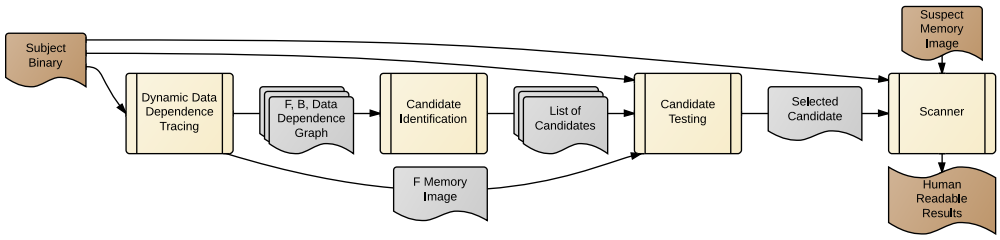

Figure 2: Overview of DSCRETE workflow.

chine. However in many forensic investigations only the memory snapshot and hard disk image are available. In this case the Volatility [26] `linux_proc_maps` and `linux_dump_map` plug-ins (or `memmap` and `memdump` for Windows) can be used to identify and extract process pages and mapping information from a whole system memory image.

3 System Design

In this section, we explain each phase of DSCRETE.

3.1 Dynamic Data Dependence Tracing

The first phase of DSCRETE, "tracing," collects a dynamic data dependence trace from the subject application binary. This trace must contain some portion of the future scanner's code (i.e., the code responsible for rendering a data structure of interest as human-understandable output). To collect this trace, we (as the central lab staff producing the scanners for field investigators) interact with the application to perform the following actions:

1) Create and populate an instance of the data structure used to store the data of interest. However, we make no assumptions on the knowledge about this data structure. We only assume that *some* data structure exists in the application which holds forensically interesting information in its fields.

2) The data structure of interest must be emitted as observable outputs (e.g., to files, network packets, or displayed on screen). This is to allow the scanner production staff to express their forensic interest by marking (part of) the output.

Again let us use `gnome-paint` to illustrate this procedure. To accomplish Step 1, we only need to execute `gnome-paint` with some input image. This will cause `gnome-paint` to create and populate numerous internal data structures to store the image's content. To accomplish Step 2, we only need to save the image to an output file. `gnome-paint` will process the image for output and call the GDK library's `gdk_pixbuf_save` function with the image's content as a parameter. While this may seem like a highly simplified example, the case studies in Section 4 show that in general we do not need to perform lengthy or in-depth interaction with an application to accomplish these two requirements.

Meanwhile, DSCRETE will be collecting each instruction's data dependence and recording any library functions or system calls invoked by the application as well as their input parameters. This is used to later identify which known external functions, specifically those which emit data to external devices, were invoked with the forensically interesting content as a parameter (`gdk_pixbuf_save` from our `gnome-paint` example). Note that since our analysis is at the binary level without symbolic information, we consider a parameter to be any memory read inside a function that depends on a value defined prior to the function's invocation. The memory may be accessed inside the function, subsequent functions, or as an argument to a system call[2], and the content read is logged as parameters. We exclude any memory not previously written to by the application or a previous library function, allowing us to ignore any memory which is private to the library function and not related to the parameter (i.e., the transformed data structure). This logging results in an output file containing the list of invoked external functions and parameters to each (similar to the Linux `strace` utility).

It is important to note here that DSCRETE saves a snapshot of the process's stack and heap memory at the invocation of any external library function which leads to an output-specific system call (i.e., `sys_write`, `sys_writev`, etc.). We (as the forensics lab staff) may, optionally, further specify individual library functions for which a snapshot should be taken. For example, if we know that the forensic evidence will be rendered on the application's GUI, then we may choose to only log visual-output related library calls in the GTK library. These snapshots will later be used to test possible *closure points* (defined in Section 3.2).

Once Steps 1 and 2 are accomplished, we may terminate the subject binary and search the log of external function calls for one in which the forensically in-

[2]We assume that system call interfaces are known and thus we can mark which parameters and memory ranges are read and which are written to.

teresting data is seen as parameters. Once suitable functions are chosen, DSCRETE only needs to identify which bytes of the parameters for those function invocations are of forensic value.

The chosen function invocations and set of parameter bytes will be important for two reasons: First, the parameter bytes will serve as the source nodes in our data dependence graph. Second, the function(s) will be used as the termination point for our scanner and the corresponding bytes will be the *output* of the scanner. For brevity, these functions will be referred to as F and the selected forensically interesting bytes of F's parameters as the set B. For our running `gnome-paint` example, consider `gdk_pixbuf_save` as F and the image buffer it prints to the output file as B.

Finally, a data dependence graph is generated using the trace gathered during dynamic instrumentation. The graph begins with the instructions responsible for computing the bytes of B as source nodes. Then in an iterative backwards fashion, any instruction which a graph node depends on is also added to the graph. Eventually, the graph will contain any instruction instance which led to the final value of B's bytes. This process is identical to that of typical dynamic slicing [13], we just chose to ignore control dependence as it is not required for identifying the functional closure (to be described next).

3.2 Identifying Functional Closure

Given F, B, and the data dependence graph, DSCRETE must find a *closure point* for the rendering function P. We define a closure point as an instruction in the data dependence graph which satisfies: 1) It directly handles a pointer to the forensically interesting data structure and 2) Any future instruction which reads a field of the data structure must be dependent on the closure point. This leads to the nice property that by changing the pointer handled by the closure point, we can change the data output by P. Returning to the `gnome-paint` example, the closure point is the instruction which moves a `GdkPixbuf` pointer into an argument register during `file_save`.

However, without source code or the effort of reverse engineering the subject binary, we cannot know the closure point for certain a priori. In fact, there may be multiple closure points in a program, any of which will satisfy our criteria above. To find a valid, usable closure point we use a combination of a graph closure algorithm and heuristics to output a list of *closure point candidates*. Each candidate is a tuple of the following: the address of an instruction which may satisfy the above criteria, the register or memory operand which it stores a pointer to, and the value of that pointer from the data dependence trace taken during tracing (Section 3.1).

Algorithm 1 Identifying *Closure Point* Candidates

```
Input: DataDepGraph(V, E), p
Output: Candidates[]
  SubGraphs[] ← ∅
  Previous_Candidate ← ∅
  for node n ∈ V in Reverse Temporal Order do
    G(Vn, En) ← ∅                          ▷ Build subgraph rooted at n
    Vn ← {n}
    for (n, t) ∈ E do          ▷ Each t that depends on n (may be ∅)
      Gt(Vt, Et) ← SubGraphs[t]            ▷ SubGraph rooted at t
      Vn ← Vn ∪ Vt
      En ← En ∪ Et ∪ (n,t)
    SubGraphs[n] ← G
    if Is_Store_Instruction(n) then        ▷ Apply heuristics to n
      val ← Stored_Value(n)
      loc ← Store_Location(n)
      if Is_Possible_Pointer(val) then
        if |SubGraph[n]|>|SubGraph[Previous_Candidate]| then
          Candidates ← Candidates ∪ (n, loc, val)
          Previous_Candidate ← n
    if |SubGraphs|> p%×|DataDepGraph| then
      break                    ▷ Only consider p% of DataDepGraph
```

We call this phase "candidate identification." The algorithm to identify closure point candidates is given in Algorithm 1. Starting from each byte in B, the algorithm steps through the data dependence graph in reverse temporal order (i.e., from the last instructions executed to the first). For each node visited (n) the algorithm builds a graph containing all previously visited nodes which depend on n (G in Algorithm 1). Essentially, graph G will resemble a subgraph rooted at n with its leaves accessing some bytes of B.

For each node n added to these subgraphs, the algorithm performs the following heuristic checks; any node which passes these checks is considered a closure point candidate. First, n must store a value (either to a register or memory location) which could be a possible data structure pointer (any integer value that falls within a memory segment marked readable and writable). Second, the size of the dependence subgraph rooted at n must be larger than the previous candidate's subgraph. The intuition here is that a correct closure point will take as input a pointer to a data structure instance, and store this pointer to be reused by the rendering function P. Thus for the part of the data dependence graph responsible for rendering a data structure instance, the largest subgraph must have the closure point at its root. Consider a data dependence graph for the `file_save` function from `gnome-paint`: The largest subgraph of this data dependence graph should be rooted at the input `GdkPixbuf` pointer.

Another heuristic is to stop the algorithm after only a small percent of the data dependence graph is analyzed. Note that the data dependence graph contains instructions from F back to the application's `main` function. Further, P will be close to F in the graph and signif-

icantly smaller than the rest of the application's code. This percentage is taken as a configurable input (p in Algorithm 1) and is set via a forward iterative approach. In our evaluations in Section 4, we started with a p value of 1 and incremented p until a valid closure point was found. Even in the extreme case (`top`), p was never more than 10 and was often less than 5.

In all of our evaluations, the number of candidates never exceeded 102 and was often below 30. Additionally, as will be explained in the next section, we never need to verify (or even see) any of the candidates. The testing of candidates is done mostly automatically.

3.3 Finding the Scanner's Entry Point

To test each closure point candidate, DSCRETE will run a modified version of the memory scanner described in the next section. This modified scanner, named the candidate "tester," takes as input: 1) the known end point of the scanner (i.e., F), 2) the memory image taken when F was executed, 3) the list of candidates, and 4) the subject binary. The modified scanner will treat F's memory image as the "suspect" memory image to scan. We assume that this memory image contains a valid instance of the data structure which held the data seen in B because the application was in the process of rendering/emitting this data structure instance's fields when the memory image was captured.

The candidate tester will re-execute the subject binary from the beginning, but before the process is started the scanner maps the "suspect" memory image's segments into the address space. Each segment (a set of pages) is mapped back to the address from which it was originally taken[3]. This ensures that pointers in these memory segments will still be valid in the new process's address space. Note that ASLR is disabled during DSCRETE operations. At this point, the new process is unaware of the added memory segments and executes normally using only its new allocations. Later, we will intentionally force the new process to use a small portion of the old process's data session to test closure point candidates, a technique we call *cross-state execution* (discussed in Section 3.5).

In the new execution, the forensically interesting data seen in this run of the application should be altered (e.g., executing `gnome-paint` with a different image). This will later allow the user to easily determine which candidate's output is correct (from the data structure in the memory image).

[3]We have not seen any cases where critical segments overlapped. This is because the segments are being mapped into ranges usually reserved for heap and stack space. Since these segments are almost universally relocatable the new process is simply allocated pages around our memory image.

The application runs until a closure point candidate instruction is executed. Here, the tester forks an identical copy-on-write child of the subject application to perform the actual scan; the parent process will be paused until the child has completed. The scanner looks up which register or memory operand this candidate stores its pointer value into and overwrites this location with the pointer's value stored in the candidate. Note that if this candidate is a correct closure point, then the stored pointer value is a valid pointer to a data structure instance in the mapped memory image. This assumes that the data structure instance is not corrupted from the beginning of the rendering function P (for which this candidate may be an entry point) to the invocation of F. Since all candidates are reasonably close to the invocation of F (within p% of the total trace size), we find that this is never a problem in practice.

Further, if this candidate is a correct closure point, the child process will now execute P, access the old process's memory segments (via the changed pointer value), generate the same bytes for B, and invoke F with these bytes. Imagine that, for our `gnome-paint` example, this candidate is the instruction which moves a `GdkPixbuf` pointer into a register during `file_save` (P). Now `file_save` will execute in the child process with the `GdkPixbuf` structure inside the memory image and should call `gdk_pixbuf_save` (F) with an identical image as was previously rendered (B). Also, recall that the forensically interesting information seen in the new run is altered. This is to easily partition between output generated from the memory image and output from the new execution of the application.

During testing, if the child process crashes after the pointer replacement, then the candidate is assumed incorrect and thrown out. When the F function(s) execute to completion (recall that in our `gnome-paint` example F is `gdk_pixbuf_save`) then the content given as input to F is recorded as a result for this closure point candidate test. An example of this recorded output is given later in Figure 6 (Section 4.3.1). The end of a scan is determined as follows: When F is a single function invocation, the child process is killed after F returns. If F consists of multiple invocations, the scan continues until the execution call stack returns to a point before the closure point. The parent process is then resumed, and this is repeated until all candidates are tested. A candidate is considered a valid closure point if it has accurately recreated the bytes chosen for B.

3.4 Memory Image Scanning

Once the data structure rendering function P has been identified, DSCRETE can build a memory scanning+rendering tool out of the subject binary. In fact, the production memory scanner is quite similar to the mod-

ified scanner used for testing candidates in the previous section. The difference is that we do not know where in a suspect memory image the data structures may be. The input to the memory image scanner tool are: 1) the chosen entry point and exit point of the printing function *P*, 2) the subject binary, and 3) the suspect memory image (as described in Section 2.3).

Again the scanner will re-execute the subject binary with the suspect memory segments mapped back into their original placements. Like before, the suspect memory segments will not be used until scanning begins, and until then the process executes using only its new allocations. With the same application input from candidate testing, the execution will reach *P*'s entry point, where the scanner pauses the application. For each address in the memory image, the scanner will fork an identical copy-on-write child and assign *P*'s pointer to the next address in the memory image. In essence, the scanner is executing *P* with a pointer to each byte of the suspect memory image. The scanning child process executes until *P*'s end point (as defined in the previous section) and then *P*'s output is recorded to a log or the child process crashes.

The intuition behind re-executing the application from the beginning is to automatically rebuild any dependencies required by *P*. DSCRETE requires that *P*'s only input be a pointer to a possible data structure. In reality, *P* may depend on multiple parameters set up by the application prior to the closure point. By re-executing the application from the beginning, we ensure that any other dependencies *P* has are taken care of before the scanner injects a data structure pointer.

The execution of *P* is done in a child process to isolate side effects. Not surprisingly, the vast majority of addresses will cause invalid memory accesses or other exceptions, and by scanning each byte in a separate process the scanner ensures that side effects do not contaminate future scans or global values. To speed up scanning, multiple child processes can be spawned to run in parallel.

In some rare cases, *P* is too simple (performs too little input processing) to crash on invalid input. For such cases, we allow for a user-defined post-processing phase. We still assume no use of source code or reverse engineering effort, but the user may perform sanity checks based on the known format or value ranges for an application's output. For instance, in our `top` case-study we had to remove any output which had a negative process ID or blank user or process name field. In our experiments, only three cases — `CenterIM`, `top`, and `Firefox VdbeOp` — required any post-processing. Further, this only occurs for very simple textual *P* functions — complex cases such as those requiring content reverse engineering naturally involve more strict parsing and input sanitization.

3.5 Cross-State Execution

DSCRETE maps one process's address space into the address space of another. Further, when DSCRETE executes the function *P*, this code will evaluate data in both the old and new address spaces. Once DSCRETE replaces a data structure pointer at the closure point, the scanning process will then access fields from the data structure in the old address space while still using stack and other heap objects in the new address space.

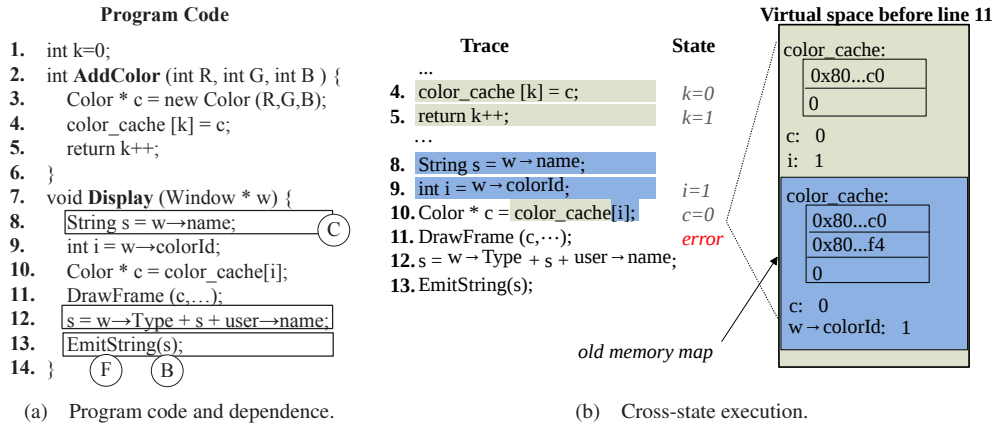
Ideally, any sub-execution that depends on the closure point would exclusively access the state from the old address space. In other words, we expect the continuation after the pointer replacement would consist of two disjoint sub-executions, one corresponding to running *P* on the old address space and the other corresponding to the rest of the execution exclusively on the new address space. However, due to the complex semantics of real world programs, such separation may not be achievable. There are two possible problems: 1) An instruction execution may depend on state from both address spaces, resulting in some state that is infeasible in either the original or the new execution. We call such instructions *confounded instructions*. 2) Since the old memory snapshot may not be complete, an instruction may access a location in the old space that is not mapped in the new space. Note that this location may now correspond to a valid address in the new space such that the access becomes one to the new space. We call this a *trespassing instruction*. Both could cause crashes and hence false negatives.

Consider the example in Figure 3. Figure 3a shows two functions[4]. The first function (lines 2 - 6) creates a `Color` object and adds it to the `color_cache`. The other (lines 7 - 14) renders a window, including drawing the `Color` to a frame and emitting the window title as a string. Note that different executions may add different `Color` objects to the cache. Specifically, the number of `Color` objects and their order vary across executions. Later, the window rendering function will look up a `Color` object from the cache using its id.

Assume we (as forensics lab staff) mark the `EmitString()` function at line 13 as *F* and `s` (the window title) as *B*. Following the candidate identification algorithm, we compute the backward data-dependence of *B* as those boxed statements. We further identify line 8 as the closure point candidate.

However, when we test this candidate, cross-state execution leads to undesirable results if not properly handled. Let us assume that two `Color` objects were cached during the original execution, whereas only one `Color` is added in the candidate test execution. Figure 3b shows the trace of the candidate test execution on the left, and,

[4]Our discussion is at the source code level for readability, whereas our design and implementation assume only the application binary.



(a) Program code and dependence.

(b) Cross-state execution.

Figure 3: Example for cross-state execution.

on the right, it shows the state of the new address space right before the execution of line 11. Note that the pages of the old address space are mapped inside the new address space. Each executed statement in the trace is colored based on the address space it operates on. Particularly, lines 4 and 5 execute before the pointer `w` is replaced at line 8, and hence belong to the new space. In contrast, lines 8 and 9 belong to the old space, as their values are loaded from locations derived from the replaced `w`. Line 10 is a confounded instruction, as the array `color_cache` belongs to the new space while `i` belongs to the old space. As a result, an invalid color is loaded, leading to a crash. However, observe that lines 10 and 11 are not in the data dependence of B, as such we could potentially skip them.

Therefore, given a closure point candidate C and its termination point F, DSCRETE scans the original execution trace from C to F during the candidate identification phase. For each address dereference it encounters, it tests if the address is exclusively dependent on the pointer parameter at C. If not, it is a confounded dereference. DSCRETE further tests if the dereference is in the data-dependence graph of B, and if not, marks the instruction as an irrelevant dereference to be skipped during test execution and later scanning executions. In practice, we observed confounded memory dereferences in only one of the cases we studied.

Handling trespassing instructions is relatively easier. Given a closure point candidate C and its termination point F, DSCRETE scans the original execution trace from C to F and marks each address dereference that it encounters and is dependent on the pointer parameter at C. At runtime, if a marked dereference accesses a location in the new space, it is a trespassing access and can be skipped.

4 Evaluation

DSCRETE leverages the PIN binary analysis platform [19] to perform instrumentation. Since PIN executes before the subject binary is loaded, this allows us to map the memory image into the new process's address space before the operating system's loader can claim stack and heap regions. DSCRETE relies on minimal OS-specific knowledge (i.e., system call and application binary interface definitions), thus DSCRETE can easily be ported to any operating system that PIN supports. In the remainder of this section, we present results from evaluating DSCRETE with a number of real-world applications and focus on a subset which highlight the use of DSCRETE and a few critical observations.

4.1 Experimental Setup

Our evaluation used a Ubuntu 12.10 Desktop system as the "suspect" machine. Each application was installed on the machine and interacted with by the authors to generate sufficient allocations and deallocations of data structures. We used `gdb` to capture memory images from the application periodically during the system's use. To attain ground truth, we manually instrumented the applications to log allocations and deallocations for data structures corresponding to the output of forensic interest (i.e., B in Section 3.1). This log was later processed to measure false positives (FP) and false negatives (FN). For analysis, we employed a Ubuntu 12.10 virtual machine. To recreate the suspect machine's running environment, we copied the applications and needed configuration files from the suspect machine's hard disk. We then performed all forensic investigation within the virtual machine.

Application	F	Forensically Interesting Data	Size B (bytes)	p%	#C	#O	#P
CenterIM	`SSL_write`	Username & Password	336	5%	46	1	1
convert	`fwrite`	Output Image Content	81902	9%	18	7	2
gnome-paint	`gdk_pixbuf_save`	Image Content	670900	1%	18	2	2
gnome-screenshot	`gdk_pixbuf_save_to_stream`	Screenshot Content	1139791	1%	5	4	3
gThumb	`gtk_window_set_title`	File Info Window Title	85	1%	102	4	2
	`gdk_pixbuf_save_to_bufferv`	Image File Content	20360	1%	10	3	3
Nginx	`write`	HTTP Access Log	181	5%	25	1	1
PDFedit	`fwrite, fputc`	Edited PDF Content	30416	1%	46	6	3
SQLite3 Shell	`fputs`	Database Query Results	19	2%	4	1	1
	`fprintf`	Database Op. Log	38	2%	17	5	1
top	`putp`	Process Data	132	10%	1	1	1
Xfig	`fprintf`	Figure Content	1001	1%	9	3	3

Table 1: Results from identifying applications' P functions (#C shows the number of identified candidates, #O shows how many of those produced output, and #P shows the final subset which are valid closure points).

4.2 Function Identification Effectiveness

This section presents results of isolating the data rendering function P in each tested application. From the `CenterIM` instant messenger, we target the component which emits the user's login and password (still in plain text) to an SSL socket. Also, given the importance of image content to investigations, we isolate image rendering functions from three common image editors: `convert`, `gnome-paint`, `gThumb`, as well as the `gThumb` GUI function which displays the current image's name to the window title. The output function of `gnome-screenshot` can allow an investigator to see what screen-shot a suspect was capturing. Additionally, we reuse `Xfig`'s figure saving P function to reconstruct a vector figure that was being worked on. As we introduced in Section 1, the PDF saving functionality of `PDFedit` allows investigators to recover the edited PDF file. For internal application data, we identified P functions for `SQLite`'s query results and operations log (more on how these scanner+render tools are used later in this section). It is very common for attackers to tamper with server log files, so we isolated the `Nginx` webserver's connection logging function, thus an investigator can compare with the uncovered in-memory connections. Finally, for details on all running processes in a suspect system, we identified the process data printing logic in the `top` utility.

Table 1 shows a summary of the results from each of these applications. The application name and F function are shown in Columns 1 and 2 respectively. Column 3 details the forensically interesting data that were to be emitted by $F(B)$ and Column 4 shows the size of B in bytes. The percentage of the data dependence graphs used to generate candidates is shown in Column 5. Finally Columns 6 to 8 show the number of candidates identified by our algorithm (#C), how many of those produced any output (#O), and the final subset which accurately recreated B and could be used for valid closure points (#P), respectively.

From Table 1 we make the following observations: First, our algorithm/heuristics used to identify closure point candidates are accurate enough to limit the number of candidates to a reasonable search space. Although candidates are tested automatically during the candidate tester's execution, we aim to minimize the number of candidates to test. From Table 1, we see that 11 out of the 12 applications have less than 50 candidates. The only application with more than 50, `gThumb`, has 102, and as we see in Row 5 of the table, they are drastically narrowed down by the candidate tester. Manual investigation revealed that `gThumb`'s larger number of candidates was due to extra data dependencies caused by another parameter to its F function (`gtk_window_set_title`).

The second observation we make is that, of the total number of candidates identified, very few will be true closure points. This is intuitive since there is only one true entry to the P function in the application. Third, since the number of candidates which produced valid output is so small, it is relatively simple for a DSCRETE user to identify which candidate accurately reproduced B.

On average, each candidate testing component rendered application output for only three closure point candidates. The maximum, `convert`, rendered only seven outputs during candidate testing. Further, *more than half* of the applications produced ideal candidates — all candidates that rendered output were valid candidates. For the other five applications, about 45% of candidates

which produced output accurately recreated the expected forensically interesting data (i.e., the new output matched that seen before). This shows that: 1) Visually inspecting candidate output is a reasonably quick and practical task and 2) DSCRETE can identify and validate closure point candidates with high accuracy.

Table 1 shows that it is not uncommon for multiple correct closure points to exist for a *P* function. Manual investigation revealed that this is caused by two program features: nested data structure pointers and register-to-stack spilling. In the nested data structure situation, if a data structure A has a pointer to structure B and *P* uses the B pointer within A, then either the A pointer or its internal B pointer may be valid closure points for *P*. For the register-to-stack spilling situation, a pointer to an input data structure is initially stored in a register, but when contention forces that register to be spilled onto the stack, either the initial register or its later stack-saved location may be used for closure points.

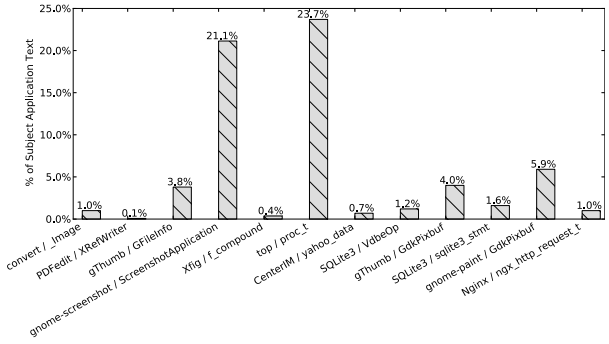


Figure 4: Normalized size of *P* vs. entire binary code.

Table 1 also shows that a valid closure point is typically located in the bottom 5% of the data dependence graph. Thus, the actual rendering function being reused is often only a small percentage of the binary's text. Figure 4 shows the normalized percentage of the host binary which we reuse for each scanning function. The size of the reused code is measured as the total in-memory size of all unique instructions observed during all re-executions of *P*. `Top`, `gnome-screenshot`, and `gnome-paint` are outliers due to the relatively small size of the applications and the resulting dependence graphs.

SQLite *P* Functions. An interesting application of DSCRETE can be seen in the experiments with SQLite. For these experiments DSCRETE was used with the SQLite3 command shell and a homemade database file to find *P* functions for a database query's result (`struct sqlite3_stmt`) and operations log (`struct VdbeOp`). These data structures are defined by the SQLite3 library and exported to client applications. The *P* functions DSCRETE identifies would be used to build memory scanner+renderer tools which could discover those data structures and render their content in the same format as the SQLite3 command shell.

These scanners could then be used on memory images from *any application which uses SQLite*. Since these data structures are defined by the SQLite library, any application using SQLite should transitively allocate and use these data structures. Further, we are reusing the SQLite3 command shell's *P* functions, so even if an application never outputs the data held in these structures, we can still discover and interpret them using the more general SQLite memory scanners. In the next section, we show results from applying these scanner+renderer tools to memory images from Mozilla Firefox and darktable image editor.

4.3 Memory Scanner Effectiveness

Table 2 reports the effectiveness of the DSCRETE-generated scanner+renderer tools when scanning a context-free memory image from each application. The application name is shown in Column 1. The subject data structure (input to *P*) and the structure's size are shown in Columns 2 and 3[5]. The number of true instances in the suspect memory image is shown in Column 4[6]. Column 5 shows the total number of output generated by each scanner+render tool. Columns 6 to 10 show the number of generated output which are: true positives (TP) - backed by true data structure instances, false positives (FP) and the percentage of FPs in the total output (FP%), and false negatives (FN) and the corresponding FN percentage.

This table shows that the *P* function identified by DSCRETE is almost always well defined. This allows DSCRETE to uncover and render valid data structure instances with 100% accuracy for most cases. Specifically, Table 2 shows that DSCRETE's scanner+renderer tools are perfectly accurate (i.e., no FP and no FN) in 11 out of the 13 cases. We analyze the two FP/FN cases in detail later in this section. More importantly, DSCRETE overcomes the data structure content reverse engineering challenge by displaying the results in each application's original output format. The test cases covered in Table 2 span a wide range of application data: usernames and passwords, images, PDF files, vector-based graphics, as well as formatted and unformatted textual output. This portrays the generality of DSCRETE and represents several key types of evidence that would be very difficult

[5]Such information was obtained via manual instrumentation, inspection, and reverse engineering only for the purpose of evaluation. DSCRETE does not need or have access to this information during operation.

[6]This includes all the data structure instances which were allocated and not yet released and overwritten when the memory image was captured.

Application	Subject Data Structure	Size (bytes)	True Instances	Total Output	TP	FP	FP%	FN	FN%
CenterIM	`yahoo_data`	160	1	1	1	0	0.0%	0	0.0%
convert	`_Image`	13208	1	1	1	0	0.0%	0	0.0%
darktable	`sqlite3_stmt`	272	1	1	1	0	0.0%	0	0.0%
Firefox	`sqlite3_stmt`	272	1	1	1	0	0.0%	0	0.0%
	`VdbeOp`	24	788	1384	753	502	40%	35	4%
gnome-paint	`GdkPixbuf`	80	51	51	51	0	0.0%	0	0.0%
gnome-screenshot	`ScreenshotApplication`	88	1	1	1	0	0.0%	0	0.0%
gThumb	`GFileInfo`	48	382	381	381	0	0.0%	1	0.4%
	`GdkPixbuf`	80	63	63	63	0	0.0%	0	0.0%

top	`proc_t`	720	382	382	382	0	0.0%	0	0.0%
Xfig	`f_compound`	112	1	1	1	0	0.0%	0	0.0%

Table 2: Results from DSCRETE-generated scanner+renderer tools.

(if at all possible) to reconstruct from raw data structure contents.

Table 2 shows that many of the subject data structures are smaller than the resulting application output (*B* from Table 1). Our manual analysis of these structures reveals that 10 of the 12 data structures contain several pointers to other data structures used by *P*. This confirms our intuition that, in order to recover usable evidence from a memory image, numerous data structures must be uncovered and interpreted. Note that an investigator never actually sees any of these structures, but rather is presented only the application output rendered from the structures' contents. Figure 1a in Section 1 is one such example.

Another metric to report is the time taken to scan, which varies depending on: 1) the complexity of the rendering function *P* and 2) the size of the memory image being scanned. Figure 5 shows the scanning speed in bytes-per-second for each scanner function in our evaluation. During our experiments, the size of the applications' heaps ranged from 400KB to about 5MB, and total heap scanning time ranged between 15 minutes to just over 2 hours, with most taking about 30 to 45 minutes. Admittedly the scanning and rendering of evidence is slower than typical signature-based memory scanners, but still well within the typical time taken to process digital evidence, with the added benefit that evidence is presented in a human-understandable form. Ayers [1] points out that it may take "several hours or even days when processing average volumes of evidential data," which is confirmed by our collaborators in digital forensics practice.

False Positive and False Negative Analysis. We notice that only the gThumb and Firefox `VdbeOp` experiments experienced any negative results. Manual investigation into these two experiments' false negative results (i.e., true data structure instances not discovered by DSCRETE) revealed that those structures were allocated, but did not contain enough data to be rendered by *P*. They were either in the process of initialization or deletion or being used as empty templates by the application.

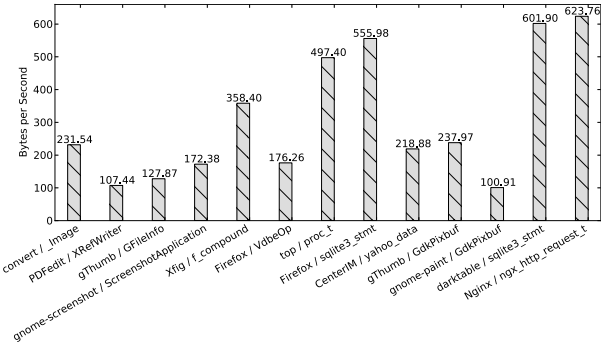

Figure 5: Observed throughput of each scanner.

Interestingly, the Firefox `VdbeOp` case study (SQLite's operations log structure) represents a counter-example to our hope that *P* be well defined. In this case, *P* performs little parsing and no sanity checks on its input. A `VdbeOp` structure is essentially a set of seven integer values, and SQLite3 uses these integers as indices in a global string table, without any sanity checks. Since this *P* function performs such trivial parsing, a large number of false inputs produce typical SQLite3 Shell output. We consider this a worst-case scenario for DSCRETE, and believe it is also the case for many other memory forensic techniques when facing such a trivial data structure.

In Section 1 we introduced one example of forensic

data which would be uninterpretable without data structure content reverse engineering. The complex multi-level data structure representing a PDF file requires non-trivial processing to locate the fields which contain any usable PDF content. Further, many fields are encoded, compressed, or computed only when outputting the PDF file. In the remainder of this section, we present several other application case studies with DSCRETE.

4.3.1 Case Study: `convert`

This case study highlights DSCRETE's content reverse engineering capability for image data structures. The `convert` utility is used to apply various transformations to an image file. The source image file is processed and converted into internal data structures, (i.e., an `_Image` and array of `_PixelPacket` structures). Various transformations (such as scaling, blurring, etc.) are applied, and the pixels are re-composed into an image and written to a file. It would be considerably difficult to reconstruct the image from its in-memory representation, even with a deep understanding of these structures' syntax and semantics. However, DSCRETE is able to overcome this challenge by identifying and reusing the image output component (function `WriteImage`) which constructs an output image file from an input `_Image` structure.

As shown in Row 2 of Table 1, *B* (the image's content) was seen as an argument to the `fwrite` function. Using this, DSCRETE identified 18 closure point candidates in the bottom 9% of the data dependence graph. Of these candidates, 16 clustered around the handling of `_PixelPacket` structures in the image reconstruction routine, and the remaining 2 candidates handled the input `_Image` structure at the entry to the `WriteImage` function.

The DSCRETE candidate tester component eliminated 16 candidates which handled `_PixelPacket` structures. For the remaining two candidates, DSCRETE produced the log and application output shown in Figure 6. From Figure 6 we see that Candidates 1 and 2 successfully executed *P* (ending with `fwrite`). More importantly, DSCRETE accurately rendered the `_Image` data structure's content – presenting proof that both candidates form valid *P* functions which can reconstruct the image seen previously. As Table 2 shows, this *P* function was well-defined and the resulting scanner located and rendered the "image of interest" in the memory image with no false positives or false negatives.

4.3.2 Case Study: `Xfig`

The second case study is with `Xfig`, in which data content reverse engineering is essential to uncovering usable evidence from data structure instances. `Xfig` is a Linux-based vector graphics editor which defines several types of data structures for different drawable shapes (i.e., ellipse, spline, etc.). From `Xfig`, we intended to build a scanner+renderer tool to reveal the figure a suspect was drawing. Referring back to Table 1, DSCRETE located 9 closure point candidates in the bottom 1% of the data dependence graph. DSCRETE tested these 9 candidates and decided that 3 of them which rendered output were valid closure points. One of those was chosen (DSCRETE prefers the closure point highest in the dependence graph) to build a scanner+renderer for `Xfig`'s `f_compound` data structure.

An `f_compound` structure is a container for several shape structures. Each shape structure stores its dimensions, coordinates, color, etc. In order to reconstruct a figure, each of these shape structures must be recovered from a memory image, interpreted, and shape-specific rendering functions must be invoked. Existing signature-based memory scanners could present an investigator with a list of shape data structures instances from a memory image, but without the interpretation logic and shape-specific rendering, the investigator cannot see what the figure looks like. By comparison, the DSCRETE-generated scanner+renderer can locate the figure's `f_compound` structure, traverse all the contained shape structures (in the *P* function), and output `Xfig`'s original figure content. Table 2 shows that this *P* function is well-defined and recovered the figure's content with 100% accuracy from the target memory image.

```
Candidate 1 ===== Scanning from 0x6a16c0:
  fwrite@libc ( 0x6ba360 ["<89>PNG<0d0a>"...], 1, 81902, 0x6b7320 [data] )
    Arg 1 written to file "c1_0x6ba360.out"

Candidate 2 ===== Scanning from 0x6a5c90:
  fwrite@libc ( 0x6ba360 ["<89>PNG<0d0a>"...], 1, 81902, 0x6b7320 [data] )
    Arg 1 written to file "c2_0x6ba360.out"
```

(b) Output image file for Candidate 1.

Figure 6: Candidate testing output. (a) Each *P* function is shown, similar to the Linux strace utility, with parameters seen during invocation. If the tester component is set for file output, the file name is also printed. (b) Shows the output file for Candidate 1.

4.3.3 What You Get Is More Than What You See

We observe that some applications will construct more data structures than they intend to display. Without content reverse engineering, these extra data structures would all need to be manually interpreted for investigation. DSCRETE intuitively renders such additional evidence, allowing an investigator to quickly determine if it is forensically valuable.

In our experiment with `top`, the true number of `proc_t` instances is 382, whereas while executing `top` only 31 processes were displayed at a time. Since all 382 `proc_t` structures were in `top`'s memory image, DSCRETE was able to uncover and present each as they would have been displayed by the original `top` process.

Another example is `gThumb`, which displays an image being edited and other images in the same directory. `gThumb`'s memory contained valid data structures for 63 images: 56 GUI icons and 7 suspect images, and DSCRETE recovered them all, including the 7 suspect images. More importantly, 3 of the 7 suspect images were not being displayed by the GUI. Without DSCRETE, determining which raw data structures were icons and which were evidence would require extensive manual effort. With DSCRETE, an investigator can immediately see the distinction. Note also, that those GUI icons are not false positives. Instead, they are valid and relevant image data structures, because the investigator may use such GUI artifacts to infer which application screen the suspect was focusing on.

5 Discussion and Future Work

Still at its early stage, DSCRETE represents a new approach for digital evidence collection. The prototype presented here has several limitations that will be addressed in our future work.

As mentioned in Section 3.5, cross-state execution may cause conflicting memory access patterns (i.e., confounded or trespassing instructions). DSCRETE selectively skips unnecessary instructions which may cause cross-state conflicts. However, this method is limited to the instructions recorded during tracing, and cannot reason about instructions that *were not executed*. Although we did not encounter such complications in our experiments, we do believe that they exist and will explore using static dependence analysis in the future.

DSCRETE relies on each application's own rendering logic to differentiate between valid and invalid input (data structures to be rendered). As we see in Section 3.4, this can be problematic if the rendering function performs very little input processing and validation. Our experiment suggests that this problem exists for highly simplified data structures, which may still be of forensic value. Handling such data structures is our ongoing work. Additionally, since DSCRETE reuses application binary logic, an interesting problem is to handle data which contains *exploits* against the rendering logic.

Another current limitation which we leave for future work is replacing multiple input data dependencies for a rendering function. Currently, DSCRETE identifies and replaces only a single data structure pointer seen as input to P. However, it is assumable that a single application output be generated from *multiple* unrelated data structures. Although we have not encountered such need, the problem is realistic and requires enhancements to the closure point identification and the scanning algorithms.

Like many binary analysis-based tools, DSCRETE is not yet ready to handle self-modifying code or binaries with highly obfuscated control flows, which may cause problems in dependence detection or state crossing. However, these problems are common in malware programs and hence worth solving. One future direction is to develop DSCRETE on an obfuscation-resistant binary analysis platform (e.g., [29]).

The methodology used in DSCRETE is designed to operate directly on a target machine binary. As such, it is not applicable to programs written in *interpreted* languages (e.g., Java). Such programming languages add layers of indirection between the machine instructions observed by DSCRETE and the application's true syntax and semantics (i.e., data structures and rendering functions). Developing new techniques to handle programs written in interpreted languages is an intriguing direction for our future research.

6 Related Work

Memory Image Forensics. Previous research in memory forensics has mainly centered around uncovering data structure instances using signature-based brute force scanning. Such techniques can be roughly classified into value-invariant based [2,3,9,21,23,26,27] and structural-invariant based [5, 15, 16].

Value-invariant signatures seek to classify data structures by the expected value(s) of their fields. More recently, DEC0DE [27] enhances value-based signatures with probabilistic finite state machines to recover evidence from smartphones. Structural-invariant based signatures are derived by mapping interconnected data structures. SigGraph [16] uses such signatures for brute-force memory image scanning. Later, DIMSUM [15] attempts to probabilistically locate data structure instances in un-mappable memory. Further, numerous forensic tools and reverse engineering systems [7, 14, 17, 20, 29] make use of data structure traversal.

Compared with these techniques, DSCRETE does not require data structure definitions or data structure field

value profiles as input. Moreover, DSCRETE can intuitively interpret data structure contents (e.g., rendering an image in memory). To the best of our knowledge, no existing memory forensic tool has similar capability.

Binary reverse engineering techniques [14, 17, 24] can reverse engineer data structure definitions (e.g., field types) from binaries. They can also reverse engineer semantic information to a certain extent. As such, they can be used in forensic analysis. However, these techniques can only reverse engineer semantics of generic data such as timestamps and IP addresses. Such approaches are hardly applicable to interpreting contents of application-specific and encoded data structure fields.

Binary Component Identification and Reuse. At the heart of the DSCRETE technique is application logic reuse. DSCRETE uses dynamic binary program tracing to identify which functional component of a binary application is responsible for generating forensically interesting output. It hence shares some common underlying techniques with existing binary identification and reuse techniques [4, 12, 18] and program feature identification [11, 28].

Similar to how DSCRETE employs a data dependence graph, Wong et. al. [28] use program slicing to identify the code region for a program feature. To further understand which application components contribute to an observed runtime behavior, Greevy et al. [11] use feature-driven dynamic analysis to isolate computational units of an application. In contrast, DSCRETE uses only an application's data dependence to identify candidates for later construction of a memory scanner+renderer.

Binary Code Reutilization (BCR) [4] involves using a combination of dynamic and static binary analysis to identify and extract malware encryption and decryption functions. The goal of BCR was to reuse such extracted logic as a functional component in a different program developed by the user. Inspector Gadget [12] uses dynamic slicing to identify specific malware behavior for extraction and later reuse/analysis. Lin et al. [18] suggested using dynamic slicing to identify applications' functional components to compose reuse-based trojan attacks. DSCRETE does not aim to extract application logic from a target binary, but rather re-execute it in-place to scan a memory image and render subject data structure contents.

Virtuoso [8] involves using dynamic slicing to identify logic from in-guest applications which could be reused for virtual machine introspection. However, Virtuoso is not able to handle input that is not encountered during off-line training. A DSCRETE-generated scanner can handle any input that the original *P* function could handle. Later, VMST [10] and Hybrid-Bridge [22] use system-wide instruction monitoring to allow introspection of one VM's kernel data from another. VMST redirects memory accesses for every instruction of the reused logic, whereas DSCRETE only needs to replace the data structure pointer at the closure point. Further, VMST relies on system call definitions to start logic reuse, while DSCRETE must automatically identify such a starting point (i.e., the closure point) in the subject binary.

7 Conclusion

We have presented DSCRETE, a data structure content reverse engineering technique which reuses application logic from a subject binary program to uncover and render forensically interesting data in a memory image. DSCRETE is able to recreate intuitive, human-observable application output from the memory image, without the burden of reverse engineering data structure definitions. Our experiments with DSCRETE show that this technique is able to effectively identify interpretation/rendering functions in a variety of real-world applications, and DSCRETE-generated scanner+renderer tools can uncover and render various types of data structure contents (e.g., images, figures, and formatted files and messages) from memory images with high accuracy.

Abstract

Malware analysis relies heavily on the use of virtual machines for functionality and safety. There are subtle differences in operation between virtual machines and physical machines. Contemporary malware checks for these differences to detect that it is being run in a virtual machine, and modifies its behavior to thwart being analyzed by the defenders. Existing approaches to uncover these differences use randomized testing, or malware analysis, and cannot guarantee completeness.

In this paper we propose Cardinal Pill Testing—a modification of Red Pill Testing [21] that aims to enumerate the differences between a given VM and a physical machine, through carefully designed tests. Cardinal Pill Testing finds five times more pills by running fifteen times fewer tests than Red Pill Testing. We further examine the causes of pills and find that, while the majority of them stem from the failure of virtual machines to follow CPU design specifications, a significant number stem from under-specification of the effects of certain instructions by the Intel manual. This leads to divergent implementations in different CPU and virtual machine architectures. Cardinal Pill Testing successfully enumerates differences that stem from the first cause, but only exhaustive testing or an understanding of implementation semantics can enumerate those that stem from the second cause. Finally, we sketch a method to hide pills from malware by systematically correcting their outputs in the virtual machine.

1 Introduction

In today's practice of analyzing malware [3, 14, 16, 26, 23], system virtual machines are widely used to facilitate fine-grained dissection of malware functionalities (e.g., Anubis [4], TEMU [6, 24], and Bochs [17]). For example, virtual machines can be used for dynamic taint analysis, OS-level information retrieval, and in-depth behavioral analysis. Use of virtual machines also protects the host, by isolating it from potentially malicious actions.

Malware authors have devised a variety of methods to hinder automated and manual analysis of their code, such as anti-dumping, anti-debugging, anti-virtualization, and anti-intercepting [10, 11]. Recent studies [7, 18] show that anti-virtualization and anti-debugging techniques have become the most popular methods of evading malware analysis. Chen et al. [8], find in 2008 that 2.7% and 39.9% of 6,222 malware samples exhibit anti-virtualization and anti-debugging behaviors respectively. In 2011, Lindorfer et al. [18] detect evasion behavior in 25.6% of 1,686 malicious binaries. In 2012, Branco et al. [7] analyze 4 million samples and observe that 81.4% of them exhibit anti-virtualization behavior and 43.21% exhibit anti-debugging behavior.

Upon detection of a virtual environment or the presence of debuggers, malicious code can alternate execution paths to appear benign, exit programs, crash systems, or even escape virtual machines. It is critically important to devise methods that handle anti-virtualization and anti-debugging, to support future malware analysis. In this paper we focus only on anti-virtualization handling, and specifically on CPU semantic attacks.

We observe that malware can differentiate between a physical and a virtual machine due to numerous subtle differences that arise from their implementations. Let us call the physical machine an *Oracle*. Malware samples execute sets of instructions with carefully chosen inputs (aka *pills*), and compare their outputs with the outputs that would be observed in an Oracle. Any difference leads to detection of VM presence.

These attacks are successful because there are many differences between VMs and physical machines, and existing research in VM detection [21, 20, 15] uses ad-hoc tests that cannot fully enumerate these differences. Since malware is run within a VM, all its actions are visible to the VM and all the responses are within a VM's control. If differences between a physical machine

and a VM could be enumerated, the VM could use this database to provide expected replies to malware queries, thus hiding its presence. This is akin to kernel root kit functionality, where the root kit hides its presence by intercepting instructions that seek to examine processes, files and network activity, and provides replies that an uncompromised system would produce.

In this paper we attempt to enumerate all the differences between a physical machine and a virtual machine *that stem from their differences in instruction execution*. These differences can be used for CPU semantic attacks (see Section 2). Our contributions are:

1. We improve on the previously proposed Red Pill Testing [21, 20] by devising tests that carefully traverse operand space, and explore execution paths in instructions with the minimal set of test cases. We use 15 times fewer tests and discover 5 times more pills than Red Pill Testing. Our testing is also more efficient, 47.6% of our test cases yield a pill, compared to only 0.6% of Red Pill tests. In total, we discover between 7,487 and 9,255 pills, depending on the virtualization technology and the physical machine being tested.

2. We find two root causes of pills: (1) failure of virtual machines to strictly adhere to CPU design specification and (2) vagueness of the CPU design specification that leads to different implementations in physical machines. Only 2% of our pills stem from the second phenomenon.

3. We propose how to modify virtual machines to automatically hide presence of detected pills from malware, through introduction of additional interrupt vectors and by utilizing QEMU's interrupt handling mechanism for guest systems (Tiny Code Generation mode).

We emphasize that our testing methodology produces test cases selected at random from chosen input parameter ranges for each instruction – these ranges are chosen to exercise all execution paths in the given instruction's handling. If a test case's execution produces different outputs in a physical versus a virtual machine we say that this test case is a *pill*. While we only test one value from each parameter's range, if this test case is a pill, all values from the same parameter ranges would also lead to pills because they are all handled by the same path in that instruction's execution. Let us call a pill resulting from a test case a *test pill* and all related test cases that draw parameter values from the same input ranges as the test pill the *individual pills*. In this paper, all counts of pills we report are for test pills. Similar practice is adopted by related work [21, 20, 19]. The counts of individual pills are many times higher.

In Section 2 we give an overview of various anti-virtualization techniques. We survey related work in Section 3 and propose Cardinal Pill Testing in Section 4. We provide the details for the pills we find in Section 5 and analyze their root causes and completeness. In Section 6 we propose how to hide most of these pills from malware and we conclude in Section 7. All the scripts and test cases used in our study are publicly released at `http://steel.isi.edu/Projects/cardinal/`.

2 Anti-Virtualization Techniques

Anti-virtualization techniques can be classified into the following broad categories [8, 15]:

CPU Semantic Attacks. Malware targets certain CPU instructions that have different effects when executed under virtual and real hardware. For instance, the `cpuid` instruction in Intel IA-32 architecture returns the `tsc` bit with value `0` under the Ether [9] hypervisor, but outputs `1` in a physical machine [22]. As another example found in our experiment, when moving hex value `7fffffffh` to floating point register `mm1`, the resulting `st1` register is correctly populated as `SNaN` (signaling non-number) in a physical machine, but has a random number in a QEMU-virtualized machine. Malware executes these pills and checks their output to identify presence of a VM.

Timing Attacks. Malware measures the time needed to run an instruction sequence, assuming that an operation takes a different amount of time in a virtual machine compared to a physical machine [11]. Contemporary virtualization technologies (dynamic translation [5], bytecode interpretation [17], and hardware assistance [9]) all add significant delays to instruction execution that are measurable by malware [1].

String Attacks. VMs leave a variety of traces inside guest systems that can be used to detect their presence. For instance, QEMU assigns the "QEMU Virtual CPU" string to the emulated CPU and similar aliases to other virtualized devices such as hard drive and CD-ROM. A simple query to Windows registry would reveal the VM's presence immediately [8].

In this work we focus on handling the CPU semantic attacks as they are the most complex category to explore and enumerate. We note that string attacks can easily be handled through enumeration and hiding of VM traces, which can be done by comprehensive listing and comparison of files, processes and Windows registry with and without virtualization. Also, timing attacks can be handled through systematic lying about the VM clock, as proposed in [15]. While neither of these approaches

[1] This method can also be used to detect debuggers, because stepping code adds large delays.

is implemented today, both could be implemented as extensions of our work on lying to applications about CPU semantics (Section 6).

3 Related Work

Martignoni et al. present the initial Red Pill work in EmuFuzzer [21]. They propose Red Pill Testing—a method that performs a random exploration of a CPU instruction set and parameter spaces looking for pills. Testing is performed by iterating through the following steps: (1) initialize input parameters in the guest VM, (2) duplicate the content in user-mode registers and process memory in the host, (3) execute a test case, (4) compare resulting states of register contents, memory and exceptions raised—if there are any differences, the test case is a pill. In KEmuFuzzer [20], Martignoni et al. extend the state definition to include the kernel space memory, and test cases are embedded in the kernel to facilitate testing of privileged instructions. In their recent work [19], they use symbolic execution to translate code of a high-fidelity emulator (Bochs) and then generate test cases that can investigate all discovered code paths. Those test cases are used to test a lower-fidelity emulator.

While these works are seminal in pill detection they have several deficiencies that we seek to handle in this paper: (1) EmuFuzzer [21] tests boundary and random values for explicit input parameters, but does not cover implicit parameters. Their approach cannot guarantee that all types of pills will be detected. The symbolic execution approach [19] will discover differences between low-fidelity and high-fidelity emulators but not between an emulator and a physical machine. In addition, use of symbolic execution precludes test generation for floating-point instructions. We improve on these works by using instruction semantics to carefully craft test cases that explore all code paths. (2) Martignoni et al. use QEMU with Intel VT-x (in [21]) or Bochs emulator (in [19]) as an Oracle, while we use physical machines with no virtualization. This improves fidelity of testing and ensures detection of more pills.

Dinaburg et al. [9] aim to build a transparent malware analyzer, Ether, by implementing analysis functionalities out of the guest, using Intel VT-x extensions for hardware-assisted virtualization. nEther [22] work finds that Ether still has significant differences in instruction handling when compared to physical machines, and thus anti-virtualization attacks are still possible, i.e., Ether does not achieve complete transparency.

Kang et al. [15] propose a method to identify anti-emulation checks and modify virtual system states to "lie" to the malware, using semi-manual execution trace analysis. They record the malware trace in Ether, using it as an Oracle, and utilizing its debugging functions. They then automatically taint the variables in this trace, and manually identify those variables whose values are used in an anti-emulation check under QEMU. Their method requires manual intervention while we seek to overcome differences in execution environments automatically. Furthermore, since Ether is not identical to a physical machine, this approach will fail to detect some differences between a VM and a physical machine that we do detect.

Other works [25, 18, 2] focus on detecting anti-virtualization functions of malicious binaries based on profiling and comparing their behavior in virtual and physical machines. These works do not uncover the details of anti-virtualization methods that each individual binary employs, and they can only detect anti-virtualization checks deployed by their malware samples, while we detect many more differences that could be used in future anti-virtualization checks.

4 Cardinal Pill Testing

We now describe the architecture, test case generation and testing methodology for our Cardinal Pill Testing.

4.1 Architecture Overview

Our testing architecture is shown in Figure 1. It consists of three physical workstations: a master, a slave hosting a virtual machine (VM), and a slave running Windows 7 Pro x86 on a bare-metal as reference (Oracle). The slaves are connected to the master through two separate serial wires. The master is responsible for generating test cases (Section 4.3) and scheduling their execution in slaves. In both slaves, we configure an additional daemon in the testing system that helps the master set up a specific test case in each testing round.

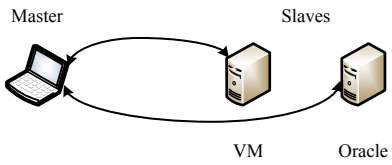

Figure 1: Architecture Overview

4.2 Logic Execution

The execution logic of our Cardinal Pill Testing is illustrated in Figure 2. The master maintains a debugger that issues commands to and transfers data back from the slaves. The Oracle and the VM have the same test case set and the daemon; we only show one pair of test case

and daemon in Figure 2 for clarity. We set the slaves in kernel debugging mode so that they can be completely frozen when necessary. At the beginning, the master reboots the slave (either VM or Oracle) for fresh system states. After the slave is online, the daemon signals its readiness to the master, which then evaluates test cases one by one in terms of rounds.

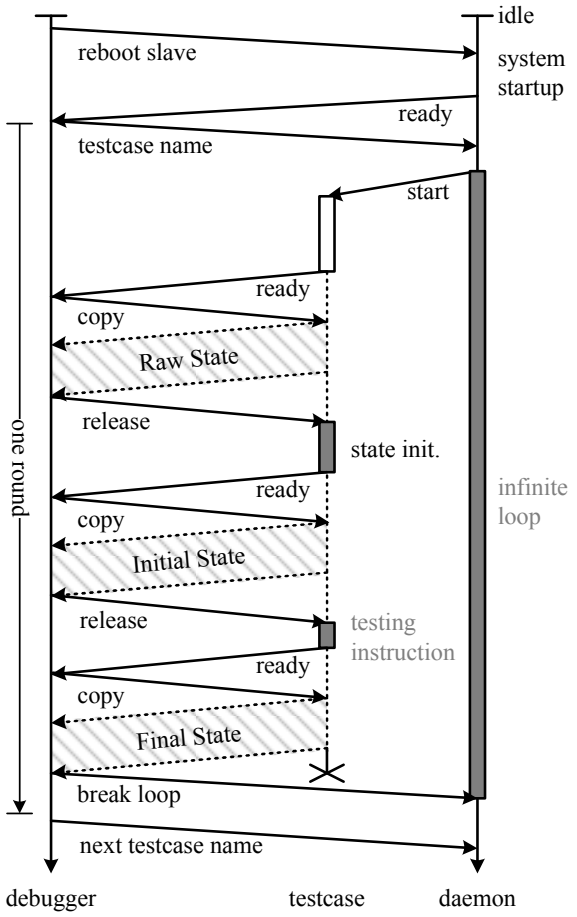

Figure 2: Logic Execution

We define the *state* of a physical or virtual machine as a set of all user and kernel registers, and the data stored in the part of code, data, and stack segments that our test case accesses for reading or writing.

In each round, the master interacts with the slave in three main phases. In the first phase, it issues a test case name to the daemon, which resides in a slave, and the daemon will ask the slave system to load this test case stored in its local disk. Then the system starts allocating memory, handles, and other resources needed by the test case program. After this *system loading* completes, the test case executes an interrupt instruction (`int 3`), which notifies the master and halts the slave. At this moment, the master saves the *raw state* of the slave locally. We use this raw state to identify *axiom pills* (see Section 4.3), instead of discarding it, as is done by EmuFuzzer [21] and KEmuFuzzer [20].

In the second phase, the master releases the slave which then executes the test case's initialization code and raises the second interrupt. Instead of using the same initial system state for all test cases, we carefully tailor register and memory bits for each test case, such that all possible exceptions and semantic branches can be evaluated (see Section 4.3). The master copies back the resulting *initial state* and releases the slave again.

In the third phase, the slave executes the actual instruction being tested and raises the last interrupt. The master will store this *final state* and use it to determine whether the tested instruction along with the initial state is a cardinal pill (see Section 5.1). It may happen that a test case drives the slave into an infinite loop or crashes itself or its OS. To detect this, we set up an execution time limit for each test case, so that the master can detect incapacitated slaves and restore them.

4.3 Test Case Generation

The quality of test cases is the key component of efficient pill discovery. The Red Pill work [21] generates test cases via two approaches: random generation and CPU-assisted generation. The former method randomizes data and code without conforming to any semantic rules, which may encode invalid instruction sequences. The latter combines each known opcode with some predefined operand values. Both approaches have the following deficiencies: (1) They only consider operands encoded in the instruction and fail to consider implicit arguments whose value may lead instruction execution to a different path in the code. For example, `rep stosb` takes no arguments but it depends on multiple register values. It stores contents of `al` register at the address specified by `es:(e)di`, and does this `ecx` times. Different values placed into those registers will result in different scenarios for `rep stosb` command use, such as writing into a valid versus invalid memory location, overwriting the instruction itself, using a zero, negative or very large positive value for the number of repetitions, etc. (2) They generate operands for instructions at random, which also does not explore all possible code paths. Our test case generation algorithm addresses both of these challenges.

4.3.1 Testing Goals

We aim to generate a minimal set of test cases for each instruction that explore all possible code paths in this instruction's handling. We start from the definitions of instruction handling recorded in a CPU manual. In this

work we focus on Intel's x86 CPU processor [13]. The manual details inputs and outcomes for each instruction, for normal execution and for exception handling. We call register modifications and exceptions whose semantics are fully defined in the manual *defined behaviors*. An instruction may also affect registers and raise exceptions that are specified in the manual as affected but the manner of their modification by the instruction is not specified. We call these modifications *undefined behaviors*.

For example, the `aaa` instruction adjusts the sum of two unpacked binary coded decimal (BCD) values to create an unpacked BCD result. The `al` register is the implied source and destination operand for this instruction. It also reads the `AF` flag in the `EFLAGS` register and writes to the `ah` register. Its normal execution will set `AF` and `CF` flags to `1` if the adjustment results in a decimal carry; otherwise it will set them to `0`. This is the defined behavior for the `aaa` instruction. In our testing we find that physical machines also set or reset the `SF`, `ZF`, and `PF` flags. While these flags are listed as affected by the instruction in the manual, there are no details of how they are calculated or what semantics they carry for the `aaa` instruction. This is the undefined behavior for the `aaa` instruction. In our work we explore both defined and undefined behaviors for each instruction, because both of these can be the source of pills.

Based on these observations, we set up the following goals of our test case generation algorithm:

- For defined behaviors for a given instruction, all branches should be evaluated. All flag bit states that are read implicitly or updated using results must be considered.
- All potential exceptions must be raised, such as memory access and invalid input arguments.
- Undefined behaviors should be investigated to reveal undocumented implementation specifics.

In the following sections, we first illustrate our test case template and then discuss how we group instructions and populate the template.

4.3.2 Test Case Template

We program a template to automatically generate test cases for most instructions, as shown in Figure 3. This program notifies the master and then halts the slave as soon as it enters the main function (line 2), so the master can save the states. The same interaction happens at lines 27, 29, and 38, after the test case completes a certain step. Then the program installs a structured exception handler for the Windows system (line 4 – 7). If an exception occurs, the program will ignore Windows' built-in exception handling routine and jump to line 31 directly, so we can save the system state before exception handling.

```
 1 main proc
 2   int 3               ; Raw State
 3
 4   push offset handler ; install SEH
 5   assume fs:nothing
 6   push fs:[0]
 7   mov  fs:[0], esp
 8
 9   ;; populate reg and memory
10   mov eax, 0000001bh
11   mov ebx, 00001000h
12   ...
13   ;; double precision floating-point
14   mov eax, 00403080h
15   mov dword ptr [eax], 0h
16   mov dword ptr [eax+4], 7ff00000h ; +Infi
17   ...
18   ;; single precision floating-point
19   mov eax, 0040318ch
20   mov dword ptr [eax], 0ff801234h  ; SNaN
21   ...
22   ;; double-extended precision FP
23   ...
24   ;; unsupported double-extended precision
25   ...
26   [state_init]      ; specific init
27   int 3             ; Initial State
28   [testing_insn]    ; instruction in test
29   int 3             ; Final State
30   call ExitProcess
31 handler:
32   ;; push exception information onto stack
33   mov edx, [esp + 4]        ; excep_record
34   mov ebx, [esp + 0ch]      ; context
35   push dword ptr [edx]      ; excep_code
36   ...
37   push dword ptr [edx + 0c0h] ; eflags
38   int 3           ; Final State (exception)
39   mov eax, 1h
40   call ExitProcess
41 main endp
42 end main
```

Figure 3: Test Case Template (in MASM assembly)

From line 9 to 25, we perform *general-purpose initialization*. Registers and memory are populated using pre-defined values, including all floating point and integer formats. This step occurs in all test cases and the carefully chosen, frequently used values, are stored in the registers to minimize the need for specific initialization. After this, the *specific initialization* (line 26) makes tailored modifications to the numbers, if needed for a given test case. For example, the `eax` is set to `1bh` at line 10 for all test cases. One particular test case may need `0ffh` value in this register and will update it at line 26. The actual instruction is being tested at line 29, where all defined and undefined behaviors use will be evaluated in various test cases. When compiling test cases, we disable

linker optimization and use a fixed base address, which does not affect testing but eases the interaction between the master and slaves.

4.3.3 Instruction Grouping

To test each instruction's behaviors in different execution stages, we need to vary the content in all registers and memory that the instruction reads. As discussed earlier and demonstrated in our evaluation in Section 5, random test generation cannot guarantee coverage of all code paths and execution branches. In our method, we manually analyze instruction execution flows defined in Intel manuals [13] and classify all possible input parameter values into ranges that lead to distinct execution flows.

IA-32 CPU architecture contains 906 instruction codes, and a human must reason about each to identify its inputs and outputs and how to populate them to test all execution behaviors. To reduce the scale of this human-centric operation, we first group the instructions into five categories: arithmetic, data movement, logic, flow control and miscellaneous. Arithmetic and logic category are further subdivided into general-purpose and FPU categories based on the type of their operands, We then define parameter ranges to test per category, and adjust them to fit finer instruction semantics as described below. This grouping greatly reduces human time investment and reduces chance of human errors. It took one person on our team a month and a half to devise all test cases. Table 1 shows the number of different mnemonics, examples, and parameter ranges we evaluate for each category.

Arithmetic Group. Instructions in this group first fetch arguments and then perform arithmetic operations. The arguments include actual data bits they operate on and certain flag bits that decide execution branches. We classify instructions in this group into two subgroups, depending on whether they work only on integer registers (general-purpose group), or also on floating point registers (FPU group). The instructions in the FPU group include instructions with x87 FPU, MMX, SSE, and other extensions.

Based on the argument types and sizes, branch conditions, and the number of arguments, we divide both subgroups into finer partitions. For example, `aaa`, `aas`, `daa`, and `das` in the general-purpose subgroup all compare the `al` register (holding one packed BCD argument 8-bits long) with `0fh` and check the adjustment flag `AF` in the `EFLAGS` register. This decides the output of the instruction. To test instructions in this set we initialize the `al` register to minimal (`00h`), maximal (`0ffh`), boundary (`0fh`), and random values in different ranges (`[01h, 0eh]`, `[10h, 0feh]`). We also flip `AF` between clear and set for different `al` values.

If a mnemonic takes two parameters, we select at least three value pairs to ensure that a greater-than, equal-to, and less-than relationship between them is satisfied in our test set. For the FPU subgroup, the parameter ranges are separated based on the sign, biased exponent, and significand, which splits all possible values into 10 domains: ±infi, ±normal, ±denormal, 0, SNaN, QNaN, and QNaN floating-point indefinite. We sample values from all these ranges to test behaviors in the arithmetic FPU group. For example, `fadd`, `fsub`, `fmul`, and `fdiv` each use one operand that can be specified using four different addressing modes; one of them is `m64fp`, which stands for a double precision float stored in memory. These instructions add/sub/mul/div the `st(0)` register with the operand's value and store the result in `st(0)`. In addition, they also read control bits in the `mxcsr` register and `fdiv` checks the divide-by-zero exception. In our test cases we generate values for the two floating point operands from the 10 identified ranges and permute the relevant bits in the `mxcsr` register. Because instructions in this subgroup can also access memory to read operands, we devise additional test cases to evaluate the memory management unit. We place the `m64fp` argument in and out of the valid address space of a data segment, into a segment with and without required privileges, and into a segment that is paged in and paged out of memory. By combining these test cases together, all potential memory access exceptions can be raised along with all potential arithmetic exceptions.

Data Movement. Data movement instructions copy data between registers, main memory, and peripheral devices and usually do not modify flag bits. There are several execution branches that we explore in tests. The source and the destination operands may be located outside segment limits. If the effective address is valid but paged out, a page-fault exception will be thrown. If alignment checking is enabled and an unaligned memory reference is made while the current privilege level is 3, the system will raise an alignment exception. Some instructions also check direction and conditional flags, and a few others validate the format of floating point values. All these input parameters and the states that influence an instruction's execution outcome must be tested.

For example, we group 30 conditional movement instructions `cmov`*`cc`* `r32, r/m32` of distinct *`cc`* together because they move 32 bit signed or unsigned integers from the second operand (32 bit register or memory) to the first operand (32 bit register). The *`cc`* conditions are determined by the `CF`, `ZF`, `SF`, `OF` and `PF` flags. To access arguments outside the segment limit, we compile our test cases with the fixed base (Section 4.3.2). The starting addresses for code, data, and stack segment are `401000h`, `403000h`, and `12e000h` respectively, and each has a size of 4KB. It is difficult to test page faults

Category	Instruction Count	Example Instructions	Parameter Coverage
arithmetic	48	aaa, add, imul, shl, sub	min, max, boundary values, randoms in different ranges
	336	addpd, vminss, fmul, fsqrt, roundpd	±infi, ±normal, ±denormal, ±0, SNaN, QNaN, QNaN floating-point indefinite, randoms
data mov	232	cmova, fild, in, pushad, vmaskmovps	valid/invalid address, condition flags, different input ranges
logic	64	and, bound, cmp, test, xor	min, max, boundary values, >, =, <, flag bits
	128	andpd, vcomiss, pmaxsb, por, xorps	±infi, ±normal, ±denormal, ±0, SNaN, QNaN, QNaN FP indefinite, >, =, <, flag bits
flow ctrl	64	call, enter, jbe, loopne, rep stos	valid/invalid destination, condition flags, privileges
misc	34	clflush, cpuid, mwait, pause, ud2	analyze manually and devise dedicated input

Table 1: Instruction Grouping

directly because the Windows system does not provide APIs for page swapout. To work around this, we run other memory-consuming programs between test cases that use memory operands to force the values to be paged out of memory. In our evaluation, we find that this strategy works well and we successfully raise page faults when we need to test them. To raise the alignment checking exception, we store instruction operands at unaligned memory addresses. We permute the condition bits in the same way as we do for testing of arithmetic instructions.

Logic Group. Logic instructions test relationship and properties of operands and set flag registers correspondingly. We divide these instructions into general-purpose and FPU depending on whether they use EFLAGS register only (general-purpose) or they use both EFLAGS and mxcsr registers (FPU). We further partition logic instructions based on the flag bits they read and argument types and sizes. When designing test cases, in addition to testing minimal, maximal, and boundary values for each parameter, for instructions that compare two parameters we also generate test cases where these parameters satisfy larger-than, equal, and less-than conditions.

For example, one of the subgroups has bt, btc, btr, and bts instructions because all of them select a bit from the first operand at the bit-position designated by the second operand, and store the value of the bit in the carry flag. The only difference is how they change the selected bit: btc complements; btr clears it to 0; and bts sets it to 1. The first argument in this subgroup of instructions may be a register or a memory address of size 16, 32, or 64, and the second must be a register or an immediate number of the same size. If the operand size is 16, for example, we generate four input combinations (choosing the first and the second argument from 0h, 0ffffh values), and we repeat this for CF = 0 and CF = 1. Furthermore, we produce three random number combinations that satisfy less-than, equal and greater-than relationships. While the operand relationship does not influence instruction execution in this case, it does for other subgroups, e.g. the one containing the cmp instruction.

In the FPU subgroup, we apply similar rules to generate floating point operands. We further generate test cases to populate the mxcsr register, which has control, mask, and status flags. The control bits specify how to control underflow conditions and how to round the results of SIMD floating-point instructions. The mask bits control the generation of exceptions such as the denormal operation and invalid operation. We use ldmxcsr to load different values into mxcsr and test instruction behaviors under these scenarios.

Flow Control. Similar to logic instructions, flow control instructions also test condition codes. Upon satisfying jump conditions, test cases start execution from another place. For short or near jumps, test cases do not need to switch the program context; but for far jumps, they must switch stacks, segments, and check privilege requirements.

The largest subgroup in this category is the conditional jump *jcc*, which accounts for 53% of flow control instructions. Instructions in this group check the state of one or more of the status flags in the EFLAGS register (CF, OF, PF, SF, and ZF) and, if the required condition is satisfied they perform a jump to the target instruction specified by the destination operand. A condition code (*cc*) is associated with each instruction to indicate the condition being tested for. In our test cases we vary the

status flags and set the relative destination addresses to the minimal and maximal offset sizes of byte, word, or double word as designated by mnemonic formats. For example, `ja rel8` jumps to a short relative destination specified by `rel8` if `CF = 0` and `ZF = 0`. We permute `CF` and `ZF` values in our tests, and generate the destination address by choosing boundary and random values from the ranges `[0, 7fh]` and `[8fh, 0ffh]`.

For far jumps like `jmp ptr16:16`, the destination may be a conforming or non-conforming code segment or a call gate. There are several exceptions that can occur. If the code segment being accessed is not present, a `#NP` (not present) exception will be thrown. If the segment selector index is outside descriptor table limits, an exception `#GP` (general protection) will signal the invalid operand. We devise both valid and invalid destination addresses to raise all these exceptions in our test cases.

Miscellaneous. Instructions in this group provide unique functionalities and we manually devise test cases for each of them that evaluate all defined and undefined behaviors, and raise all exceptions.

5 Detected Pills

We detect pills using our implementation of the architecture shown in Figure 1. We use two physical machines in our tests as Oracles: (**O1**) an Intel Xeon E3-1245 V2 3.40GHz CPU, 2 GB memory, with Windows 7 Pro x86, and (**O2**) Xeon W3520 2.6GHz, 512MB memory, with Windows XP x86 SP3. The VM host has the same hardware and guest system as the first Oracle, but it has 16 GB memory, and runs Ubuntu 12.04 x64. We test QEMU (VT-x), QEMU (TCG), and Bochs, which are the most popular virtual machines deploying different virtualization technologies: hardware-assisted, dynamic translation, and interpretation respectively. We allocate to them the same size memory as in the Oracle. We test QEMU versions 0.14.0-rc2 (**Q1**, used by EmuFuzzer), 1.3.1 (**Q2**), 1.6.2 (**Q3**), and 1.7.0 (**Q4**), and Bochs version 2.6.2. The master has an Intel Core i7 CPU and installs WinDbg 6.12 to interact with the slaves. For test case compilation, we use Microsoft Assembler 10 and turn off all optimizations. Our test cases take around 10 seconds to run on a physical machine and 15–30 seconds to run on a virtual machine.

Counting the different addressing modes, there are 1,653 instructions defined in the IA-32 Intel manual [13]. Out of these, there are 906 unique mnemonics. We generate a total of 19,412 test cases for these instructions.

5.1 Evaluation Process

We classify system states into user registers, exception registers, kernel registers, and user memory. The user registers contain general registers such as `eax` and `esi`. The exception registers are `eip`, `esp`, and `ebp`. The differences in the exception registers imply differences in the exceptions being raised. The kernel registers are used by the system and include `gdtr`, `idtr`, and others. In our evaluation, we do not populate kernel registers in the initialization step because this may crash the system or lead it to an unstable status. Further, initialization of kernel registers would require a system reboot and would make testing prohibitively expensive in a virtual machine. But, kernel register contents are saved as part of our states and compared to detect differences between physical and virtual machines.

For each test case, we first examine whether the user registers, exception registers, and user memory are the same in the Oracle and the virtual machine in the initial state. If they are different, it means that the VM fails to virtualize the initialization instructions (line 26 in Figure 3) to match their implementation in the Oracle. We mark this test case as "fatal" and discard it. If the initial values in these locations agree with each other, we then compare the final states. A test case will be tagged as a pill in two scenarios: (2) when the user registers, exception registers, and memory in the final states are different and (2) when the values in a certain kernel register are the same in the initial states but different in the final states.

5.2 Results

Table 2 shows the results of comparing various virtual machines to Oracle1 (O1).

The second column shows the number of pills for different virtual machines. Both QEMU (TCG) and Bochs exhibit moderate transparency—almost half of the test cases report different states between O1 and VMs. For Q2 (VT-x) 38.5% of our test cases result in pills, but there were no fatal cases. The pills we find for Q2 (VT-x) occur because QEMU does not preserve the fidelity provided by hardware assistance. Therefore, we should be careful when using hardware-assisted VMs for fidelity purposes. Their transparency depends on how they utilize the hardware extension.

The third column counts test cases that crash the system. For QEMU (TCG), one test case crashes the Oracle 1 and another one crashes the virtual machine. Another five crash both of them. For QEMU (VT-x) and Bochs, two test cases crash the physical and the virtual machine.

The number of fatal test cases are shown in the last column. All of them are related to FPU movement instructions. In some test cases that use denormals, SNaN, or QNaN values, the virtual machines could not populate the operand register as required. We note that we find no fatal test cases for VT-x technology.

Table 3 shows the breakdown of pills per instruction

VMs	pills	crash	fatal
Q1 (TCG)	9,255/47.7%	7/<0.1%	1,378/7%
Q2 (TCG)	9,201/47.4%	7/<0.1%	1,376/7.1%
Q1 (VT-x)	7,523/38.7%	2/<0.1%	3/<0.1%
Q2 (VT-x)	7,478/38.5%	2/<0.1%	0/0%
Bochs	8,958/46.1%	2/<0.1%	950/4.9%

Table 2: Results Overview

Category		Q1 (TCG)	Q2 (TCG)	Q1 (VT-x)	Q2 (VT-x)	Bochs	Total tests
arith	gen	877	872	633	626	920	2,702

total		9,255	9,201	7,523	7,478	8,958	19,412

Table 3: Pills per Instruction Category

category from Figure 1. The FPU arithmetic, FPU logic and data movement categories contain the most pills—around 83%. Table 4 shows the breakdown of the pills with regard to the resource that is different between a physical and a virtual machine in the final state. Most pills occur due to differences in the kernel registers.

5.2.1 Comparison with EmuFuzzer Pills

EmuFuzzer [21] generates 3 million test cases and the authors select 10% randomly to test in different virtual machines. The authors publish 20,113 red pills for QEMU 0.14.0-rc2 which is about 7% of the tested cases. Because they do not publish the entire test case set, we cannot directly compare our test cases with theirs, but instead we only compare the pills found by them and by us.

A *unique pill* is a pill whose mnemonic and parameter values do not appear in any other pill. We use the same QEMU version as EmuFuzzer (Q1 (TCG)) and run all the 20,113 red pills they found. We successfully extract operand values for 20,102 pills. After removing duplicate pills, there are 1,850 unique red pills (9%) and 136 different instruction mnemonics found by EmuFuzzer. Our 9,255 pills for Q1 (TCG) are all unique and there are 630 different instruction mnemonics. Furthermore, out of our 19,412 test cases we find 9,255 pills, which is 47.6% yield, while EmuFuzzer's yield is 1,850/300,000 = 0.6%. While direct comparison between our pills and EmuFuzzer's is difficult because both approaches select values of operands to test at random from specific ranges, we compare the ranges of the pills. This comparison shows that we detect all types of pills found by EmuFuzzer.

We conclude that our approach is more comprehensive than EmuFuzzer's and far more efficient. We cover all instruction mnemonics in our tests and find pills for 494 more instructions than EmuFuzzer. Overall we find five times more pills running 300,000/19,412 = 15 times fewer tests than EmuFuzzer. This illustrates the significant advantage of careful generation of operand values in tests over random fuzzing.

We further wanted to compare our pills with pills found by [19]. The Hi-Fi tests for Lo-Fi emulators [19] generate 610,516 test cases, out of which 60,770 (9.95%) show different behaviors in QEMU, and 15,219 (2.49%) show different behaviors in Bochs. Since the tests used for [19] are not publicly released we could not compare against them.

5.2.2 Root Causes of Pills

The differences detected by a pill can be due to registers, memory or exceptions that an instruction was supposed to modify, according to the Intel manual [13]. We call these instruction targets *defined resources*. However there are a number of instructions defined in the Intel manual that may write to some registers (or to select flags) but the semantics of these writes are not defined by the manual. We say that these instructions affect *undefined resources*. For instance, the `aas` instruction should set the `AF` and `CF` flags to `1` if there is a decimal borrow; otherwise, they should be cleared to `0`. The `OF`, `SF`, `ZF`, and `PF` flags are listed as affected by the instruction but their values are undefined in the manual. Thus the `AF` and `CF` flags are defined resources for the instruction `aas` and `OF`, `SF`, `ZF`, and `PF` flags are undefined.

Table 5 shows the number of pills that result from dif-

Category	Q2 (TCG)	Q2 (VT-x)	Bochs
user reg	2,416	34	1,671
excp reg	1,578	21	1,566
kerl reg	8,398	7,457	8,572
mem cont	46	9	20

Table 4: Details of Pills with Regard to the Resource Being Different in the Final State—in Some Cases Multiple Resources Will Differ so the Same Pill May Appear in Different Rows

ferences in undefined and defined resources for each instruction category compared to Oracle 1.

We note that a small number of pills that relate to general-purpose arithmetic and logic instructions occur because of different handling of undefined resources by physical and virtual machines. These comprise roughly 2% of all the pills we found.

For pills originating from defined resources, we analyze their root causes and compare them against those found by the symbolic execution method [19]. We find all root causes listed in [19] that are related to general-purpose instructions and QEMU's memory management unit.

In this work we do not extensively analyze pills that originate from differences in kernel-space handling of instructions, and thus cannot compare their root causes with those specified in [19]. Due to the extensive time required for testing (reboot is required after each test case) we leave this for future work.

Because the symbolic execution engine in [19] does not support FPU instructions, we discover additional root causes that are not captured by their method. First, we find that QEMU does not correctly update 6 flags and 8 masks in the `mxcsr` register when no exception happens, including invalid operation flag, denormal flag, precision mask, overflow mask. It also fails to update 7 flags in `fpsw` status register such as stack fault, error summary status, and FPU busy. Second, QEMU fails to throw five types of exceptions when it should, which are: float_multiple_traps, float_multiple_faults, access_violation, invalid_lock_sequence, and privileged_instruction. Third, QEMU tags FPU registers differently from Oracles. For example, it sets `fptw` tag word to "zero" when it should be "empty", and sets it to "special" when "zero" is observed in Oracles. Finally, the floating-point instruction pointer (`fpip`, `fpipsel`) and the data pointer (`fpdp`, `fpdpsel`) are not set correctly in certain scenarios. The details of all these root causes are given on our Web page.

5.2.3 Identifying Persistent Pills

Differences found in our tests between an Oracle and a virtual machine may not be present if we use a different Oracle or a different virtual machine, i.e. a difference may stem more from an implementation bug specific to that CPU or VM version than from an implementation difference that persists across versions. Furthermore, outdated CPUs may not support all instruction set extensions that are available in recent ones. Finally, recent releases of VM software usually fix certain bugs and add new features, which may both create new differences and remove the old differences between this VM and physical machines. We hypothesize that *transient* pills are not useful to malware authors because they cannot predict under which hardware or under which virtual machine their program will run, and we assume that they would like to avoid false positives and false negatives.

To find pills that persist across hardware and VM changes, we perform our testing on multiple hardware and VM platforms. We select 13 general instructions that can be executed in all x86 platforms (`aaa`, `aad`, `aas`, `bsf`, `bsr`, `bt`, `btc`, `btr`, `bts`, `imul`, `mul`, `shld`, `shrd`) and generate 2,915 test cases for them to capture more pills that are caused by modification of undefined resources. We evaluate this set on the two physical machines (Oracle 1 and Oracle 2), three different QEMU versions (Q2, Q3, and Q4), and Bochs. We find 260 test cases that result in different values in `EFLAGS` register in Oracle 1 and Oracle 2 and will thus lead to transient pills. Bochs' behavior for these test cases is identical to the behavior of Oracle 2. Out of the remaining 2,655 test cases, we find 989 persistent pills that generate different results in the three QEMU virtual machines when compared to the physical machines. They are all related to undefined resources. Bochs performs surprisingly well and does not have a single pill for these particular test cases. Thus we could not find persistent pills that would differentiate between any physical and any virtual machine in our tests but we found pills that can differentiate between any of the QEMU VM versions and configurations that we tested and any of the physical machines we tested.

We further investigate the persistence of pills that are caused by modifications to undefined resources, across different physical platforms. We select five physical machines with different CPU models in DeterLab [1]. Out of 195+23 = 218 pills that were found for Oracle 1 and Q2 (TCG) we were able to map 212 pills to all five physical machines (others involved instructions that did not

Table 6: Undefined EFLAGS Behaviors

exist in some of our CPU architectures). Fifty of those were persistent pills—the undefined resources were set to the same values in physical machines. We conclude that modifications to undefined resources can lead to pills that are not only numerous but also persistent in both physical and virtual machines. This further illustrates the need to understand the semantics of these modifications as this would help enumerate the pills and devise hiding rules for them without exhaustive tests.

5.2.4 Completeness of Pills

Our test cases were designed to explore effects of input parameters on defined resources. We thus claim that our test cases cover all specified execution branches for user-space instructions and part for kernel instructions defined in Intel manuals. Our test pills should thus include all possible individual pills that can be detected for defined resources in user space. We cannot claim the same completeness for test pills that relate to defined or undefined resources in kernel space since we do not extensively test instructions that manipulate these resources, due to the reboot requirement.

We now further explore the pills stemming from modifications to undefined resources, to evaluate their impact on the completeness of our pill sets and to attempt to devise semantics of these modifications. The only undefined resources from the Intel manual are flags in the EFLAGS register.

We analyze the user-space instructions that affect one or more flags in the EFLAGS register in an undefined manner. We generate additional test cases for each instruction to explore the semantics of modifications to undefined resources in each CPU. Although the exact semantics differ across CPU models, we consider four semantics of flag modifications that are the superset of behaviors we observed across tested hardware and software machines: a flag might be (1) cleared, (2) remain intact,

(3) set according to the ALU output at the end of an instruction's execution, or (4) set according to an ALU output of an intermediate operation.

We run our test cases on a physical or virtual machine in the following manner. For each instruction, we set an undefined flag and execute an operation that yields a result inconsistent with the flag being set; for example, `ZF` is set while the result is `0`. If the flag remains set we conclude that the instruction does not modify it. Similarly, we can test if the flag is set according to the final result. If none of these tests yield a positive result, we go through the sub-operations in a given instruction's implementation, as defined in the CPU manual, and discover which one modifies the flag. For example: `aaa` adds `6` to `al` and `1` to `ah` if the last four bits are greater than `9` or if `AF` is set. The instruction affects `OF`, `SF`, `ZF` and `PF` in an undefined manner. We find that in some machines `ZF` and `PF` are set according to the final result, while in others `PF` is set according to an intermediate operation, which is `al = al + 6`.

Table 6 shows different semantics for each instruction, which are consistent across 5 different CPU models. Empty cells represent defined resources for a given instruction. Character "I" means the flag value is intact while "F" means that the flag is set according to the final result. Otherwise, the flag is set to the value in the cell.

To detect pills between a given virtual machine and one or many physical machines we repeat the same tests on the virtual machine, and look for differences in instruction execution semantics. If many physical machines are compared to a virtual machine we look for such differences where physical machines consistently handle a given instruction in a way that is different from how it is handled in a virtual machine. For example in Table 6, instruction `aad` either clears `OF`, `AF` and `CF` flags or sets them according to the final result. If a virtual machine were to leave these flags intact we could use this behavior as a pill.

Our test methodology will discover all test pills (and thus all possible individual pills) related to modifications of undefined resources by user-space instructions *for a given physical/virtual machine pair*. Since the semantics of undefined resource modifications vary greatly between physical CPU architectures, as well as between various virtual machines and their versions, all possible test pills cannot be discovered in a general case.

To summarize, our testing reveals pills that stem from instruction modifications to user-space or kernel-space registers. These modifications can further occur on defined or on undefined resources for a given instruction. We claim we detect all test pills (and thus all the individual pills) that relate to modifications of defined, user-space resources. We can claim that because we fully understand semantics of these modifications, and all physical machines we tested strictly adhere to this semantics as specified in the manual. We cannot claim completeness for pills that relate to modifications of undefined resources because physical machine behaviors differ widely for those. We further cannot claim completeness for pills that relate to modifications of kernel-space resources because we do not properly test initialization of these resources – such testing would require frequent reboots and would significantly prolong testing time.

5.2.5 Axiom Pills

In addition to comparing final states across different platforms we also compare raw states upon system loading. We define an *axiom* pill as a register or memory value whose raw state is consistently different between a physical machine and a given virtual machine. This pill can be used to accurately diagnose the presence of the given virtual machine. We select 15% of our test cases and evaluate them on Oracle 2, Q2, Q3 and Bochs. The axiom pills are shown in Table 7. For example, the value of `0ffffffffh` in the `edx` register can be used to diagnose the presence of Q2 (VT-x).

6 Improving Virtualization Transparency

EmuFuzzer [21] defines the virtualization transparency as how closely a virtual machine resembles the physical one. A perfect transparency means that programs in guests must not be able to tell if they are being executed in a virtual machine or not. The pills we find reflect the flaws of current virtual machine implementations, and specifically persistent pills reflect persistent flaws that can be used effectively by malware to detect virtualization. It would thus be desirable to develop techniques that hide the presence of reliable pills from malware. This could be achieved via multiple ways: (1) through patching of the current virtual machine implementations, (2) through overwriting of values in registers and memory with values consistent with physical machine deployment using kernel debuggers, (3) through modification of the guest OS so that malware reads of registers and memory after execution of pill instructions are intercepted and values consistent with physical machine deployment are returned (similar to kernel rootkit functionality), (4) through modifications of the host OS.

Out of all these approaches, patching VMs or guest OS are both time-consuming, may introduce other pills or bugs and do not apply to closed source implementations. Modifications to host OSes cannot hide all pills; for example in the TCG mode of QEMU, guest code translation happens in QEMU's user space, and the host cannot directly inspect guest instructions to detect pill execution. We thus choose to overwrite registers and memory

Reg	O1	Q1 (TCG)	Q2 (TCG)	Q1 (VT-x)	Q2 (VT-x)	Bochs
edx	vary	vary	vary	0ffffffffh	0ffffffffh	vary
dr6	0ffff0ff0h	0	0	0ffff0ff0h	0ffff0ff0h	0ffff0ff0h
dr7	400h	0	0	400h	400h	400h
cr0	8001003bh	8001003bh	8001003bh	8001003bh	8001003bh	0e001003bh

gdtr	vary	80b95000h	80b95000h	80b95000h	80b95000h	80b95000h
idtr	vary	80b95400h	80b95400h	80b95400h	80b95400h	80b95400h

Table 7: Axiom Pills

after pill instructions.

This overwriting can either happen in the virtual machine, through modification of VM code, or it could be performed by the same environment that is used for malware analysis, e.g. Anubis or Ether. We explore the first strategy here. We select QEMU TCG mode as our experiment platform since it has gained great popularity [6, 24, 4, 12]. We first explain how QEMU handles guest code translation and then describe how we integrate our pill hiding strategy into its translation code.

6.1 The Underhood of QEMU with TCG

Figure 4 describes two pivotal functionalities of QEMU: how TCG uses translation blocks to organize translated host code (x86 guest to x86_64 host in the example) and how QEMU executes translation blocks. A translation block is a consecutive memory of a few kilobytes located in a data segment, which consists of translated host code, prologue, and epilogue. It provides a full function layout as if generated from a compiler. As the name implies, the translated host code section stores host opcode generated by TCG, which acts as a function body. The prologue prepares the stack and registers for use within the function, while the epilogue restores the stack and registers to the state they were in before the function was called.

TCG translates guest instructions in two different ways. Simple guest instructions are mapped to host opcode directly; for example in Figure 4, the guest instruction `mov al, 8` is transformed to three host instructions. The actual translation operates at the opcode level without disassembling and compilation. For complex guest instructions, TCG uses helper functions to implement their semantics. For example, the guest `int` instruction will be replaced by a call to `helper_raise_int()`. Inside this function, QEMU checks the current CPU mode and then dispatches the interrupt. In dispatching, QEMU calculates the destination vector in the interrupt description table that should be selected. After the desired interrupt service routine is found, QEMU sets the guest code segment selector, offset, and instruction pointer, such that the guest will enter interrupt handling immediately after QEMU

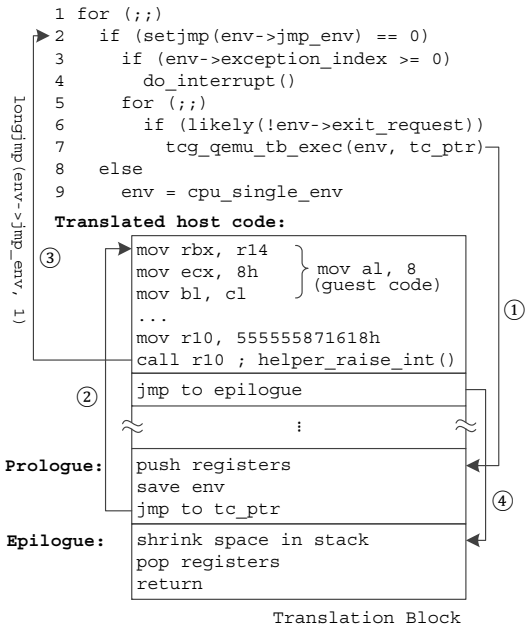

Figure 4: QEMU with TCG Translation and Execution.

yields control to the guest. Typically, QEMU stops translation if it encounters an `int` in the guest code, and `helper_raise_int()` will be the last instruction in a translation block in this case.

We summarize QEMU's main execution loop in lines 1–9 in Figure 4. It attempts to deliver all pending interrupts and exceptions and then finds the next translation block to execute. It takes advantage of the `setjmp()` and `longjmp()` facility provided by the C standard library to implement non-local jumps. At line 2, the QEMU context is saved to `jmp_env` by `setjmp()`. If this statement is actively called in place, line 3 will be examined and any pending interrupts and exceptions will be handled here. Otherwise, if the program flow returns here from a `longjmp()`, line 9 will be executed to reload CPU environment; then line 1 starts the next iteration. Lines 5–7 denote an infinite loop inside which QEMU repeatedly finds and executes translation blocks if no exception occurs. The function at line 7 is defined as a function pointer that is assigned to the

memory address of the prologue. At run-time, the prologue is cast as a function and executed (①) with parameters `env` and `tc_ptr`. The code bytes in the prologue save the current context and arguments to the stack. Then the program control will be transferred to the generated host code pointed to by `tc_ptr` (②). If the guest code contains an interrupt, the execution flow will follow the `helper_raise_int()` function generated by TCG (③); otherwise, this translation block will finish execution and step ④ is selected. In the first case, the helper function raises an interrupt with the vector number in the guest code, through setting of the corresponding data structures in QEMU. Then it calls `longjmp()` to jump to the latest context saved by `setjmp()`, so this function never returns. When executing line 2 following ③, the condition is not satisfied because `setjmp()` returns the argument `1` of `longjmp()`. Therefore, lines 3 – 4 will not be executed and the interrupt will not be repeatedly handled, which achieves the exact interrupt semantics. When the execution runs into the next round of the outside `for` loop, this pending interrupt will be handled in `do_interrupt()`.

6.2 Pill Hiding

Our proposed pill hiding strategy goes through three main stages: 1) detect pill instructions in the guest; 2) freeze the guest after the corresponding host code for the guest instruction has been executed; and 3) overwrite register and memory values using correct information learned from physical machines.

To detect pills, we need to compare the guest code with known pill instructions in run time. This can be achieved using either mnemonics or opcode. We choose the first approach since QEMU has a built-in disassembler.

To freeze the guest at the right point, we need to build a communication mechanism between QEMU and the guest. Debuggers achieve a similar functionality by replacing user-defined breakpoints with interrupt instructions. We cannot apply the same approach by inserting interrupts into translated code, since it will cause a trap between QEMU and the host instead. Actually, this is the reason why TCG needs to replace the guest interrupts with a call to the helper function as discussed in the previous subsection. To address this problem, we modify the QEMU's translation mechanism and utilize its interrupt handling mechanism as shown in Figure 5.

We monitor each guest instruction at line 1 by disassembling the current instruction in `pc_ptr`. If this instruction is not a pill, we directly translate it at line 11. If it is a pill, we check if the state before this instruction is saved. If not, this is the first time we encounter this instruction and we generate a `0x20` interrupt, otherwise we generate a `0x21` interrupt. Neither of these interrupt values are used by Windows. Generation of an interrupt calls `helper_raise_int()` in Figure 4 which brings the control to `do_interrupt()` as it does for other interrupt vectors. In this function we add new interrupt handlers for `0x20` and `0x21` interrupts. The handler for `0x20` saves the system state. The handler for `0x21` applies the hiding rules by overwriting the registers and memory with the values that a physical machine would set. The hiding rules can be devised by grouping pill instructions based on the resource that is the symptom of the pill (it is different in the physical and the virtual machine) and input parameter ranges. For example, we find 61 FPU instructions that always raise exceptions different from Oracles if their operands are in specific value ranges. When we detect these instructions and their operands fall in these specific ranges, we can raise the exceptions that occur in the Oracles. This would handle around 1,500 pills. Thus we can hide the presence of the pills without reimplementing instruction semantics. We emphasize here that only pills whose symptoms are not kernel registers can be hidden by our approach.

```
 1 curr_insn = disas(pc_ptr)
 2 if (curr_insn is pill)
 3     if (saved == false)
 4         gen_int(0x20)  // save states
 5         saved = true
 6     else
 7         pc_ptr = trans(pc_ptr)
 8         gen_int(0x21)  // apply hiding rules
 9         saved = false
10 else
11     pc_ptr = trans(pc_ptr)
```

Figure 5: Hooking on QEMU Translation

7 Conclusion

Virtualization is crucial for malware analysis, both for functionality and for safety. Contemporary malware tests if it is being run in VMs and applies evasive behaviors that hinder its analysis. Existing works on detection and hiding of differences between virtual and physical machines apply ad-hoc or semi-manual testing to identify these differences and hide them from malware.

In this paper we propose Cardinal Pill Testing that requires moderate manual action to identify ranges for input parameters for each instruction in a CPU manual, but then automatically that devises tests to enumerate the differences between a physical and a virtual machine. This testing is much more efficient and comprehensive than state-of-the-art Red Pill Testing. It finds five times more pills running fifteen times fewer tests. We further claim that for user-space instructions that affect defined resources, Cardinal Pill testing identifies all test pills that

could be used to generate all possible individual pills. Other categories contain instructions whose behavior is not fully specified by the Intel manual, which has led to different implementations of these instructions in physical and virtual machines. Such instructions need understanding of the implementation semantics to enumerate all the pills and devise the hiding rules. Our future work will focus on this direction. Yet other pills we have discovered stem from instructions that modify kernel-level resources. We do not properly test the initialization of these instructions because that would require reboot of machines and would be too time-consuming. Thus, we cannot claim completeness for pills that relate to kernel-level resources. We plan to test these extensively in our future work.

Abstract

The volume and the sophistication of malware are continuously increasing and evolving. Automated dynamic malware analysis is a widely-adopted approach for detecting malicious software. However, many recent malware samples try to evade detection by identifying the presence of the analysis environment itself, and refraining from performing malicious actions. Because of the sophistication of the techniques used by the malware authors, so far the analysis and detection of evasive malware has been largely a manual process. One approach to automatic detection of these evasive malware samples is to execute the same sample in multiple analysis environments, and then compare its behaviors, in the assumption that a deviation in the behavior is evidence of an attempt to evade one or more analysis systems. For this reason, it is important to provide a reference system (often called bare-metal) in which the malware is analyzed without the use of any detectable component.

In this paper, we present BareCloud, an automated evasive malware detection system based on bare-metal dynamic malware analysis. Our bare-metal analysis system does not introduce any in-guest monitoring component into the malware execution platform. This makes our approach more transparent and robust against sophisticated evasion techniques. We compare the malware behavior observed in the bare-metal system with other popular malware analysis systems. We introduce a novel approach of hierarchical similarity-based malware behavior comparison to analyze the behavior of a sample in the various analysis systems. Our experiments show that our approach produces better evasion detection results compared to previous methods. BareCloud was able to automatically detect 5,835 evasive malware out of 110,005 recent samples.

1 Introduction

The malware threat landscape is continuously evolving. Early detection of these threats is a top priority for enterprises, governments, and end users. The widely-deployed signature-based and static-analysis-based detection approaches can be easily evaded by techniques commonly seen in the wild, such as obfuscation, polymorphism, and encryption. Therefore, dynamic malware analysis tools have recently become more popular to automate the analysis and detection of these threats [1, 14, 35]. These systems execute the suspicious sample in a controlled environment and observe its behavior to detect malicious intent. While this dynamic analysis approach is more effective against common static analysis evasion techniques, it faces a different set of challenges. More specifically, a malware sample, when executed, can detect the analysis environment and refuse to perform any malicious activity, for example by simply terminating or stalling the execution.

Malware authors have developed several ways to detect the presence of malware analysis systems. The most common approach is based on the fingerprinting of the runtime environment of the analysis system. This includes checking for specific artifacts, such as some specific registry keys, background processes, function hooks, or IP addresses that are specific to a known analysis tool. These artifacts must be known to the malware authors in advance to develop the corresponding fingerprinting techniques. Another approach leverages the fact that most of the analysis systems use emulated or virtualized environments as their malware execution platform. Such execution platforms can be detected by checking the platform-specific characteristics that are different with respect to a baseline environment (i.e., an unmodified operating system installed on real hardware, often referred to as a "bare-metal" installation). Such characteristics can be the timing properties of the execution, or a small variation in the CPU execution seman-

tics [31, 32].

Public-facing malware analysis systems are particularly vulnerable to the first approach to fingerprinting. This is because an attacker can submit malware samples specifically designed to extract the malware analysis environment artifacts to be then used in fingerprinting the analysis system. Private malware analysis systems are less prone to this type of fingerprinting. However, because of the internal sharing of malware samples among these private and public analysis systems, private systems may also be vulnerable to such fingerprinting [37].

One way to prevent the fingerprinting of the analysis environment is to construct a malware analysis system indistinguishable from a real host. Such systems are also known as *transparent* analysis systems. One of the first transparent analysis systems, called Cobra [34], tries to achieve this by developing a stealthy analysis environment using binary translation. However, this approach can only prevent known fingerprinting techniques. Ether [14] is a more robust transparent analysis system that leverages hardware virtualization to maintain the CPU execution semantics of a hardware CPU. However, the system introduces significant performance overhead when performing fine-grained monitoring, which is required to produce a comprehensive malware behavioral profile. With such performance overhead, it is fundamentally infeasible to make it transparent, especially if the malware execution has access to an external timing source [20].

Instead of preventing the fingerprinting of the analysis system, some of the recent works have focused on detecting a deviation of the malware behavior in different analysis environments [9, 13, 23, 24, 28]. The approach is to execute a malware sample in different analysis environments and compare their behavioral profiles to find a deviation. A behavioral profile is a higher-level abstraction of the activities performed by a malware sample when executed. The assumption is that the presence of such deviations is evidence of an attempt to fingerprint and evade one or more analysis systems. This is a generic and robust approach because it can detect evasion regardless of the knowledge of the techniques used by the malware sample in order to fingerprint and evade the analysis system. This approach assumes that the malware shows its malicious behavior in one of the analysis systems, also known as the *reference* system. However, all previous approaches have used emulated or virtualized environments for observing the deviation in the malware behavior, and such environments are known to be detectable. If all of the analysis systems are evaded by a malware sample, no significant deviation may be present in the execution traces. Moreover, some of the analysis systems use in-guest modules for behavior extraction, which further compromises the transparency of the analysis system.

A malware analysis system that is indistinguishable from a real host is a system that uses an unmodified operating system installation that runs on actual hardware (i.e., a bare-metal system). However, this approach faces several fundamental challenges. One of the important challenges is to efficiently restore the analysis system after every analysis run. Recently, a bare-metal-based malware analysis system, called BareBox [25], proposed an efficient system-restore technique. In this technique, the physical memory of the host is partitioned and only one partition is used for the analysis environment, while another partition is used for a snapshot of the system to be restored. Whenever needed, an external operating system located outside the physical memory of the analysis environment performs the restoration of the physical-memory snapshot, without the need for a reboot. However, a sophisticated malware can forcefully probe the physical memory and detect the presence of the BareBox system. Another bare-metal based malware analysis framework is Nvmtrace [5]. This system leverages IPMI (Intelligent Platform Management Interface) technology to automate the power cycle of the bare-metal analysis system. However, a complete reboot of the system is required after every analysis run. Another challenge to the bare-metal based malware analysis system is the extraction of the behavioral profile. To this end, no process-level behavior, such as process creation, termination, and hooking activities, can be extracted from a bare-metal analysis system without introducing some form of an in-guest analysis component. However, the presence of such components inside the system violates the transparency requirement and makes the system detectable. Because of this limitation, the observable malware behavior on a pure bare-metal system is limited to the disk-level and network-level activities. When only the disk-level and network-level behaviors are available, it may not be possible to perform an in-depth behavioral analysis, but these types of activity can be effectively used for detecting evasive behavior.

In this paper, we present BareCloud, a system for automatically detecting evasive malware. BareCloud detects evasive malware by executing them on a bare-metal system and comparing their behavior when executed on other emulation and virtualization-based analysis systems. Our bare-metal system has no in-guest monitoring component. This approach provides a robust transparent environment for our *reference system* where both user-mode and kernel-mode malware can be analyzed. BareCloud transparently extracts the behavioral profile of the malware from its disk-level and network-level activity. The disk-level activity is extracted by comparing the system's state after each malware execution with the initial *clean* state. Using the understanding of the operating system of the analysis host, BareCloud also extracts

operating-system-level changes, such as changes to specific registry keys and system files. Network-level activities are captured on the wire as a stream of network packets. This approach extracts malware behavior only from the persistent changes to the system. In principle, a malware sample could perform its activities without causing any persistent change, or could revert any changes after the activities are carried out. However, to perform any substantially malicious activity, a malware has to depend on some persistent change to the system, or it has to interact with external services, such as a C&C server. Both types of activities are transparently observable in our system.

When comparing the behavior of a malware sample on multiple platforms, previous works have considered the behavioral profiles purely as sets or bags of elements drawn from a flat domain, and computed their similarity using traditional set-intersection-based methods [8, 13, 28]. Set-intersection-based measures may not accurately capture similarity when data is sparse or when there are known relationships between elements within the sets [19]. For example, if two behavioral profiles under comparison contain a large number of similar file activities, but only one profile exhibits some network activities, set-intersection-based similarity measures, such as Jaccard similarity, produce a high similarity score, and fail to properly capture the lack of similarity among network activities. One may compute the similarity of the file activities and the network activities separately. However, similar problems exist; for example, two profiles may contain large number of similar DNS activities, but only one profile contains an HTTP request. It is important to identify such small-yet-important differences while comparing behavioral profiles for detecting evasions.

When manually comparing behavioral profiles, we start from generic questions such as "Do both profiles contain network and file activities?" If they do, we move on to other questions such as "Do these activities correspond to the same network or file objects?" This way of reasoning indicates that the behavioral profiles have an inherent similarity hierarchy based on the level of abstraction of the activities. Therefore, our similarity measure is based on the notion of the similarity hierarchy. Such hierarchy-base similarity can compute similarity at different levels of abstraction and identify activities that share similar characteristics even if they are not exactly the same. We show that this approach performs better than the set-intersection-based measure while comparing behavioral profiles for detecting evasive malware.

We compare the malware behavioral profile extracted from the bare-metal system with three major malware analysis platforms that are based on emulation and different types of virtualization, and we detect evasive behavior by detecting the deviation in the behavioral profile. Note that, beside evasion, there can be other factors that may cause a deviation in the behavioral profile. Section 4 describes how we mitigate those factors.

Our work makes the following contributions:

- We present BareCloud, a system for automatically detecting evasive malware. Our system performs malware analysis on a transparent bare-metal system with no in-guest monitoring component and on emulation-based and virtualization-based analysis systems.
- We introduce a novel evasion detection approach that leverages hierarchical similarity-based behavioral profile comparison. We show that this approach produces better results compared to the previous set-intersection-based approaches.
- We evaluate our system on a large dataset of recent real-world malware samples. BareCloud was able to detect 5,835 evasive malware instances out of 110,005 samples.

2 System Overview

The goal of our system is to automatically detect evasive malware by performing automated analysis of a large number of samples on a bare-metal reference system and other dynamic analysis systems. The goal is to identify deviations in the dynamic behavior of a sample when executed on different analysis environments. BareCloud achieve this by a multi-step process as depicted in Figure 1. The large volume of input samples is first pre-screened using the Anubis malware analysis framework [1]. The purpose of the pre-screening process is to select more interesting samples that are likely to have environment-sensitive behavior. These pre-screened samples are then executed on the cluster of bare-metal analysis hosts and on three other malware analysis systems, namely, Ether [14], Anubis [1], and Cuckoo Sandbox [2]. Each analysis system consists of multiple analysis hosts. The execution of the same sample in different systems is synchronized by the Scheduler component. Analysis hosts (workers) can independently join, perform analysis, and leave the BareCloud system. BareCloud extracts behavioral profiles from each of these analysis run, and, in the next step, it processes these profiles to detect evasive behavior.

3 Monitoring Environments

In this section, we describe the four malware analysis environments we use for monitoring the behavior of malware samples.

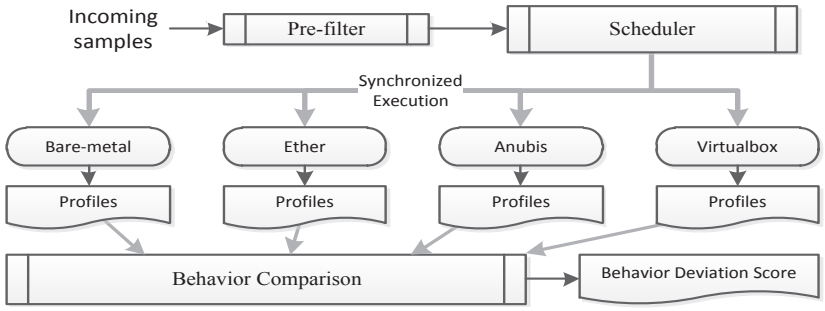

Figure 1: Overview of the system

3.1 Virtualization

We use Cuckoo Sandbox, which is based on VirtualBox [7], to provide a virtualization-based malware analysis platform. This is also known as a Type 2 hypervisor, that is, the virtualization host is a software application that runs on top of an operating system. Cuckoo Sandbox [2] supports the automation of the analysis process, and also includes function-hooking-based in-guest monitoring components. These components monitor execution-related events inside the analysis host. Several analysis and reporting plugins are available for specific needs. In this work, we use the analysis reporting plugin that includes Windows API call traces and network traffic. We use this trace to build the behavioral profile of a malware sample in the virtualized environment.

3.2 Emulation

We use the Anubis platform [1] to analyze malware in an emulated environment. Anubis is a whole-system emulation-based malware analysis platform. The emulator is based on Qemu [12]. No monitoring component is present inside the analysis environment other than some commonly used GUI automation tools. The emulator performs execution monitoring by observing the execution of pre-computed memory addresses. These memory addresses corresponds to important system API functions. Anubis is able to extract additional information about the API execution by inserting its own instructions to the emulator's instruction execution chain. Anubis implements a host of techniques, such as Product ID randomization, to prevent straightforward detection of the analysis system.

3.3 Hypervisor

We use Ether [14] to analyze malware in a hypervisor-based analysis environment. Ether is a Xen-based transparent malware analysis framework that utilizes Intel's VT hardware virtualization extensions [3]. The use of the hypervisor makes it possible to execute most of the malware instructions as native CPU instructions on the real hardware without any modifications. Thus, it does not suffer from inaccurate or incomplete system emulation issues that might affect emulation-based analysis systems. Ether can monitor a wide range of dynamic malware behaviors, such as system calls, memory writes, and fine-grained instructions execution. However, monitoring of memory writes and instruction-level trace introduces a substantial overhead and is only suitable for manual analysis. In this work, we only use Ether's coarse-grained system call trace collection capability. In addition, we also record all network communications during the malware execution. We combine the information from the system call trace and the network traffic to generate the behavioral profile.

3.4 Bare-metal

Our bare-metal malware analysis system is a cluster of hardware-based modular worker units. The workers' disks are based on a remote storage disk. This allows BareCloud to leverage copy-on-write techniques to perform disk restoration more efficiently when compared to a complete local disk overwrite. The bare-metal system also has a software-based remote control mechanism to automate the malware execution process on the workers. This mechanism is based on the IPMI remote administration features (e.g., IPMI allows to control the power cycle of the analysis worker units). We use the iSCSI protocol (Internet Small Computer System Interface) to attach remote disks to worker units. We used Logical Volume Manager (LVM)-based copy-on-write snapshots to host the remote disk used by the analysis system running on the worker units. After the completion of each malware analysis, the corresponding volume snapshot is recreated from a clean volume.

One of the critical components of a malware analy-

sis system is the *malware initiator*, which is the component that starts the execution of the malware. Usually, this component is implemented as some form of in-guest agent that waits for a malware sample through a network service. If the analysis system reboots after each analysis run, another approach can be to install a start-up entry in the system configuration that executes an application from a specific path. A malware sample can then be updated at this specific path for each analysis run by directly modifying the disk-image when the analysis system is offline. However, precise control over the malware execution duration is difficult when using this approach, as the overall execution time includes the system reboot time, which can vary among multiple reboots..

For a bare-metal analysis system, making its *malware initiator* component transparent is very important. This is because the malware can simply check for the presence of this component to fingerprint the environment. To this end, our system uses the network-based approach. The *malware initiator* removes itself and all of its artifacts after initiating the malware. This network-based approach also makes the malware execution duration more accurate, as it does not account for the reboot time.

3.5 User Environment

Apart from stock operating system, the environment installed inside the malware analysis systems includes some data and components that are usually present on a real host, such as saved credentials for common social networks, browser history, user document files, and other customizations. With this setup, we can observe additional malware behavior that we could not have observed using a bare user environment.

4 Behavior Comparison

In this section, we discuss malware behavioral deviation, behavioral profile extraction, and formalize behavioral profile comparison.

4.1 Behavior deviation

There are many factors that may cause a malware sample to show deviations in the dynamic behavior associated with different analysis environments. Hereinafter, we discuss each of these factors in detail.

- Evasive behavior of the malware sample:

  Deviation in the behavior may be the result of a successful fingerprinting of the analysis environment. This deviation is observable due to the change in the activities performed by the malware after the detection. This is the type of deviation we are interested in.

- Intrinsic non-determinism:

  A malware may have intrinsic non-determinism embedded in the code. That is, malware behavior might depend on some random value that it reads at the time of execution. For example, a malware sample may create a file with a random name. Randomization in the behavior can also result from the use of certain system services and APIs. For example, a successful call to `URLDownloadToFile` creates a random temporary folder to download the web content.

- Internal environment:

  Difference in the software environment of the different analysis systems may trigger different dynamic behaviors of the malware sample. For example, some malware may depend on a .NET framework installed in the analysis system, or may depend on the availability of a specific version of a system DLL. If one of the malware analysis environments does not contain such software components, the resulting malware behavior may be different.

- External environment:

  Another critical factor that may cause a deviation in the malware behavior is the external environment with which a malware sample can interact. In the context of malware execution, this external environment largely comprises of different network services, such as DNS and C&C servers. The non-deterministic nature of such network services may introduce deviations in the dynamic behavior of a malware sample. One simple way to minimize this factor is to completely disable access to external network environments. However, the network activity of a malware sample is one of the most important aspects to characterize the behavior of the sample. Hence, a successful behavior comparison of a malware sample requires the inclusion of its network activities.

Since our goal is to identify behavior deviations caused by the evasive technique employed by the malware sample, we need to minimize the effect of the three other factors that may cause a behavior deviation.

One approach to identifying intrinsic non-determinism is to execute the same sample in the same environment multiple times. By comparing the execution traces from

these different execution runs, non-deterministic behavior can be identified. Previous work [28] used this approach to filter out randomized behavior. However, this approach is resource- and time-expensive. Moreover, not all malware exhibit such randomized behavior.

In this work, we propose a more efficient hierarchical similarity-based approach to behavior comparison, described in Section 4.4. This approach is able to minimize the effect of intrinsic randomization without requiring multiple execution runs of the same sample in the same analysis environment. In order to address deviation caused by different internal environments, we must provide identical software environments to all analysis systems. Therefore, we prepared identical base software environments for all of our analysis systems.

Precisely controlling the behavior deviation introduced by the external environment is difficult. This is because these factors are not under our direct control. However, failure to minimize the impact of these factors may result erroneous behavior deviations. This consideration is important because most malware communicates with the external environment to carry out its malicious activities. To minimize the effect of the external environment, we implemented the following strategies.

- Synchronized execution: We execute the same malware sample in all analysis environments at the same time. The scheduler component facilitates the synchronization among different analysis hosts. By doing this, we minimize the behavior deviation that may be introduced by the variation of the external factors over time. For example, a malware may try to connect to a *fast-flux* network. The availability and the returned response of the C&C server and the DNS server may vary over time. If the malware is executed in different environments at different times, such variations in external environment may result in a spurious behavior deviation. Synchronized execution mitigates such differences.

- Identical local network: Malware can interact with the local network by different network-related activities, such as probing available local network services and accessing file shares. We expose all analysis systems to identical simulated local network environments.

- Network service filters: One approach to minimize the non-determinism introduced by different network services is to actively intercept network communications and maintain identical responses to identical queries among all instances of a malware running in different analysis environments. This requires an application-level understanding of the network services. To this end, we intercept all DNS and SMTP communications and respond with consistent replies in all analysis system. For example, the system responds with identical IP information to identical DNS queries coming from different analysis environments. With this setup, we are also able to sinkhole non-existent domain and SMTP communications to the local simulated network. This helps us observe more network behavior of a malware sample, which otherwise may not be observable.

4.2 Behavioral profile

After the execution of a malware sample in different analysis environments, we need to extract its behavioral profile for comparison. Usually, the behavioral profile is extracted from some form of dynamic execution trace, such as a system-call trace. Bayer et al. have introduced a comprehensive method of extracting behavioral profile from an augmented system-call trace. The additional information provides taint tracking of input and output parameters of system calls that provides dependency information between different system calls [10]. This approach has been used to cluster a large number of malware, and to compare malware behaviors [10, 28]. Similar approaches can be used in three of our analysis environments, where system-call traces are available. However, this system-call based approach is not directly applicable to our bare-metal malware analysis system, as we do not have access to the system-call trace.

Transient and resultant behavioral profile

A transient behavioral profile is a profile that represents all of the operations performed by a malware sample during its execution. The system-call-based behavioral profile discussed previously is a type of transient behavioral profile. This represents a more comprehensive view of *how* a malware performs its malicious activities. The resultant behavioral profile consists of the cumulative changes made by the malware from the beginning to the end of its execution. This includes those operations that make persistent changes to the system. Multiple similar operations to the same object are combined and represented as one operation to reflect the resulting effect of the operations. This represents a more summarized view of *what* a malware does to the system. A malware can obfuscate its transient behavior to evade transient behavior-base similarity detection. However, similar malicious activities produce similar resulting behavioral profiles, even if the transient behavior is obfuscated or randomized. This makes the comparison of malware behavior based on the resultant behavioral profile more robust.

The transparency requirement of our bare-metal analysis system limits us to the extraction of only the resulting behavioral profile. That is, the transient behaviors of process activities and filesystem activities are not available. However, we can extract the resulting filesystem behavior by comparing the disk contents from before and after the malware execution. Extraction of network behavior is straightforward using an external traffic capture component.

With these constraints in hand, we model our behavioral profile based on the model introduced by Bayer et al. [10], such that only the objects and the operations are used. That is, we take into consideration the object upon which a malware performs an operation that causes a persistent change to the object. Formally, a behavioral profile Π is defined as a 3-tuple.

$\Pi = (O, R, P)$

Where, O is the set of all objects, R is the set of all operations that causes persistent changes, and $P \subseteq (O \times R)$ is a relation assigning one or more operations to each object. Unlike in the model proposed in [10], where the objects and the operations are conceptualized as OS Objects and OS operations, we generalize the objects and operations to any environment entity with which a malware can interact. More details on objects and operations are provided hereinafter.

Objects

An object represents an entity, such as a file or a network endpoint, upon which a malware can perform some operation.

It is a tuple of `type` and `name` formally defined as follows.

$O = (obj\_type, obj\_name)$

$obj\_type ::= file|registry|sysconf|mbr|network$

The *file* type represents filesystem-specific file objects of the disk, the *registry* type represents registry keys, the *sysconf* type represents OS-specific system configurations, such as the boot configuration, *mbr* represents OS-independent Master Boot Record, and the *network* type represents network entities, such as a DNS server.

Operations

An operation generalizes the actions performed by a malware sample upon the above-described objects. An operation is formally defined as:

$R ::= (op\_name, op\_attribute)$

That is, an operation has a name and a corresponding attribute to provide additional information. As mentioned previously, only those operations that cause a persistent change to the system are included. For example, in case of a *file* type object, only the creation, deletion, and modification operations are included in the profile.

4.3 Behavior extraction

Our bare-metal system can only access the raw disk contents. We extract the filesystem behavior by comparing the filesystem state before and after the execution of a malware sample. A detailed understanding of the filesystem internal structures is required to extract such information. We leverage the functionalities provided by the SleuthKit framework [6] for extracting the file meta-data information from the raw disk image. By doing this, we are able to extract all file names in the disk, including some recently deleted files, along with their corresponding meta-data, such as size and modification date. We first build two sets representing the file object meta-data: the *clean* set and the *dirty* set, corresponding to the disk content before and after a malware execution. Extracting the deletion and creation operations of a file object are simple set operations. That is, any file not present in the dirty set is considered as deleted, and any file only present in the dirty set is considered as created. If a file is present in both sets with different meta-data, it is considered as modified. However, if a malware writes to a disk-sector (other than MBR) that is invisible to the filesystem, or modifies an existing file without changing the size and file-date meta-data, the current approach will not detect such changes. The straightforward way of comparing all file contents between two disk states can be very inefficient. This limitation can be mitigated by first detecting such changes in the disk sectors from copy-on-write data or iSCSI communication, and mapping the dirty sectors to files. Similar approach has been previously proposed [29]. To this end, we leave this improvement as a future work.

Registry behavior is extracted using a similar approach. We extract the meta-data of all the registry keys from the raw registry hive (registry database file) using the *registryfs* filesystem extension of the SleuthKit framework. Again, we build two sets representing the registry meta-data corresponding to the registry hive content before and after the malware execution. We perform set operations similar to the case of the filesystem to extract malware operations on the registry objects.

To extract the behavior of type *sysconf*, we process the filesystem and registry behavior to identify critical modifications to the system configuration. Some examples of the system configuration locations are listed in Table 1.

For the three other analysis systems, we process system-call traces to extract behavior information.

Table 1: Examples of the configuration locations

obj_type	obj_name	System path
sysconf	startup	HKLM/Software/Microsoft/Windows/CurrentVersion/Run
sysconf	startup	HKCU/Software/Microsoft/Windows/CurrentVersion/Run
sysconf	startup	HKLM/System/CurrentControlSet/Services
sysconf	boot	%SYSTEMROOT%/BOOT.INI
sysconf	autoexec	%SYSTEMROOT%/AUTOEXEC.BAT
sysconf	sysini	%SYSTEMROOT%/WINDOWS/SYSTEM.INI
sysconf	winini	%SYSTEMROOT%/WINDOWS/WIN.INI

Behavior normalization

Behavioral profile extracted from the difference of the initial and final disk states contains both malware behavior as well as the background operating system behavior. We need to filter out the features of the behavioral profile that do not correspond to the malware execution. One way to filter such features is to use the file modification timestamp of the file objects. That is, by selecting only those files that are created and modified during the time when the malware is executed, one can filter out unrelated file modifications that occur before and after the malware execution. However, some unrelated filesystem changes caused by the *base* operating system might still be present in the filtered profile. Moreover, many malware samples actively modify the system time, or tamper with the file meta-data to revert the file's modification time. Although the simple file time-stamp-based filter is efficient, this approach will fail in such situations.

Another approach to filter the background behavior is to first learn the behavioral profile of the *base* operating system and then filter this behavior from the profile generated by a malware execution. By doing this, we can overcome many of the shortcomings of the timestamp-based approach. This approach may exclude some malware operations that match the operation performed by the *base* operations. However, it is difficult to perform malicious actions using only operations that are also performed by the base operating system. Also, such operations are less important in defining the malicious behavior of the malware. We use this approach to filter our profiles. To extract the background behavior of the analysis system, we wrote a "void" program that does nothing other than stall infinitely. For each analysis environment, we extract the behavioral profile of the "void" program from all of its analysis hosts and combine them to build a generalized background profile. We use this profile to filter the behavioral profile of a malware execution.

Some objects used to describe the profile may be referenced using multiple names. For example, `\\?\C:\Documents and Settings` and `C:/DOCUME~1/` correspond to the same file object. We convert such identifiable object names to the same format. Different usernames may also result in different physical names for semantically similar file locations. For example, the locations `C:/DOCUME~1/USERA` and `C:/DOCUME~1/USERB` are semantically similar locations, which is the user's home directory. Some system APIs that create temporary files also generate different file paths, which are semantically similar. Many such temporary path names have known root locations and can be identified by their naming structure. We replace such occurrences in the object names with corresponding generic tokens.

4.4 Behavior comparison

Previous works have compared the persistent change-based behavioral profile using set-intersection-based methods over the feature set [13, 28]. However, when comparing behavioral profiles that only considers persistent changes, one can expect a sparse feature set. Furthermore, features within the profile are highly related and can be categorized in groups and subgroups. However, when the features are sparse or when there are known relationships between features within the set, set-intersection-based measures may not accurately capture the similarity [19].

Unlike previous works, we use a hierarchical similarity measure to overcome this problem. The hierarchy is associated with the different abstraction levels present in the behavioral profile. This approach makes our similarity measure less sensitive to randomization introduced by non-determinism in malware code. This is because the randomization is usually introduced only in one level of the hierarchy while keeping other levels of the hierarchy identical. For example, a malware may randomize the filename (obj_name) it creates, but perform the same *create* operation (op_name) on a *file* object (obj_type) with the same operation *attribute* ($op\_attribute$).

4.5 Hierarchical similarity

The notion of the hierarchical similarity is often used in text similarity, in mining association rules, and in various computer vision tasks for finding similar shapes [16, 17, 21]. We use a similar notion of hierarchical similarity to compare behavioral profiles. The similarity hierarchy of the behavioral profile is represented in Figure 2. As one can see, knowledge of the semantics and of the relationship between the objects is encoded in the representation. The leaves of the tree are the actual feature elements of the behavioral profile. The first level of similarity hierarchy is obj_type. An obj_type may have one or multiple obj_name, and each such obj_name can be associated with one or more op_name corresponding to various operations. Each such operation has one leaf node corresponding to the associated attribute of the operation. The leaf nodes are the feature elements whose attributes are represented by its parent nodes. For example, in the Figure 2, the ele-

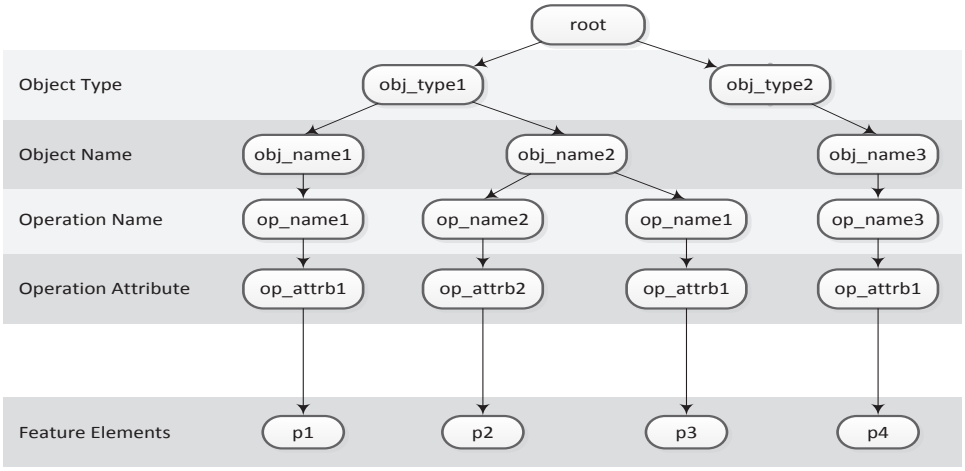

Figure 2: Behavior similarity hierarchy

ment p_1 is a feature element having the feature attributes $(obj\_type1, obj\_name1, op\_name1, op\_attrb1)$.

We compute the similarity in a two-step process. First we identify the matching nodes in the hierarchies of two behavioral profiles. We do this iteratively, starting from the first level (obj_type). For each of these matching nodes, we identify the matching nodes among their child nodes, i.e., the next level of hierarchy. We compute the similarity measure at each hierarchy level. Finally, we aggregate level similarity measures to compute the overall similarity.

The model

Let H be a rooted tree representing the similarity hierarchy, where all nodes have associated labels. For example, Figure 2 is an instance of H. Let L_H be all labels in H, and $L(H,d)$ be the set of labels of the nodes of H at depth d. Let δ be the height of the tree such that $L(H,\delta)$ is the set of all labels of the leaves of H. The set of labels $L(H,\delta)$ represents the feature elements p such that $p \in P$, where P represents the behavioral profile. In the example Figure 2, the leaf nodes p_1, p_2, p_3, and p_4 represents the feature elements of the behavioral profile. $L(H,\delta)$ and P are equivalent, one represented as leaves of the tree structure, another represented as a tuple of the feature attributes. With this, any P can be mapped into H. There is a hierarchy in $L(H,\delta)$, and hence in P, superimposed by H.

Let P_1 and P_2 be two behavioral profiles of a malware sample m from analysis systems a_1 and a_2. Let these behavioral profiles be mapped into hierarchies H_1 and H_2, instances of the hierarchical model H. Let $PL(H,l)$ be the label of the parent node of a node with label l, where $l \in L_H$, the set of all labels in H. Here, we want to find nodes with matching labels at each depth d whose parent nodes also have matching labels. We recursively define $match$ and $candidate$ for each level d as:

$$match_{H_1,H2}(d) = L(H_1,d) \cap L(H_2,d) \mid \forall l \in match_{H_1,H2}(d), PL(H_1,l) = PL(H_2,l) \text{ and } PL(H_1,l) \in match_{H_1,H2}(d-1) \quad (1)$$

$$candidate_{H_1,H2}(d) = L(H_1,d) \cup L(H_2,d) \mid \forall l \in candidate_{H_1,H2}(d), PL(H_1,l) \cup PL(H_2,l) \in match_{H_1,H2}(d-1) \quad (2)$$

where,

$$match_{H_1,H2}(0) = root. \quad (3)$$

We define $levelsim_{H_1,H_2}(d)$, the similarity of H_1 and H_2 at level d, as the Jaccard similarity coefficient. That is,

$$levelsim_{H_1,H_2}(d) = \frac{|match_{H_1,H2}(d)|}{|candidate_{H_1,H2}(d)|}. \quad (4)$$

We define the overall hierarchical similarity between behavioral profiles P_1 and P_2 as the arithmetic average of similarity at each level:

$$Sim(P_1,P_2) = \frac{1}{\delta}\sum_{d=1}^{\delta-1} levelsim_{H_1,H_2}(d). \quad (5)$$

This definition is consistent, since the right side of this equation always lies between 0 and 1. Hence, the *behavior distance* between P_1 and P_2 can simply be defined as:

$$Dist(P_1,P_2) = 1 - Sim(P_1,P_2). \quad (6)$$

This is possible because $Sim(P_1,P_2)$ is derived from the Jaccard similarity coefficients.

Finally, we define the behavior *deviation score* of a malware sample D among different analysis system $a_1 ... a_n$ with respect to the behavioral profile P_r extracted from the reference system a_r as the quadratic mean of the behavior distances as follows.

$$Deviation(D) = \sqrt{\frac{1}{n}\sum_{i=1}^{n} Dist(P_r,P_i)^2}, \quad (7)$$

where n is the number of analysis systems, and P_i is the behavioral profile extracted from the analysis system a_i. This deviation score D is in interval [0,1], where the value of 0 means no deviation and the value of 1 means maximum deviation. We define a deviation threshold t. If the deviation score D exceeds this value, we consider the sample as evasive.

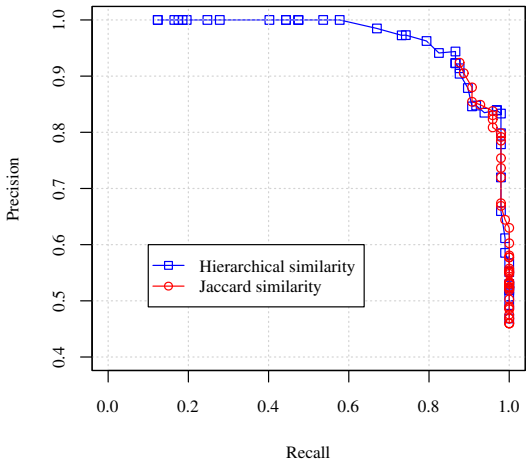

Figure 3: Precision-Recall analysis of the hierarchical similarity-based and the Jaccard similarity-based behavior comparison.

5 Evaluation

We evaluated our approach using Windows XP SP2 as the operating system for all analysis systems, as the weaker security measures of this operating system allow us to observe more malware behavior.

We conducted two experiments, which are detailed in the following sections.

5.1 Experiment I

In this experiment, we evaluated our hierarchical similarity-based behavior comparison approach.

Dataset

We first built the ground truth dataset of evasive malware and non-evasive malware samples. We received 234 recent and possibly evasive malware samples from a security company. We manually analyzed them and confirmed 111 samples from 29 families to be evasive (i.e., they fingerprint and evade at least one of the considered analysis environments). To build the dataset of non-evasive samples, we manually analyzed recent samples submitted to Anubis. By doing this, we selected 119 samples from 49 families that did not exhibit evasive behavior in any of the analysis environments.

We extracted the behavioral profiles of these samples from all analysis environments and computed the hierarchical similarity-based deviation score D with respect to the bare-metal analysis environment. We also computed the Jaccard distance-based deviation score as proposed in [28]. That is, the behavioral profile distance is computed as the Jaccard distance:

$$J(P_1,P_2) = 1 - \frac{P_1 \cap P_2}{P_1 \cup P_2}.$$

The Jaccard distance-based deviation score JD is computed as the maximum of the distances among different analysis systems as:

$$JD = \max_{1<i<n} \{ \max_{1<j<n, i\neq j} \{J(P_i,P_j)\}\}.$$

Since we do not extract multiple behavioral profiles of same malware sample from the same analysis environment, we did not compute the *intra-sandbox distance* as proposed in [28]. Instead, we wanted to compare the two different similarity approaches when the available behavioral profiles are limited to one profile per analysis environment.

We performed a precision-recall analysis by varying the threshold t for these deviation scores. If the deviation score is greater than t, the sample is considered evasive. The result is presented in Figure 3. We can clearly see that the hierarchical similarity-based deviation score gives better results. It is able to produce higher precision results while maintaining a high recall rate. While the highest precision the regular Jaccard distance-based similarity could produce is limited to 88.54%. This is because some non evasive samples have the same Jaccard distance-based deviation score as other evasive samples having highest deviation score. Hence, no matter how we vary the threshold t, precision does not increase.

Figure 4 shows the precision-recall characteristics of

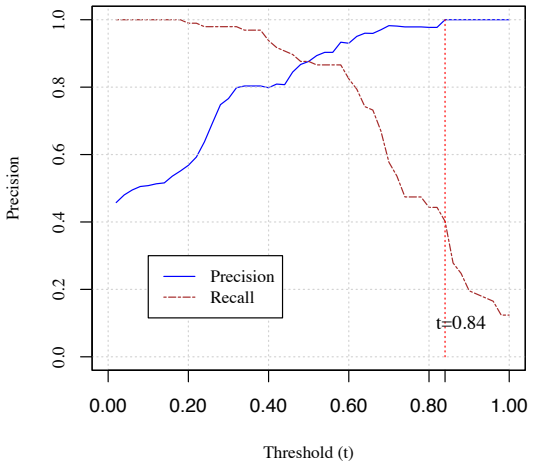

Figure 4: Precision-recall analysis of the behavior deviation threshold value t. Threshold value $t = 0.84$ gives the highest recall rate with 100% detection precision.

the hierarchical similarity-based deviation score with respect to different values for deviation threshold t. We can see that with the threshold value $t = 0.70$, more than half of the evasive samples can be detected with above 98% precision. While with threshold $t = 0.84$, we get 100% precision with the recall rate of 40.20%. In the next large-scale experiment, we used this threshold value $t = 0.84$ to have a high confidence on the detection results.

5.2 Experiment II

In this experiment, we applied our behavior comparison approach to the incoming malware feed received by Anubis. We first filtered the incoming samples based on the size and the type of the behavioral profile extracted in the Anubis analysis environment. This is required to select *interesting* samples from the large volume of the incoming malware without introducing any strong bias. This *pre-selection* process randomly selects samples from the following four groups.

- Samples with minimal activity: These are the samples that show minimal to no activity in the Anubis analysis environment (less than 1000 events). This group may contain evasive malware that successfully evade Anubis analysis environment.

- Samples with high system and network activity: These are the samples that show a substantial amount of system-related activity (more than 1000 events) and network activity in the Anubis analysis environment. We include this group to see if similar behavior can be observed in all other analysis environments.

- Samples with high network activity: These are the samples that show minimal system activity but high network activity (more than 10 packets) in the Anubis analysis environment.

- Samples with high system activity: These are the samples that show no network activity but high system activity in the Anubis analysis environment.

We selected 110,005 samples from the above groups observed during a four months period, starting from July 2013. We extracted behavioral profiles of these samples from all four analysis environments and computed the deviation scores. We used the behavior deviation threshold of $t = 0.84$ that was selected in the previous experiment. With this threshold, we were able to detected 5,835 samples as evasive. That is, these evasive samples evade one or more analysis environments. Since we do not have the ground truth for this dataset, we cannot provide the true precision of this detection.

We also categorized these evasive samples into environment-specific evasions by using the number of events observed within the various analysis environments. That is, if no activity that results in persistent change is observed in an analysis environment a_x while the same sample shows persistent change activities in at least one of the other analysis environments $[a_1, ..., a_n]$, we considered that as an evasion of the analysis environment a_x. The results are presented in Table 2. We found that 2,530 samples showed no activity that resulted in persistent change in all three common malware analysis environments, while such persistent change activities were observed in the bare-metal analysis environment. We see that many samples were able to evade the Ether environment, which is considered as a transparent environment. Manual analysis of those samples revealed that many samples were able to fingerprint Ether by leveraging the dependency of the Xen-hypervisor on Qemu-based *device models* to emulate required virtual devices, such as hard disks. Since Ether is based on Xen-hypervisor, it also requires the Qemu-based device models to run the unmodified guest, which acts as the transparent analysis host. Therefore, if a malware sample inside Ether tries to fingerprint its devices, it might identify Ether as a Qemu-based analysis system. In addition, system call tracing in Ether introduces additional overhead to the system, and, in some of the cases, regular timing-based attacks were successful in detecting the presence of the analysis system.

Table 2: Evasion detection on different environments

Environment	Detection count	Percentage
Anubis	4,947	84.78
Ether	4,562	78.18
VirtualBox	3,576	61.28
All	2,530	43.35
Total	5,835	

6 Limitations

In this section, we discuss the limitations of our approach.

One of the limitations inherent to all dynamic analysis systems is the inability of handling stalling code in a general way. A malware sample can wait for some time (e.g., tens of minutes) before performing any malicious activity. Kolbitsch et al. have proposed a technique to detect and mitigate malware stalling code [26]. However, the mitigation technique is only possible where fine-grained analysis is possible. The technique is not applicable in our bare-metal system. A more sophisticated stalling attack may encrypt the malicious payload with some weak encryption key, which the malware will brute-force during the execution. It is difficult to expedite such process to reveal the malicious activities within a limited execution time. To this end, BareCloud will not be able to observe activity in malware with stalling code.

Malware may employ heuristic checks for anomalies in the internal or external environments that are specific to malware analysis systems. For example, it can wait for real user activities, or try to resolve known non-existent domain using a public DNS server. If there is no user activity in the system or if every non-existent domain is resolved, it is likely that the system is an analysis environment. One of the mitigation techniques can be to remove external anomalies by not actively intercepting and modifying the network communication. User activities can be injected into the system by using automation techniques. However, transparently performing such automation in a bare-metal system is challenging. To this end, such heuristic checks will be able to detect our bare-metal analysis system.

Although, our similarity measure is less sensitive to randomization introduced by the non-deterministic code of a malware sample, high levels of randomization in the persistent changes will result in an erroneous detection of evasion. Other mitigation techniques, such as the multiple execution of the malware on the same analysis system, can be performed to mitigate this problem at the expense of more computational resources.

Both known and unknown fingerprinting techniques focused on detecting virtualized or emulated platforms will fail to detect BareCloud, because we are executing malware on a bare-metal hardware. However, there is the possibility that our system can be fingerprinted by examining unique software/hardware environment features, such as the MAC address of the network device or the presence of the iSCSI driver. In the case of emulated/virtualized environments, it is trivial to randomize such information for each malware analysis run. Since our system uses real hardware, introducing this randomization while preserving the transparency is difficult. The iSCSI driver detection can be mitigated by using more expensive hardware iSCSI initiator instead of a software iSCSI initiator. A hardware iSCSI initiator is a host bus adapter (HBA) that appears to the OS as a hardware storage device. To this end, our system runs as a private malware analysis framework and all outside network communications are blocked. A limited access to the Internet is provided through proxy. As long as the unique environment variables are not leaked to the malware authors, the system can be kept undetectable. However, a dedicated attacker may detect any dynamic analysis system that allows external network communications like ours by using active reconnaissance-based attacks [37]. Malware writers can upload decoy samples to public malware analysis systems so that it is eventually picked up by private analysis systems, such as ours. Such samples can leak unique environment artifacts of these analysis systems using "phoning home" technique and can be used for active reconnaissance.

7 Related works

7.1 Dynamic analysis

Researchers have developed many dynamic analysis tools to analyze malware. These tools mostly focus on extracting system call or Windows API call traces. Many of these analysis systems are based on sandboxing techniques [1, 4, 14, 35]. A sandbox is an instrumented execution environment that executes the malware sample in a contained way. Some of these sandboxes leverage in-guest techniques to trace Windows API calls, such as CWSandbox [35] and Norman Sandbox [4]. Other sandbox systems are implemented using emulation or virtualization technologies. VMScope [22], TTAnalyze [11], and Panorama [36] are some of the examples of emulation-based malware analysis systems. All of them are based on Qemu [12] and implement whole-system emulation. Other tools, such as Ether [14] and HyperDBG [15] are based on hardware-supported virtualization technology. While most system deal with user-land malware samples, some of the analysis systems are specifically targeted to analyze kernel-mode malware [27, 30].

7.2 Transparent analysis

Many transparent malware analysis systems have been proposed to defeat evasive malware. Cobra [34] was the first analysis system specifically focused on defeating anti-debugging techniques. However, Cobra runs its tool at the same privilege level as the malware. In principle, this approach makes it impossible to provide absolute transparency.

Many of the malware analysis tools based on the out-of-VM approach are designed to provide better transparency [1, 14, 22], as the analysis system is completely external to the execution environment. However, detection techniques have been developed to detect these analysis systems as well. There are several techniques to detect VMWare [9, 18, 33], as well as Bochs and Qemu [9, 18, 31]. Pek et al. [32] have shown that hardware virtualization-based Ether [14] can be detected using local timing attacks.

The most effective way to provide transparency is to run on real hardware, with an environment that has not been extended with analysis artifacts. BareBox [25] and Nvmtracer [5] both provide bare-metal environments for malware analysis.

7.3 Evasion detection

Chen et al. proposed a detailed taxonomy of evasion techniques used by malware against dynamic analysis system [13]. Lau et al. have employed a dynamic-static tracing technique to detect VM detection techniques. Kang et al. [24] proposed a scalable trace-matching algorithm to locate the point of execution diversion between two executions. The system is able to dynamically modify the execution of the whole-system emulator to defeat anti-emulation checks. Balzarotti et al. [9] proposed a system for detecting dynamic behavior deviation of malware by comparing behaviors between an instrumented environment and a reference host. The comparison method is based on the deterministic program execution replay. That is, the malware under analysis is first executed in a reference host while recording the interaction of the malware with the operating system. Later, the execution is replayed deterministically in a different analysis environment by providing system call return value recorded in the first run, in the assumption that any deviation in the execution is evidence of some kind of environment fingerprinting. Disarm [28] compares behavioral profiles of four emulation-based analysis environments. The behavior comparison requires each sample to be analyzed multiple times in each analysis environment. The main difference between Disarm and our work is that our analysis systems are based on four fundamentally different analysis platforms, including the transparent bare-metal environment with no monitoring component present in the hardware. Moreover, we propose an improved behavior comparison technique that captures the inherent similarity hierarchy of the behavior features, and do not require the resource-expensive execution of same sample multiple times in the same analysis environment.

7.4 Hierarchical Similarity

Hierarchies are used to encode domain knowledge about different levels of abstraction in the type of events observed. They have been used in different field of similarity detection, such as finding text similarity [16], detecting association rules using hierarchies of concepts [21], and finding similarity among deformable shapes [17]. Ganesan et al. [19] proposed a similarity measure that incorporates hierarchical domain structure. However, the similarity computation is focused on the element-level similarity rather than the profile-level similarity. It uses a modified version of cosine-similarity measure.

8 Conclusions

Dynamic analysis is an effective approach for analyzing and detecting malware that uses advanced packing and obfuscation techniques. However, evasive malware can fingerprint such analysis systems, and, as a result, stop the execution of any malicious activities. Most of the fingerprinting techniques exploit the fact that dynamic analysis systems are based on virtualized or emulated environments, which can be detected by several known methods. The ultimate way to thwart such detection is to analyze malware in a bare-metal environment.

In this work, we presented BareCloud, a system for automatically detecting evasive malware by using hierarchical similarity-based behavioral profile comparison. The profiles are collected by running a malware sample in bare-metal, virtualized, emulated, and hypervisor-based analysis environments.

Future work will focus on improving the transparency of the bare-metal analysis component and on developing an iSCSI module that can extract high-level, intermediate file system operation, providing a richer filesystem-level event trace.

Abstract

Matching function binaries—the process of identifying similar functions among binary executables—is a challenge that underlies many security applications such as malware analysis and patch-based exploit generation. Recent work tries to establish semantic similarity based on static analysis methods. Unfortunately, these methods do not perform well if the compared binaries are produced by different compiler toolchains or optimization levels. In this work, we propose *blanket execution*, a novel dynamic equivalence testing primitive that achieves complete coverage by overriding the intended program logic. Blanket execution collects the side effects of functions during execution under a controlled randomized environment. Two functions are deemed similar, if their corresponding side effects, as observed under the same environment, are similar too.

We implement our blanket execution technique in a system called BLEX. We evaluate BLEX rigorously against the state of the art binary comparison tool BinDiff. When comparing optimized and un-optimized executables from the popular GNU coreutils package, BLEX outperforms BinDiff by up to 3.5 times in correctly identifying similar functions. BLEX also outperforms BinDiff if the binaries have been compiled by different compilers. Using the functionality in BLEX, we have also built a binary search engine that identifies similar functions across optimization boundaries. Averaged over all indexed functions, our search engine ranks the correct matches among the top ten results 77% of the time.

1 Introduction

Determining the semantic similarity between two pieces of binary code is a central problem in a number of security settings. For example, in automatic patch-based exploit generation, the attacker is given a pre-patch binary and a post-patch binary with the goal of finding the patched vulnerability [4]. In malware analysis, an analyst is given a number of binary malware samples and wants to find similar malicious functionality. For instance, previous work by Bayer et al. achieves this by clustering the recorded execution behavior of each sample [2]. Indeed, the semantic similarity problem is important enough that the DARPA CyberGenome program has spent over $43M to develop new solutions to it and its related problems [7].

An inherent challenge shared by the above applications is the problem of semantic binary differencing ("diffing") between two binaries. A number of binary diffing tools exist, with current state-of-the-art diffing algorithms such as zynamics BinDiff[1] [8, 9] taking a graph-theoretic approach to finding similarities and differences. BinDiff takes as input two binaries, finds functions, and then performs graph isomorphism (GI) detection on pairs of functions between the binaries. BinDiff highlights pairs of function code blocks between the binaries that are similar and different. Although the graph isomorphism problem has no known polynomial time algorithm, BinDiff has been carefully designed with clever heuristics to make it usably fast in practice. This graph-theoretic approach pioneered by BinDiff has inspired follow-up work such as BinHunt [10] and BinSlayer [3].

While GI-based approaches work well when two semantically equivalent binaries have similar control flow graphs (CFG), it is easy to create semantically equivalent binaries that have radically different CFGs. For example, compiling the same source program with `-O0` and `-O3` radically changes both the number of nodes and structure of edges in both the control flow graph and the call graph. Our experiments show that even this common change to the compiler's optimization level invalidates this assumption and reduces the accuracy of the GI-based BinDiff to 25%.

In this paper, we present a new binary diffing algorithm that does not use GI-based methods and as a result finds similarities where current techniques fail. Our insight is that regardless of the optimization and obfuscation differ-

[1] http://www.zynamics.com/bindiff.html

ences, similar code must still have semantically similar execution behavior, whereas different code must behave differently. At a high level, we execute functions of the two input binaries in tandem with the same inputs and compare observed behaviors for similarity. If observed behaviors are similar across many randomly generated inputs, we gain confidence that they are semantically similar. The main idea of executing programs on many random inputs to test for semantic equivalence is inspired by the problem of polynomial identity testing (PIT). At a high level, the PIT problem seeks efficient algorithms to test if an arithmetic circuit C that computes a polynomial $p(x_1, \cdots, x_n)$ over a given base field $\mathbb{F}$ outputs zero for *every* one of the $|\mathbb{F}|^n$ possible inputs. The earliest algorithm for PIT was a very intuitive randomized algorithm that simply runs C on random inputs. This algorithm depends on the fact that if p is not identically zero, then the probability that C returns zero on a randomly-chosen input is "*small*."[2] By repeating this test, either we will hit an input $(x_1, \cdots, x_n)$ such that $p(x_1, \cdots, x_n) \neq 0$, or we gain confidence that p is identically zero.

There are many challenges to applying the general PIT idea to actual programs, however. Arithmetic circuits have well-defined inputs and outputs, but it is currently an area of active research to identify the inputs and outputs of functions in binary code (see, e.g., [5]). Instead, we propose seven assembly-level features to record during the execution of each function as an approximation of its semantics. Additionally, while it is straightforward to evaluate an arithmetic circuit entirely, finding a collection of inputs that can execute and thus extract the semantics of every part of a program is another open research problem. To achieve full coverage, we repeatedly start execution from the first un-executed instruction of a function until every instruction has been executed at least once.

We have implemented a dynamic equivalence testing system called BLEX to evaluate our blanket execution technique. Our system observes seven semantic features from an execution, namely the four groups of values read from and written to the program heap and stack, the calls made to imported library functions, the system calls made during execution, and the values stored in the `%rax` register upon completion of the analyzed function. We compute the semantic similarity of two functions by taking a weighted sum of the Jaccards of the seven features. Our evaluation is based on a comprehensive dataset. Specifically, we compiled GNU coreutils 8.13 with three current compiler toolchains—`gcc` 4.7.2, `icc` 14.0.0, and `clang` 3.0-6.2. Then, for each compiler toolchain, we compiled coreutils at optimization levels 0 to 3, producing 12 versions of coreutils in total.

[2]The precise upperbound on this probability is commonly known as the Schwartz-Zippel Lemma [23, 28].

Overall, our contributions are as follows:

- We propose *blanket execution*, a novel full-coverage dynamic analysis primitive designed to support semantic feature extraction (§3). Unlike previous approaches such as [25], blanket execution ensures the execution of every instruction without forced violation of branch instruction semantics.
- We propose seven binary code semantics extractors for use in blanket execution. This allows us to approximate the semantics of a function without relying on variable identification or source code access.
- We implement the proposed algorithm in a system called BLEX and evaluate it on a comprehensive dataset based on GNU Coreutils compiled on 4 optimization levels by 3 compilers. Our experiments show that BinDiff performs well (8% better than BLEX) on binaries that are syntactically similar. For binaries that show significant syntactic differences, BLEX outperforms BinDiff by a factor of up to 3.5 and a factor of 2 on average.

2 Problem Setting and Challenges

The problem of matching function binaries is a significant challenge in computer security. In this problem setting, we are only given access to binary code without debug symbols or source. We assume the code is not packed and is compiled from a high-level language that has the notion of a function, i.e., not hand-written assembly. While handling packed code is important, it poses unique challenges which are out of scope for this paper. There are many real-life examples of such problem settings in security. These include, for example, automatic patch-based exploit generation [4], reverse engineering of proprietary code [24], and finding bugs in off-the-shelf software [6].

Clearly, all compiled versions of the same source code should be considered similar by a system addressing the problem of matching function binaries. In this paper, we explicitly consider the case where different compilers and optimization settings produce different binary programs from identical source code. Changing or updating compilers and optimizers happens periodically in industry. For example, with the release of the Xcode 4.1 IDE, Apple switched the default compiler suite from `gcc` to `llvm` [1]. Furthermore, changing compilers and optimization settings is similar to an obfuscation technique. It is common for optimizers to substitute instruction sequences with semantically equivalent but syntactically different sequences. This is exactly a form of metamorphism.

As a motivating example, consider the problem of determining similarities in `ls` compiled with `gcc -O0` and `gcc -O3`, as shown in Figure 1. Although the two assembly listings are the result of the exact same source code, almost all syntactic similarities have been eliminated by the applied compiler optimizations. *If we cannot handle*

```

Figure 2: Only the CFG (b), but not (c), is the correct match for (a).

a short function in `coreutils` "obfuscated" only by different optimization levels, what hope do we have on real threats?

The difference between optimized and non-optimized code illustrates several key challenges for correctly identifying the two code sequences as similar:

- Semantically similar functions may not yield syntactically similar binaries. The length of code and operations performed between the two optimization levels is radically different although they both carry out the same simple operation.
- The analysis needs to reason about how memory is read and written. For example, the `-O0` and `-O3` access their arguments identically despite `-O3` not setting up a typical stack frame. In addition, the `cmp_name` function in the `-O0` code up to the call on line 15 indexes struct fields in a semantically equivalent manner to lines 1 and 2 of the `-O3` version.
- Inter-procedural and context sensitive analysis is a must. In `-O0`, `strcmp_name` will always call `cmp_name` with a function pointer pointing to `strcmp`, but in `-O3`, `strcmp` is called directly.

Unfortunately, existing systems both in the security and the general systems community do not address all the above challenges. Syntax-only approaches such as BitShred [12] and others will fail to find any similarities in the code presented in Figure 1. GI-based algorithms will fail because the call and control flow graphs are radically different. GI based methods, such as BinDiff, also face challenges when the control flow graphs to compare are small and collisions render them indistinguishable. Consider, for example the three control flow graphs in Figure 2. The CFG in (a) is the unoptimized version of the `md5_finish_ctx` function in the `sort` utility. While Figure (b) is the optimized version of that function, Figure (c) is the implementation of `xstrxfrm` in the same binary. However, an approach that solely relies on graph similarities, will likely not be able to make a meaningful distinction in this scenario. Alternative approaches, such as the one proposed by Jiang and Su [14] perform only intra-procedural analysis and thus are not able to identify the similarity of the two implementations. To address the above-mentioned challenges in the scope of matching function binaries, we propose a novel dynamic analysis.

3 Approach

We propose *blanket execution* as a novel dynamic analysis primitive for semantic similarity analysis of binary code. Blanket execution of a function f dynamically executes the function repeatedly and ensures that each

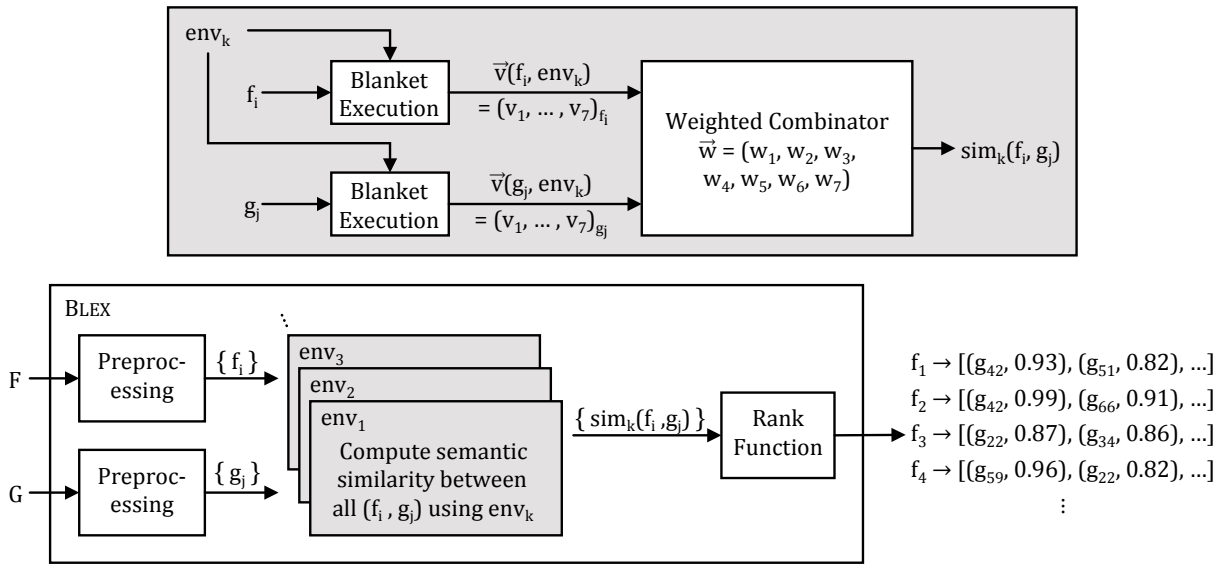

Figure 3: System overview. The upper diagram shows how blanket execution is used to compute the semantic similarity between two given functions f and g inside a given environment env_k. The lower diagram shows how the above computation is used in our BLEX system to, given two program binaries F and G, compute for each function $f_i \in F$ a list of (function, similarity) pairs where each function is a function in G and the list is sorted in non-increasing similarity.

instruction in f is executed at least once. To achieve full coverage, blanket execution starts successive runnings at so-far uncovered instructions. During these repeated runnings, blanket execution monitors and records a variety of dynamic runtime information (i.e., features). Similarity of two functions analyzed by blanket execution is then assessed by the similarity of the corresponding observed features.

More precisely, blanket execution takes a function f and an environment *env* and outputs a vector of dynamic features $\vec{v}(f, env)$ whose coordinates are the feature values captured during the blanket execution. We define the concept of "dynamic feature" broadly to include any information that can be derived from observations made during execution. As an example, we define a feature that corresponds to the set of values read from the heap during a blanket execution.

The novelty of our blanket execution approach lies in (i) *how* the function f is executed for the purpose of feature collection and (ii) *what* features are collected so that they are useful for semantic similarity comparisons. We will first look at (i) while assuming an abstract set of N features in (ii). The latter will be fully specified and explained in §4. For convenience, we will denote each coordinate of a vector $\vec{v}$ as v_i.

3.1 Environment

A key concept in blanket execution is the notion of the *environment* in which a blanket execution occurs. Blanket execution is a dynamic program analysis primitive. This means that in order to analyze a target, blanket execution runs the target and monitors its execution.

To concretely run binary code, we need to provide concrete values of the set of registers and memory locations being read. In blanket execution, we provide concrete initial values to *all* registers and *all* memory locations regardless of whether they are read or not. For unmapped memory regions, an environment also specifies a randomized but fixed *dummy* memory-page. Together, this set of values is known as "an environment." The most important property of an environment is that it must be *efficiently reproducible* since we need to be able to efficiently use a specific environment for multiple runs. This is particularly crucial due to our need to compare feature vectors collected from different functions.

3.2 Blanket Execution

Definition. Given a function f and an environment *env*, the blanket execution of f in *env* is the repeated runnings of f starting from the first un-executed instruction of f until every instruction in f has been executed at least once. Each one of these repeated runnings is called a *blanket execution run* of f, or "be-run" for short. Since we will be using a fixed environment to perform be-runs on a large number of functions, we also define a *blanket execution campaign* ("be-campaign") to be a set of be-runs using the same environment.

Notice that the description of blanket execution encompasses a notion of regaining control. There are several possible outcomes after we start to run f. For example,

f may terminate, f may trigger a system exception, or f may go into an infinite loop. We explain how to handle these possibilities in §4.2.

input : Function binary f, Environment *env*
output : Feature vector $\vec{v}(f, env)$ of f in *env*
$\mathbb{I} \leftarrow getInstructions(f)$
$fvec \leftarrow emptyVector()$
while $\mathbb{I} \neq \emptyset$ **do**
  $addr \leftarrow minAddr(\mathbb{I})$
  $(covered, v) \leftarrow be\text{-}run(f, addr, env)$
  $\mathbb{I} \leftarrow \mathbb{I} \setminus covered$
  $fvec \leftarrow pointwiseUnion(fvec, v)$
end
return $fvec$

Algorithm 1: Blanket Execution.

Algorithm. Algorithm 1 outlines the process of blanket execution for a given function f and an execution environment *env*. First, the function f is dissected into the set of its constituent instructions ($\mathbb{I}$). The system executes the function in the environment *env* at the instruction with the lowest address in $\mathbb{I}$, recording the targeted observations. Executed instructions are removed from $\mathbb{I}$ and the process repeats until all instructions of the function have been executed (i.e., $|\mathbb{I}| = 0$). All recorded feature values, such as memory accesses and system call invocations, are aggregated into a feature vector (*fvec*) associated with the function. Each element in the resulting feature vector is the union of all observed effects for the respective feature.

Rationale. A common weakness of dynamic analysis solutions is potentially low coverage of the program under test. Intuitively, this is because a dynamic analysis must provide an input to drive the execution of the program but by definition a fixed input can exercise only a fixed portion of the program. Although multiple inputs can be used in an attempt to boost coverage, it remains an open research problem to generate inputs to boost coverage effectively. Blanket execution side-steps this challenge and attains full coverage by sacrificing the natural meaning of "executing a function," namely executing from the start of it.

3.3 Assessing Semantic Similarity

The output of a blanket execution on a function f in an environment *env* is a length-N feature vector $\vec{v}(f, env)$. In this section we define how to compute $sim_k(f, g)$, the semantic similarity of two functions f and g given two feature vectors $\vec{v}(f, env)$ and $\vec{v}(g, env)$ that were extracted using blanket execution under the same environment env_k.

Definition. All our features are *sets* of values and we use the Jaccard index to measure the similarity between sets. We define $sim_k(f, g)$ to be a normalized weighted sum of the Jaccard indices on each of the N features in env_k. Mathematically, given N weights $w_1, \ldots, w_N$, we define

$$sim_k(f,g) = \sum_{i=1}^{N} \left(w_i \times \frac{|v_i(f, env_k) \cap v_i(g, env_k)|}{|v_i(f, env_k) \cup v_i(g, env_k)|} \right) / \sum_{\ell=1}^{N} w_\ell.$$

The numerator computes the weighted sum of the Jaccard indices and the denominator computes the normalization constant. The normalization ensures that $sim_k(f, g)$ ranges from 0 to 1, capturing the intuition that it is a similarity measure.

Similarity, Not Equivalence! As explained in §1, our work draws inspiration from the randomized testing algorithm for the polynomial identity testing problem. Strictly speaking, if two functions behave differently in just one environment, we can declare that they are inequivalent. However, in order to make such a judgment, we must have a precise and accurate method to capture the execution behavior of a function. While this is straightforward for arithmetic circuits, it is unsolved for binary code in general. Furthermore, in many applications such as malware analysis, analysts may intend to identify *both* identical and similar functions. This is why we assess the notion of semantic similarity for binary code instead of semantic equivalence.

Weights. Different features may carry different degrees of importance. To allow for this flexibility, we use a weighted sum of the Jaccard indexes. We explain our method to compute the weights (w_ℓ) in §5.1.2.

3.4 Binary Diffing with Blanket Execution

Given the ability to compute the semantic similarity of two functions in a fixed environment, we can perform binary diffing using blanket execution. Figure 3 illustrates the workflow of our system, BLEX.

Preprocessing. Given two binaries F and G, we first preprocess them into their respective sets of constituent functions. We denote these sets as $\{f_i\}$ and $\{g_j\}$ respectively.

Similarity Computation with Multiple Environments. Just as in polynomial identity testing, we will compute the similarity of every pair of (f_i, g_j) in multiple randomized environments $\{env_k\}$. Recall from §3.3 that $sim_k(f_i, g_j)$ is the computed semantic similarity of f_i and g_j in env_k.

Ranking by Averaged Similarity. For each (f_i, g_j), we compute their similarity by averaging over the environments. Let K be the number of environments used. Mathematically, we define

$$sim(f_i, g_j) = \frac{1}{K} \sum_k sim_k(f_i, g_j).$$

Finally, for each function f_i in the given binary F, we output a list of (function, similarity) pairs where each function is an identified function in G and the list is sorted in non-increasing similarity. This completes the process illustrated in Figure 3.

4 Implementation

We implemented the approach proposed in §3 in a system called BLEX. BLEX was implemented and evaluated on Debian GNU/Linux 7.4 (Wheezy) in its amd64 flavor. Because BLEX uses the Pin dynamic instrumentation framework [17] (see §4.2), it is easily portable to other platforms supported by Pin (e.g., Windows or 32-bit Linux).

4.1 Inputs to Blanket Execution

BLEX operates on two inputs. The first input is a program binary F, and the second input is an execution environment under which blanket execution is performed. In a first pre-processing step, BLEX dissects F into individual functions f_i. Subsequently, BLEX applies blanket execution to the f_i as explained in §3. Furthermore, Algorithm 1 uses a static analysis primitive `getInstructions`, which dissects a given function into its constituent instructions.

Reliably identifying function boundaries in binary code is an open research challenge and a comprehensive solution to the function boundary identification problem is outside the scope of this work. However, heuristic approaches, such as Rosenblum et al. [22] or the techniques implemented in IDA Pro [11] deliver reasonable accuracy when identifying function boundaries. IDA Pro supports both primitives used by blanket execution (i.e., function boundary identification and instruction extraction). BLEX thus defers these tasks to the IDA Pro disassembler.

4.2 Performing a BE-Run

A blanket execution run starts execution of a function at a given address *i* under an environment *env*. However, given a program binary, one cannot just instruct the operating system to start execution at said address. Upon program startup, the operating system and loader are responsible for mapping the executable image into memory and transferring control to the program entry point defined in the file header. We leverage this insight to correctly load the application into memory. Once the loader transfers control to the program entry point, we divert control to the address from which to perform the blanket execution run (address *i*). Letting the loader perform its intended operation means that the executable will be loaded with its valid expected memory layout. Note that valid here only means that all sections of the binary are correctly mapped to memory.

Applications frequently make use of functions imported from shared libraries. On Linux the runtime linker implements lazy evaluation of entries in the procedure linkage table (plt). That is, function addresses are only resolved the first time the function is called. However, the side effects produced by the dynamic linker are not characteristic of function behavior. Instead, these side effects create unnecessary noise during blanket execution. To prevent such noise, BLEX sets the `LD_BIND_NOW` environment variable to instruct ld.so (on Linux) to resolve all plt entries at program startup.

Once the be-run starts, BLEX records the side effects produced by the code under analysis. To this end, BLEX leverages the Pin dynamic instrumentation framework to monitor memory accesses and other dynamic execution characteristics, such as system calls and return values (see §4.3). Program code that executes in a random environment is expected to reference unmapped memory. Such invalid memory accesses commonly cause a segmentation fault. To prevent this common failure scenario, BLEX intercepts accesses to unmapped memory. Instead of terminating the analysis, BLEX replaces the referenced (unmapped) memory page with the contents of a dummy memory page specified in the environment. This allows execution to continue without terminating the analysis.

When Does a Run Terminate? A be-run is an interprocedural dynamic analysis of binary code. However, such a dynamic analysis is not guaranteed to always terminate within a reasonable amount of time. In particular, executing under a randomized environment can easily cause a situation where the program gets stuck in an infinite loop. To avoid such situations and guarantee forward progress, BLEX continuously evaluates the following criteria to determine if a be-run is completed.

1. Execution reaches the end of the function in which the be-run started.
2. An exception is raised or a terminal signal is received.
3. A configurable number of instructions have been executed.
4. A configurable timeout has expired.

BLEX detects that a function finished execution by keeping a counter that corresponds to the depth of the call stack. Upon program startup the counter is initialized to zero. Each `call` instruction increments the counter and each `ret` instruction decrements the counter by one. As soon as the counter drops below zero, the be-run is said to be completed.

To catch exceptions and signals, BLEX registers a signal handler and recognizes the end of a be-run if a signal is received. If the code under analysis registered a signal handler for the received signal itself, BLEX does not terminate the be-run but passes the signal on to the appropriate signal handler.

4.3 Instrumentation

Blanket execution monitors the side effects of program execution. A wealth of systems such as debuggers, emulators, and virtual machines have been used in the past to implement dynamic analyses. We chose to implement BLEX on Intel's Pin dynamic instrumentation framework because the tool is mature, well documented, and proven in practice.

At its core, Pin employs a just-in-time (JIT) compiler to recompile basic blocks of binary application code at runtime. Instead of running the original application code, Pin recompiles a block of code, inserting the instrumentation functionality specified by the developer. Then the recompiled code is executed. Upon completion of the code block, Pin regains control and repeats the same process for the next block of application code. The analysis functionality is specified by the developer in a so-called pintool. A pintool is a collection of instrumentation and analysis routines written in C++.

BLEX uses a pintool to instrument individual instructions and record their effects during a be-run. In our implementation we chose features that capture a variety of system level information (e.g., memory accesses), as well as higher level attributes, such as function and system calls. While the current list of features can easily be extended, the following features proved useful for establishing function binary similarity:

1. Values read from the program heap (v_1)
2. Values written to the program heap (v_2)
3. Values read from the program stack (v_3)
4. Values written to the program stack (v_4)
5. Calls to imported library functions via the plt (v_5)
6. System calls made during execution (v_6)
7. Return values stored in the `%rax` register upon completion of the analyzed function (v_7)

Each be-run results in seven sets of observations – one set for each feature. Once all instructions for a function f have been covered, BLEX combines all information pertaining to f in seven sets. That is, given a function f, all observations of v_1 are combined into a single set of values for that function (i.e., f_{v_1}). The same process is repeated for the remaining categories to produce $f_{v_2} \dots f_{v_7}$. The result after blanket execution of a program is the list of functions f_i and the seven sets of observed side effects for each f_i.

Categories $v_1 \dots v_4$ and v_7 record the numeric values used in the respective operations (e.g., values read from memory). Category v_5 records the names of the invoked functions, and v_6 records the system calls invoked. Note that the technique of blanket execution neither defines nor restricts extracted features. BLEX can easily be extended with additional features that help characterize functions. §5 shows that the seven categories of features currently extracted by BLEX are well suited to capture the semantic information of functions.

BLEX relies on the observation that many execution side effects are characteristic of function semantics and thus persist between different compilers and optimizations. While compilers certainly cannot optimize system calls without sacrificing correctness, memory accesses are commonly subject to optimizations. For example, an optimized register allocation scheme can prevent the need for aggressively spilling registers onto the stack. This means that some features are more robust and thus more indicative of function semantics than others. To address these varying degrees of influence, BLEX attributes each feature category with a weight factor ($w_1 \dots w_7$). BLEX leverages support vector machines to establish optimal values for these weights (§5.1.2). We will now discuss how BLEX monitors program execution for side effects.

Memory Accesses. The first four categories of side effects ($v_1 \dots v_4$) are derived from memory accesses. BLEX conforms to a standard memory model where reading a previously written memory cell returns the most recent value written to that cell. While this model is intuitive it only applies to valid (i.e., mapped) memory. In the case that a program tries to access unmapped memory, the operating system will raise an invalid memory reference exception. If a function makes use of global variables, or expects a pointer to mapped memory as one of its formal arguments, normal program execution will initialize such memory properly before the function is called. However, because blanket execution is oblivious to such semantic dependencies, it is common that functions access unmapped memory during blanket execution.

To prevent program termination due to unmapped memory accesses, BLEX simulates that all memory references are valid. To this end, whenever the program tries to access unmapped memory, BLEX interrupts program execution and maps a dummy page in that location. This page is then populated with the data from the dummy page specified in the execution environment.

Pin makes it easy for the developer to emulate data transfers from memory to a register. Thus, a naïve but ineffective approach to simulate that all memory is mapped would be to instrument all instructions that transfer data from memory to a register. For example, the instruction

```
mov (%rsi),%rdx
```

will copy the value pointed to by`%rsi` into register `%rdx`. Unfortunately, Pin's capabilities of intercepting memory accesses are restricted to explicit data transfers such as the above. Instructions with input and output operands that are memory cells cannot be instrumented in the same way. For example, the instruction

```
addl $0x1, $0x20(%rax)
```

will add the constant value one to the value that is stored at offset 0x20 from the memory address in `%rax`. Because Pin's instrumentation capabilities are not fine-grained enough to modify the values retrieved during operand resolution, the straight-forward approach to emulate memory accesses is not generally applicable.

Of course, BLEX needs to collect observations from all instructions that access memory and not just those that explicitly transfer values from memory to the register file or vice versa. Thus, BLEX implements the following mechanisms depending on whether an instruction reads, writes, or reads and writes memory.

Read Accesses. The Pin API allows us to selectively instrument instructions that read from memory. Furthermore, Pin calculates the effective address that is used for each memory accessing instruction. Thus, before an instruction reads from memory, BLEX will verify that the effective address that will be accessed by the instruction belongs to a mapped memory page. If no page is mapped at that address, BLEX will map a valid dummy memory page at the corresponding address[3] and the memory access will succeed.

Recall that a blanket execution environment consists of register values and a memory page worth of data that is kept consistent across all blanket execution runs for a given campaign. By seeding dummy pages with the contents specified in the environment, functions that access unmapped memory will read a consistent value. The rationale is that binary code calculates memory addresses either from arguments or global symbols. Similar functions are expected to perform the same arithmetic operations on these values to derive the memory address to access. Consider, for example, the binary implementations illustrated in Figure 1. Both implementations of `strcmp_name` expect and dereference two pointers to `fileinfo` structures (passed in `%rsi` and `%rdi`). During blanket execution these arguments contain random but consistent values as determined by the execution environment. Dereferencing these random values will likely result in a memory access to unmapped memory. By mapping the dummy page at the unmapped memory region, BLEX ensures that both implementations retrieve the same random value from the dummy page.

With this mechanism in place, BLEX can monitor all read accesses to memory by first making sure that the target memory page is mapped, and then read the original value stored at the effective address in memory.

Write Accesses. Similar to read accesses Pin provides mechanisms to instrument instructions that write to memory. However, the Pin API is not expressive enough to record the values that are written to memory. Thus, to record values that are written to memory, BLEX reads the value from memory after the instruction executed. Similar to the read access technique mentioned above, BLEX will make sure that memory writes succeed by mapping a dummy page at the target address if that address resides in unmapped memory.

Memory Exceptions. BLEX only creates dummy pages for memory accesses to otherwise unmapped memory ranges. If the program tries to access mapped memory in a way that is incompatible with the memory's page protection settings BLEX does not intervene and the operating system raises a segmentation fault. This would occur, for example, if an instruction tries to write to the read-only `.text` section of the program image.

System Calls. Besides memory accesses BLEX also considers the invocation of system calls as side effects of program execution. Pin provides the necessary functionality to intercept and record system calls before they are invoked.

Library Calls. System calls are a well defined interface between kernel space and user space. Thus, they present a natural vantage point to monitor execution for side effects. However, many functions (39% in our experiments) do not result in system calls and thus, relying solely on system calls to identify similar functions is insufficient. Therefore, BLEX also monitors what library functions an application invokes. To support dynamic linking, ELF files contain a `.plt` (procedure linkage table) section. The .plt section contains information (i.e., one entry per function) about shared functions that might be called by the application at runtime. While stripped binaries are devoid of symbol names, they still contain the names of library function names in the plt entries. BLEX records the names of all functions that are invoked via the plt.

While there is no alternative for a program to making system calls, it is not mandatory that shared library functions are invoked through the plt. For example, a developer can chose to statically link a library into her application or interface with the dynamic linker and loader directly by means of the `dlopen` and `dlsym` APIs. Thus, functions from a statically linked version of a program and those from a dynamically linked version thereof will differ in the side effects observed for category library function calls (i.e., v_5).

4.4 Calculating Function Similarity

BLEX combines all of the above methods into a single pintool of 1,036 lines of C++ code. During execution, the pintool collects all necessary information pertaining to the seven observed features. Each be-run results in a feature vector consisting of seven sets that capture the observed side effects. Once all be-runs for a single function finish, BLEX combines the recorded feature vectors and

[3] More precisely, the dummy page is mapped at the target address rounded down to a page-aligned starting address.

associates this information with the function. Because the individual dimensions in the vectors are sets, BLEX uses the set-union operation to combine the individual feature vectors, one dimension at a time. As discussed in §3.3, BLEX assesses the similarity of two functions f and g by calculating the weighted sum of the Jaccard indices of the seven dimensions in the respective feature vectors. We use the Jaccard index as a measure of similarity, because even semantically equivalent functions can result in slight differences in the observed feature values. For example, the unoptimized version in Figure 1 will write and read the passed arguments to the stack, whereas the optimized version does not contain such code. This different behavior results in slightly different values of the corresponding coordinates in the feature vectors.

5 Evaluation

BLEX is an implementation of the blanket execution approach to perform function similarity testing on binary programs. We evaluate BLEX to answer the following questions:

- Can BLEX recognize the similarity between semantically similar, yet syntactically different implementations of the same function? (§5.3)
- Can BLEX match functions compiled from the same source code but with different compiler toolchains and/or configurations? (§5.4)
- Is BLEX an improvement over the industry standard tool, BinDiff? (§5.4)
- Can BLEX be used as the basis for high-level applications? (§5.5)

We begin our evaluation with an experiment on syntactically different implementations of the `libc` function `ffs`, followed by an evaluation of the effectiveness of BLEX over BinDiff across a large set of programs with different compilers and compiler configurations, finishing with a prototype search engine for binary programs built on BLEX. Before presenting our results, we discuss the dataset, ground truth, and feature weights used in the evaluation.

5.1 Dataset

For this evaluation we compiled a dataset based on the popular coreutils-8.13 suite of programs. This version of the coreutils suite consists of 103 utilities. However, to prevent damage to our analysis environment, we excluded potentially destructive utilities such as `rm` or `dd` from the dataset, reducing the number of utilities from 103 to 95. We used three different compilers (gcc 4.7.2, icc 14.0.0, and clang 3.0-6.2) with four different optimization settings (`-O0`, `-O1`, `-O2`, and `-O3`) each to create 12 versions of the coreutils suite for the x86-64 architecture. In total our dataset consists of 1,140 unique binary applications, comprising 195,560 functions.

Feature	Accuracy
Read from heap (v_1)	40%
Write to heap (v_2)	57%
Read from stack (v_3)	58%
Write to heap (v_4)	53%
Library function invocation (v_5)	17%
System calls (v_6)	39%
Function return value (v_7)	13%

Table 1: Accuracy of individual features.

5.1.1 Ground Truth

Although BLEX does not rely on or use debug symbols, we compiled all binaries with the `-g` debug flag to establish ground truth based on the symbol names. For our problem setting, we strip all binaries before processing them with BLEX or BinDiff.

Function inlining has the effect that the inlined function disappears from the target binary. Interestingly, the linker can have the opposite effect when it sometimes introduces duplicate function implementations. For example, when compiling the `du` utility, the linker will include five identical versions of the `mbuiter_multi_next` function in the application binary. While such behavior could be explained if the compiler performed code locality optimization, this also happens if all optimization is turned off (`-O0`). This observation suggests that optimization is not the reason for this code duplication. Because these duplicates are exactly identical, we have to account for this ambiguity when establishing ground truth. That is, matching any of the duplicate instances of the same function should be treated equal and correct. In our dataset 37 different programs contained duplicates (between two and six copies) of 16 different functions. Based on these observations, we establish ground truth by considering functions equivalent if they share the same function name.

5.1.2 Determining Optimal Weights

Each feature in BLEX has a weight factor associated with it, i.e., $w_\ell | \ell = 1 \ldots 7$. To assess the sensitivity of BLEX to these weights, we performed seven small-scale experiments as a sensitivity analysis of the individual features. In each experiment, we set all but one weight to zero and evaluated the accuracy of the system when matching functions between all coreutils compiled with `gcc` and the `-O2` and `-O3` optimization settings. Table 1 illustrates how well the individual features BLEX collects can be used to assess similarity between functions.

To establish the optimal values for these weights, we leveraged the Weka[4] (version 3.6.9) machine learning toolkit. Weka provides an implementation of the sequen-

[4] http://www.cs.waikato.ac.nz/ml/weka/

tial minimal optimization algorithm [20] to train a support vector machine based on a labeled training dataset. To train a support vector machine, the training dataset must consist of feature values for positive and negative examples. We created the dataset based on our ground truth by first selecting 9,000 functions at random from our pool of functions. For each function f in a binary F we calculated the Jaccard index with its correct match g in binary G, constituting a positively labeled sample. For each positively labeled sample, we created a negatively labeled sample by calculating the Jaccard index with the feature vector of a random function $g' \in G$ such that $g' \neq g$. The support vector machine determined the weights as $w_2 = 2.4979$, $w_6 = 0.8775$, $w_4 = 0.4052$, $w_1 = 0.3846$, $w_3 = 0.3786$, $w_7 = 0.3222$, and $w_5 = 0.1082$. Using these weights in BLEX to evaluate the dataset from the above-mentioned sensitivity analysis improved accuracy to 75%.

5.2 Experimental Setup

We evaluated BLEX on a commodity desktop system equipped with an Intel Core i7-3770 CPU (4 physical cores @ 3.4GHz) running Debian Wheezy. For this evaluation we set the maximum number of instructions t_i to 10,000 instructions and the timeout for a single be-run to three seconds. We performed blanket execution for all 195,560 functions in our dataset under eleven different environments. On average, 1,590,773 be-runs were required to cover all instructions in the dataset for a total of 17,498,507 be-runs. A single be-run took on average 0.28 seconds, an order of magnitude below the timeout threshold we selected. Only 9,756 be-runs were terminated because of this timeout. 604,491 be-runs (3.5%) were terminated because the number of instructions exceeded the chosen threshold of 10,000 instructions. While performing blanket execution on all 1,140 unique binaries in our dataset required approximately 57 CPU days, performing blanket execution on two versions of the `ls` utility can be achieved in 30 CPU minutes. Because the repeated runnings in blanket execution are independent of each other, blanket execution resembles an embarrassingly parallel workload and scales almost linear with the number of available CPU cores.

5.3 Comparing Semantically Equivalent Implementations

BLEX tracks the observable behavior of function executions to identify semantic similarity independent of the source code implementation. To test our design, we acquired two different implementations of the `ffs` function from the `Newlib` and `uclibc` libraries as used in the evaluation of the system built by Ramos et al. [21] to measure function equivalence in C source code. We compiled both sources with `gcc -O2`. The resulting binaries differed significantly: the control flow graph in the `uclibc` implementation consisted of eleven basic blocks and the `Newlib` implementation consisted of just four basic blocks. We ran BLEX on both function binaries in 13 different random environments. After comparing the resulting feature vectors, BLEX reported perfect similarity between the compiled functions. This result illustrates how BLEX and blanket execution can identify function similarity despite completely different source implementations.

5.4 Function Similarity across Compiler Configurations

The ideal function similarity testing system can identify semantically similar functions regardless of the compiler, optimizations, and even obfuscation techniques employed. The task is nontrivial as different compiler options can result in drastically different executables (see Figure 1). A rough measure of these differences is the number of enabled compiler optimizations. Consider, for example, the number of optimizations enabled by the four common optimization levels in `gcc`. The switch `-O0` turns off all optimization, and `-O1` enables a total of 31 different optimization strategies. Additionally, `-O2` enables another 26 settings, and `-O3` finally adds another nine optimizations. We would expect that binaries compiled from the same source with `-O2` and `-O3` optimizations are closest in similarity. Thus, similarity testing should yield better results for such similar implementations then for binaries compiled with `-O0` and `-O3` optimizations.

We leverage our dataset to compare the accuracy of BLEX and BinDiff in identifying similar functions of the same program, built with different compilers and different compilation options.

Comparison with BinDiff. BinDiff is a proprietary software product that maps similar functions in two executables to each other. To this end, BinDiff assigns a signature to each function. Function signatures initially consist of the number of basic blocks, the number of control flow edges between basic blocks, and the number of calls to other functions. BinDiff immediately matches function signatures that are identical and unique. For the remaining functions, BinDiff applies secondary algorithms, including more expensive graph analyses. One such secondary algorithm matches function names from debug symbols. However, our experiments do not leverage debugging symbols as our efforts are focused on the performance on stripped binaries. The data presented in this evaluation was obtained with BinDiff version 4.0.1 and the default configuration.

As Figure 4 illustrates, BinDiff is very proficient in matching functions among the same utility compiled with the very similar `-O2` and `-O3` settings. Although BLEX also performs reasonably well, BinDiff outperforms BLEX on almost all utilities in this comparison.

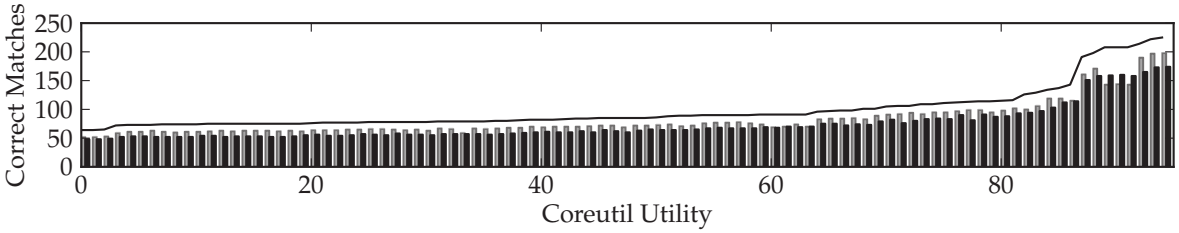

Figure 4: Correctly matched functions for binaries in `coreutils` compiled with `gcc -O2` and `gcc -O3`. BinDiff (grey), BLEX (black), total number of functions in utility (solid line).

The solid line in the figure marks the total number of functions in each utility.

Once the differences between two binaries become more pronounced, BLEX shows considerably improved performance over BinDiff. Figure 5 compares BLEX and BinDiff in identifying similar functions in binaries compiled with the `-O0` and `-O3` optimization settings. This combination of compiler options is expected to produce the least similar binaries and thus should establish a lower bound of the performance one can expect from BLEX and BinDiff respectively. This evaluation shows that BLEX consistently outperforms BinDiff, on average by a factor of two. Furthermore, BLEX matches over three times as many functions correctly for the `du`, `dir`, `vdir`, `ls`, and `chcon` utilities.

Finally, we assess the performance of BLEX and BinDiff on programs built with different compilers. Figure 6 shows the accuracy for binaries compiled with `gcc -O0` and Intel's `icc -O3`. Again, due to the substantial differences in the produced binaries, BLEX consistently outperforms BinDiff in the cross-compiler setting.

Discriminatory power of the similarity score. We also evaluated how well the similarity score tells correct from incorrect matches apart. Similarity scores are normalized to the interval [0,1] with 1 indicating perfect similarity and 0 absolute dissimilarity. In Figure 8, we illustrate the expected similarity value over 10,000 pairs of random functions. On average this expected similarity is 0.12. However, when analyzing the similarity scores of correct matches from the experiment used for Figure 4 (i.e., `gcc -O2` vs. `gcc -O3`), the average similarity score is 0.85. This indicates that the seven features BLEX uses to assess function similarity are indeed suitable to perform this task.

Effects of Multiple Environments. As discussed in §3.4, we proposed to perform blanket execution with multiple environments ($\{env_k\}$). To assess the effects of performing blanket execution under multiple environments, we evaluated how the percentage of correct matches varies as k (the number of environment) increases. Our result is shown in Figure 7. The figure shows that a mild increase (from 50% to 55%) in accuracy up until three environments are used. Interestingly, using more than three environments does *not* significantly improve the accuracy of BLEX. This is in stark contrast to the PIT theory. However, as discussed previously, real-world function binaries are not polynomials and BLEX cannot precisely identify all input and output dependencies of a function. Thus, it may not be surprising that a larger number of random environments does not significantly improve the accuracy of the system. We plan to evaluate alternate strategies for crafting execution environments in a "smart" way in the future.

5.5 BLEX as a Search Engine

Matching function binaries is an important primitive for many higher-level applications. To explore the potential of BLEX as a system building-block, we built a prototype search engine for function binaries. Given a search query (a function f) and a corpus of program binaries, we can use BLEX to find the program most likely to contain an implementation of f. Phrased differently, an analyst presented with an unknown function can search for similar functions encountered in the past. The analyst can then easily apply the knowledge gathered during the previous analysis of similar functions, reducing the time and effort spent on redundant analysis. Similarly, if a match is found in a program for which the analyst has access to debug symbols, the analyst can leverage this valuable information to speed up the analysis of the target function.

To evaluate this application, we chose 1,000 functions at random from the applications compiled with `gcc -O0`. These functions serve as the search queries. We compiled the corpus from programs in coreutils built with `gcc -O1`,`-O2`, and `-O3` respectively (29,015 functions in total). Our prototype search engine ranked the correct match as the first result in 64% of all queries. 77% of the queries were ranked under the first 10 results (e.g., the first page of search results) and 87% were ranked under the first 10 pages of results (i.e., top 100 ranks). Figure 9 depicts this information as the left-hand side of the CDF.

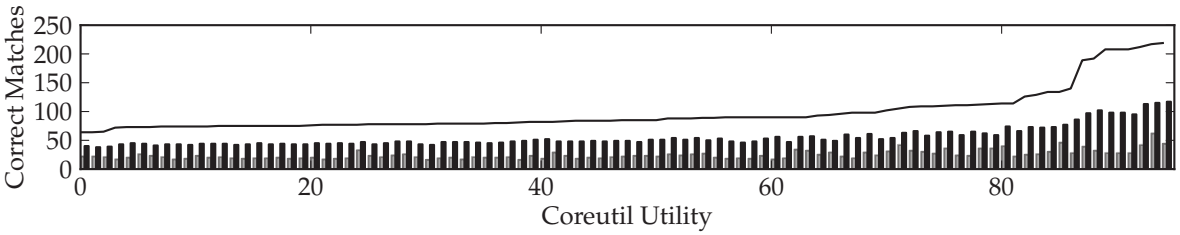

Figure 5: Correctly matched functions for binaries in `coreutils` compiled with `gcc -O0` and `gcc -O3`. BinDiff (grey), BLEX (black), total number of functions in utility (solid line).

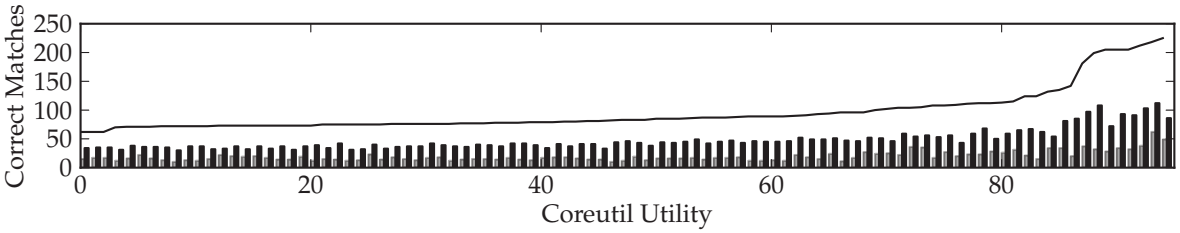

Figure 6: Correctly matched functions for binaries in `coreutils` compiled with `gcc -O0` and `icc -O3`. BinDiff (grey), BLEX (black), total number of functions in utility (solid line).

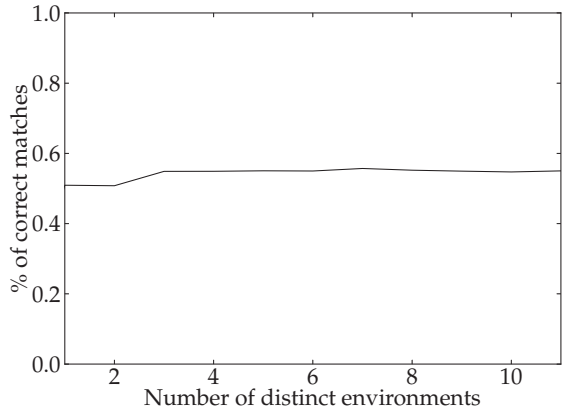

Figure 7: Matching accuracy depending on the number of used environments.

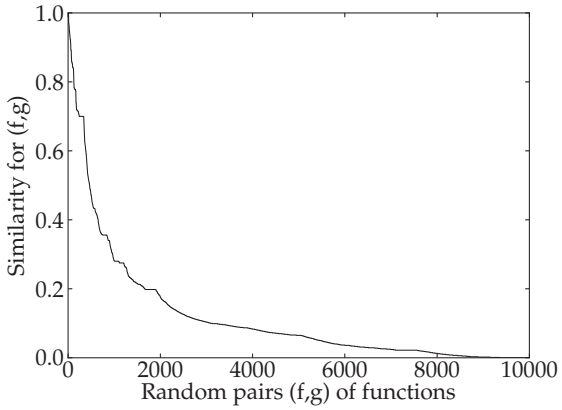

Figure 8: Distribution of similarity scores among 10,000 random pairs of functions. All compiled with `gcc -O2`.

The remaining 13% form a long tail distribution with the worst match at rank 23,261.

The usability of a search engine also depends on its query performance. Our unoptimized implementation answers search queries to the indexed corpus of size 29,015 in under one second on average.

6 Related Work

The problem of testing whether two pieces of syntactically-different code are semantically identical has received much attention by previous researchers. Notably, Jiang and Su [14] recognized the close resemblance of this problem to polynomial identity testing and applied the idea of random testing to automatically mine semantically-equivalent code fragments from a large source codebase. Whereas their definition of semantic equivalence includes only the input-output values of a code fragment and does not consider the intermediate values, we include intermediate values in our features as a pragmatic way to cope with the difficult problem of identifying input-output variables in binary code. Interested readers can see [5, 16] for some of the recent works on that problem.

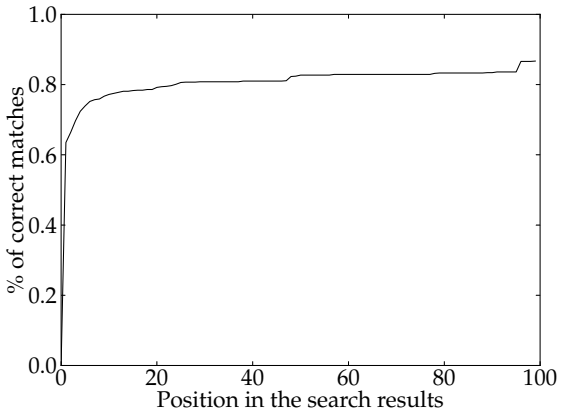

Figure 9: Left-most section of the CDF of ranks for correct matches in 1,000 random search queries.

Intermediate values can also be extremely valuable for other applications. For example, Zhang et al. [26] have investigated how to detect software plagiarism using the dynamic technique of value sequences. This uses the concept of core values proposed by Jhi et al. [13]. The idea is that certain specific intermediate values are unavoidable during the execution of any implementation of an algorithm and are thus good candidates for fingerprinting.

Intermediate values are also used by Zhang and Gupta [27] as a first step in matching the instructions in the dynamic histories of program executions of two program versions. After identifying potential matches as such, Zhang and Gupta refined the match by matching the data dependence structure of the matched instructions. They reported high accuracy in their evaluation using histories from unoptimized and optimized binaries compiled from the same source. This work was used by Nagarajan et al. [18] as the second step of their dynamic control flow matching system. The system by Nagarajan et al. also match functions between unoptimized and optimized binaries. Their technique is based on matching the structure of two dynamic call graphs.

We choose to evaluate BLEX against BinDiff [8, 9] due to its wide availability and also its reputation of being the industry standard for binary diffing. At a high-level, BinDiff starts by recovering the control flow graphs (CFGs) of the two binaries and then attempts to use a heuristic to normalize and match the vertices from the two graphs. Although in essence BinDiff is solving a variant of the graph isomorphism problem of which no efficient polynomial time algorithm is known, the authors of BinDiff have devised a clever neighborhood-growing algorithm that performs extremely well in both correctness and speed if the two binaries are similar. However, as we have explained in the paper, changing the compiler optimization level alone is sufficient to introduce changes that are large enough to confound the BinDiff algorithm.

A noteworthy successor to BinDiff is the BinHunt system introduced in [10]. This paper makes two important contributions. First, it formalized the underlying problem of binary diffing as the Maximum Common Induced Subgraph Isomorphism problem. This allowed the authors to formally and accurately state their backtracking algorithm. Second, instead of relying on heuristics to match vertices and tolerating potential false matches, BinHunt deployed rigorous symbolic execution and theorem proving techniques to *prove* that two basic blocks are in fact equivalent. Unfortunately, BinHunt has only been evaluated in three case studies, all of which support only differences due to patching vulnerabilities. In particular, it has not been evaluated whether BinHunt will perform well on binaries that are compiled with different compiler toolchains or different optimization levels.

A recent addition to this line of work is the BinSlayer system [3]. The authors of BinSlayer correctly observed that graph-isomorphism based algorithms may not perform well when the change between two binaries are large. To alleviate this problem, the authors modeled the binary diffing problem as a bipartite graph matching problem. At a high level, this means assigning a distance between two basic blocks and then pick an assignment (a matching) that maps each basic block from one function to a basic block in another function that *minimizes* the total distance. Among other experiments, the authors evaluated their algorithms by diffing GNU coreutils 6.10 vs. 8.19 (large gap) and also 8.15 vs. 8.19 (small gap). Just as the authors suspected, they observed that graph-isomorphism based algorithms are less accurate in the large-gap experiment than in the small-gap experiment.

Besides binary diffing, our work can also be seen in the light of a binary search engine. Two recent work in the area are Exposé [19] and Rendezvous [15]. Both of these systems are based on static analysis techniques; in contrast, our system is based on dynamic analysis. None of these systems has been evaluated with a dataset that varies both compiler toolchain and optimization level simultaneously.

Finally, semantic similarity can also be used for clustering. For example, Bayer et al. [2] have used ANUBIS for clustering malware based on their recorded behavior. However, this relies on attaining high coverage so that malicious functionality is exposed [25]. We believe that BLEX may also be used for malware clustering.

7 Conclusion

Existing binary diffing systems such as BinDiff approach the challenge of function binary matching from a purely static perspective. It has not been thoroughly evaluated on binaries produced with different compiler toolchains

or optimization levels. Our experiments indicate that its performance drops significantly if different compiler toolchains or aggressive optimization levels are involved.

In this work, we approach the problem of matching function binaries with a dynamic similarity testing system based on the novel technique of blanket execution. BLEX, our implementation of this technique proved to be more resilient against changes in the compiler toolchain and optimization levels than BinDiff.

Abstract

This paper analyzes the actual cost of attacking TLS implementations that use NIST's Dual EC pseudorandom number generator, assuming that the attacker generated the constants used in Dual EC. It has been known for several years that an attacker generating these constants and seeing a long enough stretch of Dual EC output bits can predict all future outputs; but TLS does not naturally provide a long enough stretch of output bits, and the cost of an attack turns out to depend heavily on choices made in implementing the RNG and on choices made in implementing other parts of TLS.

Specifically, this paper investigates OpenSSL-FIPS, Windows' SChannel, and the C/C++ and Java versions of the RSA BSAFE library. This paper shows that Dual EC exploitability is fragile, and in particular is stopped by an outright bug in the certified Dual EC implementation in OpenSSL. On the other hand, this paper also shows that Dual EC exploitability benefits from a modification made to the Dual EC standard in 2007; from several attack optimizations introduced here; and from various proposed TLS extensions, one of which is implemented in BSAFE, though disabled in the version we obtained and studied. The paper's attacks are implemented; benchmarked; tested against libraries modified to use new Dual EC constants; and verified to successfully recover TLS plaintext.

1 Introduction

On September 5, 2013, the New York Times [23], the Guardian [3] and ProPublica [16] reported the existence of a secret National Security Agency SIGINT Enabling Project with the mission to "actively [engage] the US and foreign IT industries to covertly influence and/or overtly leverage their commercial products' designs." The revealed source documents describe a US $250 million/year program designed to "make [systems] exploitable through SIGINT collection" by inserting vulnerabilities, collecting target network data, and influencing policies, standards and specifications for commercial public key technologies. Named targets include protocols for "TLS/SSL, https (e.g. webmail), SSH, encrypted chat, VPNs and encrypted VOIP."

The documents also make specific reference to a set of pseudorandom number generator (PRNG) algorithms adopted as part of the National Institute of Standards and Technology (NIST) Special Publication 800-90 [21] in 2006, and also standardized as part of ISO 18031 [15]. These standards include an algorithm called the Dual Elliptic Curve Deterministic Random Bit Generator (Dual EC). As a result of these revelations, NIST reopened the public comment period for SP 800-90.

Known weaknesses in Dual EC. Long before 2013, Dual EC had been identified by the security community as biased [8, 27], extremely slow, and backdoorable.

SP 800-90 had already noted that "elliptic curve arithmetic" makes Dual EC generate "pseudorandom bits more slowly than the other DRBG mechanisms in this Recommendation" [21, p. 177] but had claimed that the Dual EC design "allows for certain performance-enhancing possibilities." In fact, Dual EC with all known optimizations is two orders of magnitude slower than the other PRNGs, because it uses scalar multiplications on an elliptic curve where the other PRNGs use a hash function or cipher call.

The back door is a less obvious issue, first brought to public attention by Shumow and Ferguson [28] in 2007. What Shumow and Ferguson showed was that an attacker specifying Dual EC, and inspecting some Dual EC output bits from an unknown seed, had the power to predict all subsequent output bits.

Specifically, the description of Dual EC standardizes three parameter sets, each specifying an elliptic curve E over a finite field $\mathbf{F}_p$, together with points P and Q on E. The back door is knowledge of $d = \log_Q P$, the discrete logarithm of P to the base Q; an attacker creating P and Q can be assumed to know d. Shumow and Ferguson showed that knowledge of d, together with about $\log_2 p$ consecutive output bits,[1] makes it feasible to predict all subsequent Dual EC output.

Shumow and Ferguson suggested as countermeasures to vary P and Q and to reduce the number of output bits per iteration of the PRNG. However, SP 800-90 requires a particular number of bits per iteration, and states that the standard P and Q "shall be used in applications re-

[*] Date of this document: 2014.06.06.

[1] 256 bits were sufficient in all their P-256 experiments.

Table 1: Summary of our results for Dual EC using NIST P-256.

Library	Default PRNG	Cache Output	Ext. Random	Bytes per Session	Adin Entropy	Attack Complexity	Time (minutes)
BSAFE-C v1.1	✓	✓	✓†	31–60	—	$30 \cdot 2^{15}(C_v + C_f)$	0.04
BSAFE-Java v1.1	✓		✓†	28	—	$2^{31}(C_v + 5C_f)$	63.96
SChannel I‡				28	—	$2^{31}(C_v + 4C_f)$	62.97
SChannel II‡				30	—	$2^{33}(C_v + C_f) + 2^{17}(5C_f)$	182.64
OpenSSL-fixed I*				32	20	$2^{15}(C_v + 3C_f) + 2^{20}(2C_f)$	0.02
OpenSSL-fixed III**				32	$35 + k$	$2^{15}(C_v + 3C_f) + 2^{35+k}(2C_f)$	$2^k \cdot 83.32$

* Assuming process ID and counter known. ** Assuming 15 bits of entropy in process ID, maximum counter of 2^k. See Section 4.3.
† With a library–compile-time flag. ‡ Versions tested: Windows 7 64-bit Service Pack 1 and Windows Server 2010 R2.

The entries in the table are for normal TLS connections. In particular, we exclude all forms of session resumption. A ✓ in the Default PRNG column indicates whether Dual EC is the default PRNG used by the library. A ✓ in the Cache Output column indicates that the unused Dual EC output is cached for use in a subsequent call. A ✓ in the Ext. Random column indicates that the proposed TLS extension Extended Random [25] is supported in some configuration. Reported attack times do not rely on use of Extended Random. Bytes per Session indicates how many contiguous, useful output bytes from Dual EC a TLS server's handshake message reveals. For SChannel II this is an average value of useful bits, see Section 4.2. Adin Entropy indicates how many bits of unknown input are added to each Dual EC generate call. The Attack Complexity is the computational cost in terms of the cost of a scalar multiplication with a variable base point, C_v, and a fixed base point, C_f, in the worst case. With our optimizations (see Section 5), C_f is roughly 20 times faster than C_v; the exact speedup depends on context. The Time column gives our measured worst-case time for the attack on a four-node, quad-socket AMD Opteron 6276 cluster; the time for OpenSSL-fixed III is measured using $k = 0$.

quiring certification under FIPS 140-2"; this stops use of alternative points in certified implementations.

Risk assessment for this back door depends on the probability that the creator of P and Q is an attacker. Shumow and Ferguson wrote "WHAT WE ARE NOT SAYING: NIST intentionally put a back door in this PRNG"; but the September 2013 news indicates that NSA may have deliberately engineered Dual EC with a back door. Our concern in this paper is not with this probability assessment, but rather with impact assessment, especially for the use of Dual EC in TLS.

Use of Dual EC in products. Despite the known weaknesses in Dual EC, several vendors have implemented Dual EC in their products [22]. For example, OpenSSL-FIPS v2 and Microsoft's SChannel include Dual EC, and RSA's crypto libraries use Dual EC by default. RSA Executive Chairman Art Coviello, responding to news that NSA had paid RSA to use Dual EC [18], stated during the opening speech of RSA Conference 2014: "Given that RSA's market for encryption tools was increasingly limited to the US Federal government and organizations selling applications to the federal government, use of this algorithm as a default in many of our toolkits allowed us to meet government certification requirements" [5].

Practical attacks on TLS using Dual EC. This paper studies to which extent *deployed* cryptographic systems that use Dual EC are vulnerable to the back door, assuming that an attacker knows $d = \log_Q P$. Specifically, we perform a case study of Dual EC use in TLS, arguably the most important potential target for attacks. The basic attack described by Shumow and Ferguson [28] (and independently, quietly, by Brown and Vanstone in a patent application [4]) turns out to be highly oversimplified: it does not consider critical limitations and variations in the amount of PRNG output actually exposed in TLS, additional inputs to the PRNG, PRNG reseeding, alignment of PRNG outputs, and outright bugs in Dual EC implementations.

We present not just a theoretical evaluation of TLS vulnerability but an in-depth analysis of Dual EC in four recent implementations of TLS: RSA BSAFE Share for C/C++ (henceforth BSAFE-C), RSA BSAFE Share for Java (henceforth BSAFE-Java), Windows SChannel, and OpenSSL. The Network Security Services (NSS) libraries, e.g., used by Mozilla Firefox, and the TLS implementation of BlackBerry do not offer a Dual EC implementation and thus are not discussed here.

To experimentally verify the actual performance of our attacks, we replace the NIST-specified constants with ones we generate; for BSAFE and Windows this required extensive reverse-engineering of binaries to find not just P and Q but many implementation-specific constants and runtime test vectors derived from P and Q (see Section 4.4). Our major findings are as follows:

- The BSAFE implementations of TLS make the Dual EC back door particularly easy to exploit in two ways. The Java version of BSAFE includes fingerprints in connections, making them easy to identify. The C version of BSAFE allows a drastic speedup in the attack by broadcasting longer contiguous strings of random bits than one would at first imagine to be possible given the TLS standards.

- Windows SChannel does not implement the current Dual EC standard: it omits an important computation. We show that this does not prevent attacks; in fact, it allows slightly faster attacks.
- We discovered in OpenSSL a previously unknown bug that prevented the library from running when Dual EC is enabled. It is still conceivable that someone is using Dual EC in OpenSSL, since the bug has an obvious and very easy fix, so we applied this fix and evaluated the resulting version of OpenSSL, which we call OpenSSL-fixed. OpenSSL-fixed turns out to use additional inputs in a way that under some circumstances makes attacks significantly more expensive than for the other libraries.

When a TLS server uses DSA or ECDSA to sign its DH/ECDH public key, a single known nonce reveals the long-lived signing key which enables future active attacks. Our attacks reveal the inner state of Dual EC which generates the nonces and we have successfully recovered the long-term signing keys.

We also perform a brief measurement study of the IPv4 address space to assess the prevalence of these libraries on the Internet.

We summarize our results in Table 1. The BSAFE-C attack is practically instantaneous, even on an old laptop. The BSAFE-Java and SChannel attacks require more processing power to recover missing bits of Dual EC output. The OpenSSL-fixed attack cost depends fundamentally on how much information on the additional input is available. All of these attacks are practical for a motivated attacker, even when the attacks are repeated against a large number of targets.

2 Dual EC attack theory

Review of Dual EC. We focus on Dual EC using the NIST P-256 elliptic curve. For the curve equation and the standardized base points P and Q see [21, Appendix A.1]. The state of Dual EC is a 32-byte string s, which the user initializes as a secret random seed. The user then calls Dual EC any number of times; each call implicitly reads and writes the state, optionally reads *additional input* from the user, and produces any number of random bytes requested by the user.

Internally, each call works as follows. Additional input, if provided, is hashed and xored into the state. The state is then updated as follows: compute sP and then overwrite s with the x-coordinate $x(sP)$. A 30-byte block of output is then generated as follows: compute sQ, take the x-coordinate $x(sQ)$, and discard the most significant 2 bytes. The resulting 30 bytes are used as output. If more random bytes were requested, the state is updated again and another 30-byte block of output is generated; this repeats until enough blocks have been generated. Any excess bytes in the final block are discarded. The state is updated one final time in preparation for the next call, and the generator returns the requested number of bytes.

Review of the basic attack. The attack from Shumow and Ferguson works as follows. The attacker is assumed to control the initial standardization of P. The attacker takes advantage of this by generating a random secret integer d and generating P as dQ. Alternatively, if the attacker controls the initial standardization of Q rather than P, the attacker generates Q as $(1/d)P$. Either way $P = dQ$, with d secretly known to the attacker.

The idea of the attack is to reconstruct sQ from an output block (see the next paragraph) and then multiply by d, obtaining dsQ, i.e., sP. The x-coordinate $x(sP)$ is the user's next PRNG state. The attacker then computes all subsequent outputs the same way that the user does.

Recall that an output block reveals 30 out of the 32 bytes of the x-coordinate of sQ. The attacker tries all possibilities for the 2 missing bytes, obtaining 2^{16} possibilities for the x-coordinate, and then for each x-coordinate uses the curve equation to reconstruct at most 2 possibilities for the y-coordinate, for a total of at most 2^{17} possibilities for sQ. About half of the x-coordinates will not have any corresponding y-coordinate, and the other half will produce two points (x,y) and $(x,-y)$ that behave identically for the attack, because $x(s(x,y)) = x(s(x,-y))$, so the attacker keeps only one of those points and ends up with about 2^{15} possibilities for sQ. For each of these possibilities, the attacker computes the corresponding possibility for $dsQ = sP$ and for the next Dual EC output. The attacker pinpoints the correct guess by checking the next actual Dual EC output.

Attacks with additional input. Shumow and Ferguson did not analyze the case where a user provides additional input to a Dual EC call. We point out that the analysis of this case depends heavily on whether one considers Dual EC in the June 2006 version of SP 800-90, which we call Dual EC 2006, or Dual EC in the March 2007 version of SP 800-90, which we call Dual EC 2007.

Additional input is only used once at the beginning of a call and therefore does not stop the attacker from using the first 30 bytes of output from a call to predict subsequent output bytes from the same call. The remaining question is whether the attacker can predict the first 30 bytes from a call given the last 30 bytes from the previous call. This issue would be relatively minor if applications were generating many kilobytes of Dual EC output from each call; but the applications we have studied normally generate only one or two blocks from each call, so the predictability of the first 30-byte block is an important question.

If the additional input has enough entropy unknown to the attacker then the answer is no: the first 30 bytes are unpredictable. However, in the applications that we have studied, additional input is either nonexistent or potentially guessable. This is where Dual EC 2006 and Dual EC 2007 produce different answers.

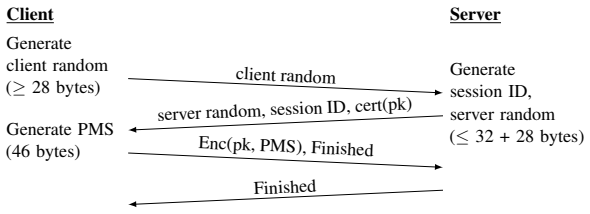
What we have described so far is Dual EC 2007. The previous call returned up to 30 bytes of sQ and produced $s' = x(sP)$ as the new state. Assume that the attacker has reconstructed sQ. This call updates s' to $s'' = x((s' \oplus \mathrm{H}(\mathsf{adin}))P)$, where H is a hash function, and then returns up to 30 bytes of $x(s''Q)$. Given sQ the attacker computes $dsQ = sP$, computes s', and then for each possible adin computes s'' and $s''Q$.

The 2006 version of Dual EC differs slightly from the 2007 version: Dual EC 2006 is missing the final step which updates the seed s at the end of each call. The previous call returned most of sQ but left s untouched. If there were no additional input, then this call would update s to $s' = x(sP)$ and return most of $x(s'Q)$. Given sQ, the attacker computes $sP = dsQ$, s', and $s'Q$. However, with additional input, the state s is updated to $s' = x((s \oplus \mathrm{H}(\mathsf{adin}))P)$ and then most of $x(s'Q)$ is returned. Given sQ, the attacker can compute $sP = dsQ$ and $x(sP)$ as before but there is no obvious way to obtain $(s \oplus \mathrm{H}(\mathsf{adin}))P$ from sP, even when adin is known.

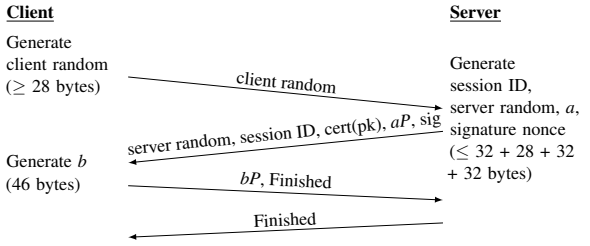
The addition of the final update step in Dual EC 2007 has the effect of making the basic attack possible when (1) the attacker has enough bytes from two consecutive calls; (2) the first call produces at most 30 bytes; and (3) additional input is used and guessable. In this case, the Dual EC 2007 state can be recovered while this is not possible for Dual EC 2006 due to the lack of an additional state update between the first and second call. In other cases, the extra state update means that attacking Dual EC 2007 is slightly slower than attacking Dual EC 2006.

Open questions. This theoretical analysis of Dual EC exploitability leaves open several obvious questions regarding the practical exploitability of Dual EC by network attackers who know the secret d. Do implementations of cryptographic protocols such as TLS actually expose enough Dual EC output to carry out the basic attack? How expensive are the computations required to compensate for missing output, and can these computations be made less expensive? Is additional input actually used, and if so is it hard to guess? Are certified implementations of Dual EC in fact implementing Dual EC 2006, Dual EC 2007, or something different?

The answers turn out to include several surprises, and in particular to rely on several implementation details and protocol details that have not been previously observed to be related to Dual EC. For example, the certified OpenSSL-FIPS implementation of Dual EC is actually non-functional, as mentioned earlier. As another example, although none of the attacks we implemented are in the case described above where exploitability relies on the difference between Dual EC 2006 and Dual EC 2007, the OpenSSL-fixed attacks are very close to this case: they avoid it solely because at one point OpenSSL-fixed calls Dual EC for 32 bytes made public through the TLS session ID, and 32 is larger than 30.



(a) TLS with RSA key transport.



(b) TLS with ECDHE exchange and ECDSA signature (P-256).

Figure 1: Simplified view of TLS handshakes.

Our analysis strongly suggests that, from an attacker's perspective, backdooring a PRNG should be combined not merely with influencing implementations to use the PRNG but also with influencing other details that secretly improve the exploitability of the PRNG. This paper does not attempt to determine whether this is what happened with Dual EC, and does not explore the difficult topic of defending against such attacks, beyond the obvious advice of not using Dual EC.

3 Attack target: TLS

TLS is the most widely used protocol for securing Internet communications [6]. TLS consists of several subprotocols, including a *record* protocol and *handshake* protocol. The handshake protocol is most relevant to the attacks discussed in this paper, so for simplicity we will describe only the relevant aspects of the handshake sub-protocol used in TLS version 1.2; further details are available in the RFC [6].

The handshake sub-protocol produces a fresh set of session keys with which application-layer data is encrypted and authenticated using the record protocol. Figure 1 de-

picts (simplified versions of) the two main handshakes for TLS: RSA key transport and ephemeral Diffie-Hellman key exchange (DHE). Ephemeral DHE uses either elliptic curve groups (ECDHE) or another suitable group. In either handshake, the client initiates a connection by sending a ClientHello message that includes a client nonce and a list of supported cipher suites. The server replies with a server nonce, a session ID, a certificate, an ephemeral DHE public key (for DHE), and a signature over the random nonces and public key. Signatures are either RSA or DSA. The specification mandates 32-byte client and server nonces, each consisting of 28 random bytes and a 4-byte timestamp. The construction of a session ID is arbitrary (i.e., up to the server implementation), though as we will see many implementations use the same PRNG that generates the ServerHello nonce and other cryptographic secrets. The client's next flow includes a client ephemeral DH public key (for DHE) or an RSA PKCS #1.5 encryption of a premaster secret (for RSA key transport). The premaster secret consists of either a 2-byte version number followed by a 46 byte random value (for RSA key transport), or the DHE secret defined by the DH public keys. Session keys are derived from the premaster secret and other values sent in the clear during the handshake, so learning the premaster secret is sufficient to break all subsequent encryption for a given session.

TLS extensions. There are many extensions to TLS, but we draw attention to four particular proposed — but not standardized — extensions. Each of these extensions has the side effect of removing the most obvious difficulty in exploiting Dual EC in TLS, namely the limited amount of randomness broadcast to the attacker. One might guess that these extensions make P-256 less expensive to exploit in TLS by a factor of 65,536 (and make P-384 and P-521 feasible to exploit), if they are actually implemented; our analysis in Section 4.1 shows that one of these extensions is in fact implemented in BSAFE, although the actual effect on exploitability is more complicated. None of these extensions have been previously described in connection with Dual EC.

One proposed extension, authored by Rescorla and Salter [25] in 2008, supports "Extended Random" client and server nonces. This extension is negotiable using the normal ClientHello extension mechanism, and includes up to $2^{16}-1$ bytes of data from a suitable PRNG. The server replies with its own Extended Random data that must be of the same length as the client's Extended Random data. The document states that this extension was requested by the United States Department of Defense with the claim that nonces "should be at least twice as long as the security level" (e.g., 256-bit nonces for 128-bit security).

Another proposed extension, "Opaque PRF" proposed by the same authors [24] in 2006, is nearly identical to Extended Random but does not require the data to be random. A third proposed extension, "Additional Random" by Hoffman [12] in 2010, is essentially the same as "Extended Random." After the initial announcement of our paper, Bodo Möller pointed out yet another similar extension, "Additional PRF Inputs" by Hoffman and Solinas [14] in 2009.

The "Internet-Drafts" describing these four extensions all expired without producing RFCs, although a generic framework [13] for such extensions was published as an Experimental RFC by Hoffman in 2012. IETF has not standardized any of these extensions.

Attack goals. We assume that the adversary's goal is to decrypt TLS packets to learn confidential material, or to steal long-lived secret keys. In the second case the secret keys need not be generated with Dual EC. We consider both small-scale *targeted* attacks and larger-scale *dragnet surveillance* attacks across broad swaths of the Internet.

Attack resources. Most of the attacks that we analyze are purely passive, relying solely on interception of TLS traffic sent through the network by the client and by the server. Usually seeing only one direction of TLS traffic is enough, and the attack can be mounted long after the fact using recorded connections. Occasionally an active attack is more powerful: for example, the range of μsecs in Section 4.3 becomes narrower if the attacker uses carefully timed connections (as in [29]) to more precisely pin down the server's clock.

The attacker is assumed to know the Dual EC back door d with $P = dQ$. All of the attacks rely on the client or server using Dual EC, but this is not an assumption; rather, it is something that we evaluate, by reverse-engineering several TLS implementations and also experimentally assessing the deployment of those implementations.

Our measurements of attack cost assume that the attacker knows the TLS software in use; otherwise the attacker has to try several of the attacks, increasing cost somewhat. See Section 6 for fingerprinting mechanisms.

The computer power required for attacking *one* Dual EC instance is very small by cryptanalytic standards: our optimized attacks (see Section 5) typically consume between $0.00001 and $1 of electricity, depending on the TLS implementation being attacked. (The exception to "typical" is OpenSSL; see Sections 4.3 and 5.2.) However, presumably the attacker's actual goal is to repeat the attack *many* times, especially in the dragnet-surveillance scenario. Our measurements allow straightforward extrapolations of the computer resources required for large-scale attacks.

4 Exploiting Dual EC in implementations

To attack each of the implementations discussed below, the attacker follows three basic steps: (1) recover Dual EC state from the session ID and/or server random fields in the TLS handshake; (2) compute the DHE or ECDHE shared secret which enables computing the 48-byte "master secret" from which all session keys are derived; and optionally (3) recover the long-lived DSA or ECDSA signing key used to sign the server's DHE or ECDHE public key.

Step (1) is an application of the basic attack which combines information exchanged in the handshake protocol messages to determine the correct Dual EC state from candidate states. Step (2) requires generating the DHE or ECDHE secret key by following the exact generation process used by the TLS implementation. Like Step (2), Step (3) duplicates the implementation's process for generating the nonce used in the signature of the public key. From the nonce, the signature, and the public key, it is straightforward to recover the signing key.

It is important to note that when a server uses DSA or ECDSA signatures, a *single* broken connection by a passive adversary is sufficient to recover the long-lived signing key which is used to authenticate the server's (EC)DHE public key. In contrast to RSA long-lived keys, recovering a server's (EC)DSA signing key does not enable future passive eavesdropping; it does allow impersonation of the server under active attack.

4.1 RSA BSAFE

Description. RSA's BSAFE family includes four libraries: Share for Java, Share for C and C++, Micro Edition Suite, and Crypto-J/SSL-J. We examined Share for Java and Share for C and C++. Although the two versions share a somewhat similar API, the implementation details differ, leading to different attacks.

The BSAFE family of libraries contains a number of options which can be configured at runtime. In order to avoid a combinatorial explosion in the number of configurations to test and attack, we focus our attention on the default configurations and the most secure cipher suites that lead to the use of the P-256 curve in Dual EC and, where applicable, ECDHE and ECDSA.[2]

Both BSAFE libraries we examined support both prediction resistance whereby the generator is reseeded on each call and output caching so that unused bytes from one call to generate can be used in subsequent calls rather than discarded. By default, neither option is enabled.

BSAFE-C. We examined the RSA BSAFE Share for C and C++ library (BSAFE-C) version 1.1 for Microsoft Windows. The library actually consists of two libraries: sharecrypto.lib implements the core cryptographic primitives, including Dual EC, and sharesslpki.lib implements TLS. Unlike the Micro Edition Suite, BSAFE-C is distributed only as static libraries with associated header files. This necessitated a minor reverse engineering effort to discover how BSAFE-C uses Dual EC in its TLS implementation.

Unlike the other TLS implementations we examined, BSAFE-C v. 1.1 does not support TLS 1.2. As a result, it does not support elliptic curve cryptography for either key exchange or digital signatures. By default, the preferred cipher suites are `TLS_DHE_DSS_WITH_AES_128_CBC_SHA` and `TLS_DHE_RSA_WITH_AES_128_CBC_SHA` so we focused our efforts on these two.

A TLS server implemented using BSAFE-C generates several pseudorandom values used during the TLS handshake to establish session keys. In order, it generates (1) a 32-byte session identifier, (2) 28 bytes for the server random, (3) a 20-byte ephemeral Diffie–Hellman (DH) secret key, and, when using DSA, (4) a 20-byte nonce. The DH parameters and the server's public key are signed with the server's RSA or DSA certificate and the session ID, server random, public key, and signature are sent in the server's first flight of messages to the client during the handshake.

Although BSAFE-C's Dual EC interface does not cache unused output bytes by default, a separate, internal interface to produce pseudorandom values wraps Dual EC and provides its own layer of caching by only requesting multiples of 30 bytes from the Dual EC interface. This internal interface is used by all of the higher-level functionality, such as generating a DH secret key and a DSA nonce. Due to a quirk of the implementation, if a request to generate n bytes of output cannot be satisfied completely from the cached bytes, $\lfloor (n+29)/30 \rfloor \cdot 30$ bytes are generated in a single call to Dual EC, even if most of the n bytes will be taken from the cached bytes.

Caching output bytes means that when a new TLS session is started, an attacker who has not seen all prior connections has no way of knowing if the first value generated by the server — the session id — begins with a full output block or if it contains bytes cached from a previous call to Dual EC. However, due to the use of the requested number of bytes rather than the number of remaining bytes after pulling from the cache, the concatenation of the 32-byte session ID and the 28 pseudorandom bytes in the server random always contains a full 30-byte output block and between one and 30 bytes of a subsequent block where both blocks are generated in the call to Dual EC for 60 bytes made while generating the session ID.

A passive network attacker can easily recover the session keys and the server's long-lived DSA secret key used to sign the ephemeral DH parameters and public key. The attacker uses the publicly exchanged values in the

[2] Share for Java additionally supports P-384 and P-521 for Dual EC, ECDHE, and ECDSA.

connection through the ClientKeyExchange handshake message. At this point, the attacker knows the session ID, the client and server randoms, the DH parameters and client and server public keys, and the signature. This contains everything needed for the attack. The session keys are computed from the public values and the DH shared secret.

To recover the inner state of Dual EC a long string of consecutive output bytes is required. First, the session ID and the pseudorandom 28 bytes of the server random are concatenated into a 60-byte value B. Since up to 29 bytes of B can come from a previous call to Dual EC, one of $B[0..29], B[1..30], \ldots, B[29..58]$ must be a full output block. The basic attack is run on each in turn until the Dual EC state for the next output block is recovered. The attacker knows that the correct state has been found by (1) generating the next output block and comparing the corresponding bytes with the remaining bytes in B and then (2) generating more bytes as needed to produce a DH secret key and comparing the corresponding public key to the server's public key. If the public keys agree, then the DH shared secret can be computed hence the session keys can be computed.

Once the session keys for a single session have been recovered, more bytes can be generated to produce the DSA nonce. The DSA secret key a can be computed from the nonce k, public key (p,q,g,y), and the signature (R,S) of the message m as $a = R^{-1} \cdot \big(S \cdot k - H(m)\big) \bmod q$.

Recovering the Dual EC internal state requires performing approximately $30 \cdot 2^{15}$ scalar multiplications with a variable base point and an equal number with the fixed point Q, in the worst case. The total attack has a cost of $30 \cdot 2^{15}(C_v + C_f)$ where C_v (resp. C_f) is the cost of performing a single scalar multiplication with a variable (resp. fixed) base point. To generate the DH key, between $3C_f$ and $5C_f$ are needed to produce enough Dual EC output bytes; $1C_f$ is needed to compute server's DH public key; and, finally $1C_v$ is needed to compute the shared DH secret (using the client's DH input). Finally, to generate the nonce, at most one more Dual EC output is needed, using $3C_f$.

BSAFE-Java. We examined the RSA BSAFE Share for Java library version 1.1 (BSAFE-Java) and focused on connections using the `TLS_ECDHE_ECDSA_WITH_AES_128_GCM_SHA256` cipher suite.

Unlike BSAFE-C, the output from Dual EC is not cached so each generated output value is aligned with a block of generator output. Unfortunately (for the attacker), the session ID value produced by the server is not a 32-byte pseudorandom value. Instead, the attacker is forced to rely on the server random.

The values generated by Dual EC are, in order, (1) 28 bytes for server random; (2) 32 bytes for an ECDHE secret key; and (3) 32 bytes for an ECDSA nonce.

As before, a passive network attacker waits until she sees the ClientKeyExchange handshake message. At this point she has all of the information she needs to mount the following, simple attack. The 28 bytes from the server random are treated as bytes 2 through 29 of the 32-byte x-coordinate. She then mounts the basic attack by guessing the remaining most significant 16-bits and least significant 16-bits of the x-coordinate. A guess is checked by generating a 32-byte ECDH secret key, computing the corresponding public key, and comparing to the server's public key.

Once a match is found, the inner state of Dual EC is known. The session keys can be derived from the ECDH shared secret and the other values sent in the clear. Similarly, the ECDSA nonce can be found by generating another 32-byte value. As with the non-elliptic-curve DSA, the server's private key can be recovered from the nonce and the signature.

In the worst case, recovering the generator state requires approximately 2^{31} scalar multiplications with a variable base point and five times that number with a fixed base point to generate candidate ECDH secret keys and corresponding public keys. In total, the attack takes $2^{31}(C_v + 5C_f)$ work.

BSAFE connection watermarks and Extended Random. The documentation for BSAFE-C and BSAFE-Java indicate that they support connection watermarking and the TLS Extended Random extension described in Section 3.

In our experiments, BSAFE-Java has watermarks enabled by default. The watermark works by setting the first 20 bytes of the session ID to be the first 20 bytes of the server random and the last 12 bytes are set to the string "`RSA␣SSLJ␣␣␣␣`." This watermark can only be disabled by setting the property `com.rsa.ssl.server.watermark=disabled` in the Java security properties file [26].

We performed an Internet-wide scan of port 443 and found very few servers on this default port that exhibited this 32-byte watermark: only 386 of 8 million servers contacted. Details on this scan are included in section 6.

From reverse engineering the BSAFE-Java shareCrypto.jar library, we determined that it contained code to support or require the proposed TLS Extended Random extension; however, this code was disabled by means of a single static final boolean variable. We surmise that this code is not "dead" in the traditional sense, but rather the value of the variable can be changed to produce versions of the library with different features.

By changing the value of this variable, we were able to verify that the Extended Random extension is supported by the server.[3] When enabled and an Extended Random

[3] An analogous variable enables support for the client.

extension is received from the client, the server generates an equal length Extended Random response consisting of bytes generated by Dual EC concatenated with the same 12-byte watermark. The client Extended Random is 32-bytes by default. Interestingly, the 28 bytes for the server random and the Dual EC generated bytes for the Extended Random are generated together in a single call to Dual EC. As a consequence, any BSAFE-Java server which supports Extended Random exposes a sufficient quantity of contiguous output bytes to enable quick recovery of the session keys. There does not appear to be a mechanism for disabling the watermark in the Extended Random extension.

The BSAFE-C library documentation indicates that both watermarking and Extended Random are supported in some versions of the library; however, the version we have appears to have been compiled without this support.[4]

For both the Java and C versions of BSAFE, we have no evidence that versions of the libraries supporting Extended Random ever shipped. On the other hand, an earlier survey [1] found that Extended Random was occasionally requested by clients (about once in every 77000 connections). Our implemented attacks do not rely on Extended Random in any way.

4.2 Windows SChannel

SChannel ("Secure Channel") is a security component in the Windows operating system (introduced in Windows 2000) that provides authentication and confidentiality for socket-based communications. Although it supports several protocols, it is most commonly used for SSL/TLS, including by Microsoft's Internet Information Services (IIS) server and Internet Explorer (IE). We focus on ECDHE/ECDSA handshakes that use P-256 (which in turn cause Dual EC to also use this curve), as used by the version of IIS distributed with Windows 7 64-bit Service Pack 1 and Windows Server 2010 R2. All information about the internal workings of SChannel and its implementation of Dual EC discussed in the following was obtained via reverse-engineering.

Description. SChannel uses Microsoft's FIPS 140-2 validated Cryptography Next Generation (CNG) API, which includes an implementation of Dual EC. CNG is implemented in two modules, one for user-mode callers (bcryptprimitives.dll) and one for kernel mode (cng.sys). Dual EC is used to generate pseudorandom bytes when the `BCryptGenRandom` function is explicitly directed to use it via a function argument or when it is selected as the system-wide default. When using Dual EC, `BCryptGenRandom` generates enough fresh blocks to satisfy the request, and discards any remaining bytes (i.e., there is no caching between requests).

Whenever SChannel requests random bytes, it calls `BCryptGenRandom` using the system-wide default. Our reverse-engineering efforts and experiments indicate that additional input is not provided by SChannel for TLS connections. TLS handshakes are performed by a separate process (lsass.exe) on behalf of IIS, which dispatches one of several worker threads to handle each request. Dual EC in CNG maintains separate state for each thread, so a successful attack on the state of one thread will not carry over to the others. Importantly, SChannel caches ephemeral keys for two hours (this timeout is hard-coded in the configurations we examined), and the cached keys are shared among all worker threads until the timeout expires.

When performing an ECDHE handshake, SChannel requests random bytes in a different order than OpenSSL and BSAFE (the number of bytes given in the following are specific to P-256 and some of them differ for other curves): (1) 32 bytes for session ID, (2) 40 bytes for ephemeral private key, (3) 32 bytes (not relevant to the attack), (4) 28 bytes for ServerHello nonce, and (5) 32 bytes for the signature (if using ECDSA). Notice the 40-byte request for the private key, even though a P-256 private key is only 32 bytes; this is because SChannel uses FIPS 186-3 B.4.1 (Key Pair Generation Using Extra Random Bits) to generate ECDHE key pairs, which specifies 8 additional bytes to reduce bias from a modulo operation. More importantly, SChannel requests bytes for the private key *before* the ServerHello random field. This means that any attempt to infer the private key must use the session ID, or random fields from previous handshakes.

Deviation from SP-800-90A. The implementation of Dual EC in CNG differs from the current SP-800-90A specification in one noteworthy way. The code in bcryptprimitives.dll that implements Dual EC (a function called `MSCryptDualEcGen`) seems to include the final update step at the end of each call — performing a point multiplication and projection on the x-coordinate after generating the necessary blocks. However, our reverse engineering efforts, as well as our experiments, indicate that the result is not copied into the seed state, and thus not used in subsequent calls to Dual EC. In short, although the CNG Dual EC implementation appears to contain code that implements the full current specification, it effectively implements Dual EC 2006 by ignoring the result of the final update step in future calls to generate. This appears to be a bug.

Fingerprint in the session ID. When an SChannel server generates a new session ID, it requests 32 bytes, $S[0,\ldots,31]$ from `BCryptGenRandom`, and interprets the first four bytes $S[0,\ldots,3]$ as an unsigned integer v. It then

[4] The header files for the version of BSAFE-C we have show that the library was compiled with the command line flags `-DNO_TLS_EXT_RAND -DNO_RSA_WATERMARK`.

computes $v' = v \bmod \texttt{CACHE\_LEN}$, and constructs the final session ID by concatenating these values, $session\_id = v'[0,\ldots,3] \| S[4,\ldots,31]$. CACHE_LEN is the maximum number of entries allowed in SChannel's session cache, which was hard-coded to 20,000 on the systems we tested. Thus, the presence of zeros in the third and fourth bytes of the session ID is a likely (although imperfect) fingerprint for SChannel implementations.

Attack 1: Using the server's random nonce. With Dual EC enabled, it is possible to use the 28-byte ServerHello nonce to learn the server's ECDHE private key, which will allow decryption of all ECDHE sessions within the two-hour window before the private key is refreshed. As previously discussed, these bytes are requested after the private key is generated, so in order to use them for the attack, we must look at previous handshake messages sent from the server. The fact that SChannel uses multiple threads to perform handshakes complicates the attack, as we cannot know which thread was used for a particular handshake unless we have learned the state of all threads and updated them as new handshakes were performed. On observing a handshake with the new server public ephemeral key, denoted h, the attacker works backwards through previous handshakes, using the random field in each ServerHello message to generate candidate Dual EC states using the basic attack. Each candidate state is checked first against the ECDSA public key to determine the state used in that handshake, and then against the session ID in h to determine if the same state was used to generate the new ephemeral key. The 32 bytes for the ECDSA nonce are generated in two calls, first 24 bytes then 8 bytes. These values are concatenated and then byte-wise reversed to obtain the nonce.

When the matching state is found, it is straightforward to generate the ephemeral private key and subsequent session keys. SChannel uses FIPS 186-3 B.4.1 to generate the private key, which corresponds to drawing 40 bytes of random input c, and computing the key as $(c \pmod{n-1})+1$, where n is the curve order. The worst-case complexity of this attack requires approximately 2^{31} scalar multiplications with a variable base point and four times as many with a fixed base point to check the ECDSA public key, totaling $2^{31}(C_v + 4C_f)$.

Attack 2: Using the session ID. The second approach uses the session ID in a handshake containing a new ECDHE public key. Denote the 32-byte session ID in the relevant handshake by S, and v' the unsigned integer corresponding to $S[0,\ldots,4]$. Recall that SChannel modifies the first four bytes of the session ID by replacing it with its value modulo CACHE_LEN. All that one must do to recover the private ephemeral key is run the basic attack on a set of inputs generated by enumerating (1) all 4-byte sequences whose unsigned integer representation v satisfies $v' = v \bmod \texttt{CACHE\_LEN}$ (for the first four bytes of the block that generated the session ID), and (2) all 2-byte sequences for the last two bytes of the first block that generated the session ID. Candidates are checked by generating the next 40 bytes, using FIPS 186-3 B.4.1 to construct a private key, and comparing the corresponding public key against that provided in the ServerKeyExchange.

This attack sidesteps the issues created by threading in SChannel, but because of the way the the session ID is generated it is actually more complex than the previous. Recall that $\texttt{CACHE\_LEN} = 20,000$ in both configurations tested, so this attack requires approximately 2^{18} guesses to deduce the first four bytes of the original session ID block, and 2^{16} for the last two bytes, giving approximately 2^{33} candidate curve points. Of these, approximately 2^{17} will agree with the last two bytes of the session ID, and we determine which is correct by generating two additional Dual EC blocks for a P-256 ECDHE private key, then performing a point multiplication to compare with the public key sent in the same handshake. The total complexity is $2^{33}(C_v + C_f) + 2^{17}(5C_f)$.

4.3 OpenSSL

Description. OpenSSL is one of the most widely used TLS libraries, due to its inclusion in many Linux/Apache distributions. While the standard edition of OpenSSL does not contain Dual EC, OpenSSL also ships a separate package called the OpenSSL FIPS Object Module. When this module is combined with OpenSSL, it provides a TLS library containing all four DRBG algorithms defined in NIST SP800-90A, including Dual EC. The Dual EC algorithm is not the default PRNG in OpenSSL, but it can be manually enabled by changing the PRNG settings through an API call at runtime.

Bug. While investigating the OpenSSL-FIPS implementation of Dual EC, we discovered a previously unknown bug that, in fact, prevented it from being run.[5] The presence of this bug may suggest that nobody has successfully run OpenSSL-FIPS configured to use Dual EC. However, the CMVP validation lists [22] show many "private" validations of the OpenSSL-FIPS module so it is possible that some commercial manufacturer has repaired this bug without propagating the fix back to the open source OpenSSL tree. For this reason, we felt it worthwhile to repair the bug in the FIPS module in order to investigate the feasibility of the attack.

Analysis of OpenSSL-fixed. We examined a repaired version of the OpenSSL FIPS Object Module ver-

[5] The bug involves a flaw in the runtime self-test mechanism that causes OpenSSL-FIPS to shut down the generator immediately upon initializing it. This bug is not triggered while the module is in TEST mode, which explains why unit and Known Answer Tests did not discover the issue. See [17] for details.

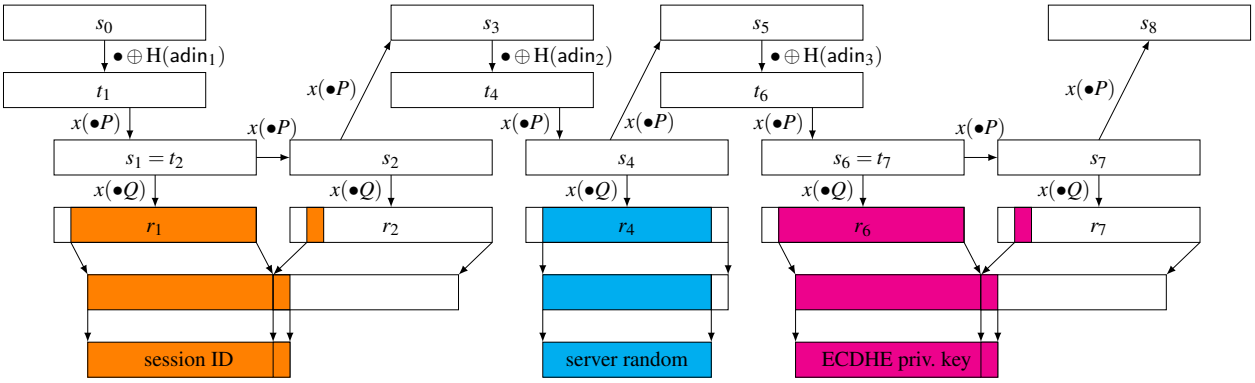


Figure 2: Dual EC usage in OpenSSL-FIPS using ECDHE with P-256.

sion 2.0.5 in combination with OpenSSL 1.0.1e (henceforth "OpenSSL-fixed"). The library consists of two components, libcrypto.a which implements the core cryptographic routines, including Dual EC, and libssl.a which implements TLS. OpenSSL documentation provides guidance on building the library, as well as usage in common scenarios.

OpenSSL-fixed supports TLS 1.2 with the full complement of elliptic curve cryptography for key exchange and digital signatures. By default, the preferred cipher suites use ECDHE key exchange and either RSA or ECDSA signatures. We investigated connections made using the ECDHE handshake.

OpenSSL includes a textbook implementation of Dual EC based on the NIST SP 800-90 March 2007 revision. On the server side of the standard ECDHE handshake, the generate function is called repeatedly to generate the following values: (1) a 32-byte session identifier, (2) a 28-byte server random,[6] (3) a 32-byte ECDHE ephemeral private key,[7] and, when ECDSA is being used, a 32-byte nonce. OpenSSL's implementation of Dual EC does not cache unused random bytes at the conclusion of a generator call, hence each sequence of random bytes begins with up to 30 bytes drawn from a single elliptic curve point. Figure 2 illustrates the generation of these values.

OpenSSL's use of additional input. While analyzing OpenSSL's implementation of SP 800-90, we discovered an important difference between OpenSSL and the other libraries analyzed in this work. Specifically, OpenSSL provides *additional input* with each call to the generate function. The additional input string is constructed uniquely by the function FIPS_get_timevec() prior to each query for random bytes. It comprises 16 bytes with the following structure.

$$\mathsf{adin} = (\text{time in secs} \parallel \text{time in } \mu\text{secs} \parallel \text{counter} \parallel \text{pid})$$

Each of the component fields in the additional input string is 4 bytes in length. On Unix-based systems the time fields are computed using gettimeofday(). The counter is a monotonically increasing global counter that is set to 0 at library initialization, and increments with each call to FIPS_get_timevec(). On operating systems where the process IDs are available, pid contains the process ID returned from getpid().

A passive attacker can capture 32 consecutive bytes of Dual EC output by observing the session ID sent to the client by an OpenSSL server. Assuming the generator is instantiated with P-256, the attacker can now execute the initial steps of the basic attack using the first 30 bytes, in order to recover multiple candidate states, and (using the additional two bytes) reduce the number of candidate states to one, or a small number. From this point, the OpenSSL attack differs from the basic attack. Given each candidate state s, the attacker now calculates the final update step $s = x(sP)$ and exhaustively guesses the additional input string used in the next call to the generate function as $s' = s \oplus \mathrm{H}(\mathsf{adin})$. This requires the attacker to iterate through a set of candidate adin input strings, executing the steps of the generate algorithm to recover a candidate ECDHE private key, and comparing this value to the intercepted ECDHE public key from a real handshake trace.

The complexity of this attack depends on two factors: the number of candidate states remaining at the conclusion of the first portion of the attack, and the number of candidate adin strings. Since we are guessing 16-bits, only about half of all strings give a valid x-coordinate, and are comparing the resultant output against 16 bits, we expect to see 1 or 2 candidate states that generate the correct first two values. We did not see more than 3 candidate states in any of our test runs, although we would

[6] Although we do not discuss attacks against the client, a recent fix to the OpenSSL client implementation increases the amount of PRNG output in the client random to 32 bytes (see `http://bit.ly/1ftSQrM`) which may decrease the attack complexity significantly.

[7] OpenSSL generates this key by drawing 32 random bytes and checking whether the result (expressed as an integer) is less than the group order n. If not, the process is repeated.

expect to occasionally see more if we repeated the attack enough times.

Since the time in seconds is already transmitted as part of the server random, the first portion of adin is known. Thus it remains to predict the time in μseconds, process ID and counter. Under reasonable assumptions about the operating system and the number of connections so far handled by the server, this can range from approximately 2^{20} (primarily guessing the μsecs field) to 2^{35} with a typical Unix range of pid values and known counter value, and possibly 2^{45} or more depending on how recently the library was initialized. Notice that once an attacker recovers the adin string for a first TLS connection, it may be relatively easy to predict these values for later connections.

The inclusion of additional input complicates the attack since recovering the Dual EC state when it is most convenient, namely during the generation of the session ID, does not immediately translate into recovering the session keys. There are two cases to consider.

In the first case, the attacker knows nothing about the state of the generator except that the counter value is no bigger than $k \leq 32$ bits. The first step is to recover the generator state (for ease of analysis, assume only one candidate state is possible). As with BSAFE-C, this requires approximately 2^{15} variable-base-point multiplications and an equal number of fixed-base-point multiplications. Next, the additional input string needs to be guessed. For each guess, this takes two fixed-base-point multiplications. There are at most 2^{35+k} additional input strings to try. A guess can be validated by comparing to the server random field. Finally, the ECDHE secret and public keys need to be computed for each guess of the second additional input string. Each guess takes five fixed-base-point multiplications; however, since the attacker has already determined the pid and the counter value, the attacker has a good estimate of the time and increments the microsecond value from there; this takes about 2^{13} guesses. This gives a total cost of $2^{15}(C_v + C_f) + 2^{35+k}(2C_f) + 2^{13}(5C_f)$. The 2^{13} is an upper bound for our observations. Usually fewer than 2^{12} tests were sufficient and on a fast Internet server even less time passes between two calls of Dual EC.

In the second case, the attacker has already broken a previous connection and so the pid and counter values are known. The cost of performing the whole attack a second time becomes $2^{15}(C_v + C_f) + 2^{20}(2C_f) + 2^{13}(5C_f)$. However, the cost of computing a scalar multiplication with a variable base point is significantly higher than for a fixed base point. It may be in the attacker's best interest to keep track of the generator's state throughout each session. This involves keeping track of counter updates and recovering the state after each encrypted TLS record sent and randomness used for ECDSA and IVs. The search space for the time in adin for these values is usually small, similar to that in the ECDHE key.

Then the cost of recovering the state at the beginning of a new connection is at most $2^{20}(2C_f)$ for testing the time (and less if better estimates of the time are known) in place of the $2^{15}(C_v + C_f)$, for a total cost of $2^{20}(2C_f) + 2^{13}(7C_f)$. This is faster if the time update for the server random call requires a smaller search space for the time after the time has been determined for the session ID.

4.4 Attack validation

We implemented each of the attacks against TLS libraries described above to validate that they work as described. Since we do not know the relationship between the NIST-specified points P and Q, we generated our own point Q' by first generating a random value $e \xleftarrow{R} \{0, 1, \ldots, n-1\}$ where n is the order of P, and set $Q' = eP$. This gives our trapdoor value $d \equiv e^{-1} \pmod{n}$ such that $dQ' = P$. We then modified each of the libraries to use our point Q' and captured network traces using the libraries. We ran our attacks against these traces to simulate a passive network attacker.

We would like to stress that anybody who knows the back door for the NIST-specified points can run the same attack on the fielded BSAFE and SChannel implementations without reverse engineering.

We describe the concrete performance results of our attacks in the next section and give details on the libraries here.

RSA BSAFE. The Dual EC implementation in BSAFE-C contains the points P and Q as well as three tables of scalar multiples of each of the points for fast multiplication. The tables contain 65, 517, and 573 multiples. After working out the corresponding scalar factor for each entry in the tables, we computed our own tables and modified the relevant object files in the library. There were no health checks or known-answer tests (KATs) to bypass.

BSAFE-Java is distributed as a signed, obfuscated jar file. We reverse engineered the code sufficiently to find and bypass the checks that prevent modification and replaced the jar's signature with our own. BSAFE-Java has a single table of 431 scalar multiples of each of P and Q.

Windows SChannel. Dual EC in SChannel is implemented both in the kernel and a user-mode library. We modified the user-mode library, which performs a KAT when the operating system first loads the module at boot, as well as continuously during operation when FIPS mode is enabled. To sidestep these checks, we disabled FIPS mode, and wrote a system service that (1) replaces Q with Q' in the the address space of the Local Security Authority Subsystem Service (IIS and IE delegate TLS handshakes to this process), and (2) makes Dual EC the system-wide default PRNG.

OpenSSL-fixed. Dual EC in OpenSSL is implemented in the separate OpenSSL-FIPS library. This library contains both runtime KATs and a check of the SHA-1 hash of the object code. Since the hash is computed each time the library is compiled, we simply fixed the bug which prevents Dual EC from being used (described above), bypassed the KATs, and substituted Q' for Q.

5 Implementation

We implemented all attacks for parallel architectures, specifically clusters of multicore CPUs. The attacks are parallelized using OpenMP and MPI, with the search space distributed over all cores of the cluster nodes, using one process per CPU and one thread per (virtual) core. The attacks are "embarrassingly parallel": there are no data dependencies between the parallel computations and thus no communication overhead and no limit on the scalability of the parallelization, other than the total number of independent computations.

5.1 Algorithmic optimizations

For finite-field arithmetic, we use the Gueron/Krasnov OpenSSL patch for NIST P-256, described in [10] and available at [11]. Square-root computations, to recover the y-coordinates, use that $p \equiv 3 \bmod 4$ and compute $\sqrt{a}$ as $a^{(p+1)/4}$. We refer to the cost of recovering a y-coordinate as C_y.

The definition of the update function in Dual EC requires all scalar multiplications to result in affine points (to derive a unique x-coordinate). To improve the performance of our implementation we compute all point operations in affine coordinates and batch the inversions using Montgomery's trick [20] across several parallel computations. We use a batch size of 256 for all experiments; increasing the batch size any further does not have a measurable effect on the runtime.

The most performance-critical operations on EC points in the attack logic are:

1. Scalar multiplications using fixed base points P and Q in order to compute the next internal state and to compute the output string respectively; P is also used as base point for ECDHE and ECDSA computations.

2. Scalar multiplications using variable base points and a fixed scalar, the back door d, in order to compute a candidate internal state given an output string.

In Table 1 we refer to the costs of a fixed-base-point scalar multiplication as C_f and those of a variable-base-point one as C_v.

For the fixed-base-point computations we use large precomputed tables of multiples of the base point. For a given width w we compute a lookup table consisting of $T_{P,i,j} = i2^{jw}P$ for $0 < i < 2^w$, $0 \le j < \lceil 256/w \rceil$. A scalar multiplication sP can then be performed as $\lceil 256/w \rceil - 1$ additions of precomputed points from the lookup table using $sP = \sum_{j=0}^{\lceil 256/w \rceil - 1} T_{P,s(j),j}$, where $s = \sum_{j=0}^{\lceil 256/w \rceil - 1} s(j)2^{jw}$. We do the same for Q in place of P. These tables are shared among all threads of each process in the implementation. We choose $w = 16$ for all our experiments for a reasonable balance between performance and lookup-table size. This brings C_f down to 15 point additions.

We implemented the scalar multiplications with the fixed scalar d using signed sliding windows with window width 5 and fully unrolled the code. This way C_v takes 253 doublings and 50 additions. Our d was a randomly chosen 256-bit integer. An attacker can choose d to minimize the cost of the fixed-scalar variable-base-point scalar multiplication by choosing d with low Hamming weight or more generally with a short addition chain, although a sufficiently low weight runs the risk that someone will discover d by a discrete-logarithm computation. To put an upper bound on the Dual EC attack time we avoid this optimization.

An independent blog post by Adamantiadis [2] has a proof of concept of the general Dual EC attack using OpenSSL's libcrypto for curve and large integer arithmetic. Adamantiadis does not implement a complete attack but recovers the state from a 30 byte random output. His proof of concept iterates through all 2^{16} candidates to recover the missing bits of the x-coordinate and computes the corresponding y coordinate. In case he discovers a point on the curve, he applies the back-door computation and computes the next random output. This proof of concept has an expected cost of $2^{16}C_y + 2^{15}(C_v + C_f)$.

On a single core of an Intel Xeon CPU E3-1275 v3, Adamantiadis's code requires about 18.5 s compiled with gcc version 4.8.1. Adamantiadis is using an older version of OpenSSL's libcrypto. For comparison, we modified Adamantiadis's code to run with libcrypto from OpenSSL version 1.0.1e; this version requires about 12.1 s. Furthermore, we reimplemented Adamantiadis's proof of concept using our optimized primitives. The optimized version requires about 3.7 s on a single core. Thus, our optimizations give an improvement by a factor of 3.3 over libcrypto.

In Adamantiadis's code (using libcrypto version 1.0.1e), the computation of a y coordinate (corresponding to cost C_y) takes about 15 µs on average. In our optimized version, this computation requires only 6 µs, which is an improvement by a factor of 2.5. The application of the back-door computation in Adamantiadis's code (scalar multiplication of a variable point by a fixed factor, cost C_v) requires about 168 µs on average; our code requires about 98 µs, which is an improvement by a factor of 1.7. Scalar multiplication with fixed base points P and Q (cost C_f) benefits the most from our optimizations. In

Table 2: Performance measurements and estimates.

Attack	Intel Xeon Reference System			16-CPU AMD Cluster
	2^{22} Candidates (s)	Expected Runtime (min)	Expected Cost	Total Runtime (min)
BSAFE-C v1.1	–	0.26	16	0.04*
BSAFE-Java v1.1	75.08*	641	38,500	63.96*
SChannel I	72.58*	619	37,100	62.97*
SChannel II	62.79*	1,760	106,000	182.64*
OpenSSL-fixed I	–	0.04	3	0.02*
OpenSSL-fixed II	–	707	44,200	83.32*
OpenSSL-fixed III	–	$2^k \cdot 707$	$2^k \cdot 44{,}200$	$2^k \cdot 83.32$

*measured

Adamantiadis's code, one scalar multiplication requires about 171 µs on average. In our optimized code, the computation for fixed base points requires only about 6µs on average, which is an improvement by a factor of 28. For an actual attack, the proportion of C_f to C_v is usually significantly larger than in the proof of concept. This increases the impact of our improvements on the attacks.

5.2 Performance measurements and estimates

All our attacks are based on the fact that some fields in the handshake messages (e.g., session ID and server random) contain a bit sequence derived from the x-coordinate of a point R. In order to recover R, we iterate through all possible combinations of the missing bits, check whether each candidate r_i actually is a valid x-coordinate and gives a point candidate R_i, apply the back door by computing dR_i, and follow all the steps (including adin for the attacks on OpenSSL-fixed) to check whether the candidate r_i eventually allows us to recover the (EC)DH secret. As the steps differ for each implementation, a different amount of computation is required for each attack (see Table 1, column "Attack Complexity").

We measure the cost of the attacks on a reference CPU, an Intel Xeon CPU E3-1275 v3, which has 4 cores and 2 hardware threads per core when enabling Hyper Threading. Table 2 lists measured and estimated performance numbers of the attacks. Turbo Boost and Hyper Threading are enabled; thus, we were using 8 OpenMP threads for the measurements on the reference system.

We measure the runtime of testing 2^{22} candidates (about 2^{21} candidate points). From these measurements, we extrapolate the expected runtime of the attack. From the expected runtime, we compute the cost of the attack as the number of Intel Xeon reference processors that would be required to perform the attack in an expected time of less than one second.

Finally, to verify the efficiency of the attack on multiple nodes, we measure the total worst-case runtime of the attack on a four-node, quad-socket AMD Opteron 6276 (Bulldozer) computing cluster. The cluster has an Infiniband interconnect and 256 GB memory per node — however, neither of these is relevant for the attacks: the attacks require less than 1 GB of RAM per process and do not need much communication.

For the timing measurements we ran each case several times to verify that there is no significant variance and finally picked the time from a representative test run. We are using gcc version 4.8.1 (Ubuntu/Linaro) with optimization level O3. In the following, all estimates for expected runtime and expected cost are rounded to three significant digits.

BSAFE-C v1.1. For the BSAFE-C attack, we simply concatenate session ID and server random and guess 16 bits of the target x-coordinate for the 30 possible cases. The complexity of the attack on BSAFE-C is $30 \cdot \left(2^{16} C_y + 2^{15}(C_v + C_f)\right)$. In the worst case this only requires testing $30 \cdot 2^{16}$ candidates which is less than 2^{22}, so we do not have a measurement for the first column in Table 2. Instead, we measured the worst-case time for the whole attack (31.12 seconds) and list half of the worst-case time, i.e., $31.12\ \mathrm{s}/2 \approx 0.26$ min as expected runtime. This gives an expected cost of 16 reference CPUs. This attack required 0.04 min on our cluster; most of this time is probably due to initialization overhead.

BSAFE-Java v1.1. In this case, the session ID of the handshake is not derived from Dual EC — so we have to use the 28 bytes of the server random, missing 32 bits of the target x-coordinate. The complexity of the attack on BSAFE-Java is $2^{32} C_y + 2^{31}(C_v + 5C_f)$. We measured a time of 75.08 s to check 2^{22} candidates. In total, this attack requires checking at most 2^{32} candidates, so the expected runtime is $2^{32-22} \cdot 75.08\ \mathrm{s}/2 \approx 641$ min on the reference CPU. Therefore, the expected cost to finish this attack within one second is about 38,500 reference CPUs.

We measured a worst-case total runtime of 63.96 min on our cluster.

SChannel I. The SChannel I attack uses the server random from the preceding handshake to hook into the random number stream and to discover the server's ECDHE private key in the handshake when the private key is refreshed. The complexity of this attack is $2^{32}C_y + 2^{31}(C_v + 4C_f)$. Checking 2^{22} candidates takes 72.58 s. This is slightly less than the time for BSAFE-Java, because this attack requires only four instead of five multiplications by a fixed base point for each point candidate. The whole attack requires checking at most 2^{32} candidates, so the expected runtime is $2^{32-22} \cdot 72.58\ \text{s}/2 \approx 619$ min. Therefore, the expected cost of the attack is 37,100 reference CPUs. The measured worst-case total time on our cluster is 62.97 min.

SChannel II. The SChannel II attack uses just one single handshake to recover the secret keys and therefore relies on the session ID (where the 4 least significant bytes have been replaced by their value modulo 20,000) to recover the state of the PRNG. The complexity of the attack is $2^{34}C_y + 2^{33}(C_v + C_f) + 2^{17}(5C_f)$, more precisely $2^{32}/20{,}000 \cdot 2^{16}\left(C_y + (C_v + C_f + 5C_f/2^{16})/2\right)$. The dominant part for each candidate check is $C_y + (C_v + C_f)/2$ which requires a smaller number of multiplications with a fixed base point than SChannel I. We measured 62.79 s to check 2^{22} candidates. This attack requires checking up to $2^{32}/20{,}000 \cdot 2^{16}$ candidates; therefore, this attack has an expected runtime of $2^{32-22}/20{,}000 \cdot 2^{16} \cdot 62.79\ \text{s}/2 \approx 1{,}760$ min. This gives an expected cost of 106,000 reference CPUs.

OpenSSL-fixed. Due to the use of adin before each random draw, OpenSSL is a special case among the implementations of Dual EC. The attack on OpenSSL takes three steps: First, we find the current state by finding the 16 missing bits for the session ID. This requires checking at most 2^{16} candidates; thus, we do not give a measurement for 2^{22} candidates in the first column of Table 2. Since this step might result in more than one state candidate, we always compute all 2^{16} candidates. If more than one candidate is recovered, the attacker either has to check all candidates (in parallel) or retry with a different handshake if applicable. In the following we investigate the expected case that only one candidate is found. In the second step, we need to find the adin used to generate server random. Here, adin consists of the current system time (including µs), the process ID (pid), and a counter value. In the last step, we need to find the next adin before the call to generate the DH key. The pid and the counter are known from the previous adin; we only need to find the µs over a very short time span by iteratively incrementing the time counter until the correct value is reached. The complexity of the OpenSSL attack is $2^{16}C_y + 2^{15}(C_v + C_f) + 2^{20+k+l}(2C_f) + 2^{13}(5C_f)$ where k is the number of unknown bits of the adin counter and l is the number of unknown bits of the adin pid.

The first step requires to check at most 2^{16} x-coordinate candidates; for the last step, we expect a maximum of 2^{13} increments to find the correct µs for the adin, as discussed earlier. Therefore, the scalability of the parallelization of step one and three is limited due to the small workload. We are using a batch size of 256. Therefore, the workload of checking 2^{16} candidates in the first step can be split across at most $2^{16}/256 = 256$ threads without loss of efficiency. The last step requires at most 2^{13} iterations, so the maximum number of threads for this step is $2^{13}/256 = 32$. Step one and three contribute to only an insignificant fraction of the total complexity when pid or counter are not known.

We examine three cases:

OpenSSL-fixed I: pid and counter are known, µs of time are unknown,

OpenSSL-fixed II: counter is known, µs of time and pid (15 bits) are unknown,

OpenSSL-fixed III: µs of time, pid (15 bits), and counter (k bits) are unknown.

The system time in seconds is known from the timestamp in the server-random field of the handshake message. Therefore, only the µs must be found by exhaustive search. The seconds might have clocked since the timestamp was obtained; thus, we need to test up to $1{,}000{,}000 + \Delta$ candidates for the µs. An upper limit on Δ is the time between the server receiving the ClientHello message and sending the ServerHello message. We use $1{,}000{,}000\ \mu\text{s} + 48{,}576\ \mu\text{s} = 2^{20}\ \mu\text{s}$ as upper limit.

The standard maximum pid on Linux systems is 2^{15}. If the attacker starts listening to the server right after bootup, he can assume the initial counter to be zero; otherwise, he may make an educated guess about the current counter state based on uptime and the average connection number.

To compute the expected runtime of this attack we measured the worst-case runtime of the case OpenSSL-fixed I. The first step to compute state candidates took about 0.96 s; the second step checking all possible 2^{20} µs for one single state candidate took 2.59 s. The final step checking the next 2^{13} µs took only 0.05 s. Therefore, the expected runtime of OpenSSL-fixed I is $0.96\ \text{s} + 2.59\ \text{s}/2 + 0.05\ \text{s}/2 \approx 0.04$ min; the expected cost is three reference CPUs. The expected runtime of OpenSSL-fixed II is $0.96\ \text{s} + 2^{15} \cdot 2.59\ \text{s}/2 + 0.05\ \text{s}/2 \approx 707$ min. We are using 8 threads in the reference system; the maximum number of threads is 256 threads for the first step and 32 threads for the last step. Therefore, the first step cannot be faster than $0.96\ \text{s}/(256/8) \approx 0.03$ s and the last step requires at least $0.05\ \text{s}/(32/8) \approx 0.01$ s in the worst

case. To finish the whole attack in one second on average, the second step must take $1\text{ s} - 0.03\text{ s} - 0.01\text{ s} = 0.96\text{ s}$ on average which requires $2^{15} \cdot 2.59\text{ s}/2/0.96\text{ s} \approx 44{,}200$ reference CPUs. For OpenSSL-fixed III these values are multiplied by 2^k, assuming k unknown bits for the counter of the adin.

We ran OpenSSL-fixed II on the cluster, testing all 2^{35} combinations of µs and pid to obtain the worst-case total runtime. The time of 83.32 min is noticeably less than 2^{15} times the time of 0.02 s taken in the OpenSSL-fixed I scenario. This is because in OpenSSL-fixed I the computations of $2^{15}C_v$ for the first step have a strong impact on the runtime; testing 2^{35} candidates gives more precise timing estimates of C_f. We can extrapolate the costs for OpenSSL-fixed III as 2^k times those of OpenSSL-fixed II because the contribution of the first and of the third step become negligible.

Summary. These runtime and cost estimates show that a powerful attacker (in case of BSAFE-C, an arbitrary attacker) is able to break TLS connections that use the Dual EC pseudorandom number generator when he possesses the back-door information. The usability of the attack on OpenSSL-fixed depends on additional knowledge about the adin; however, computing clusters of around 100,000 CPUs are realistic as of today (for example the Tianhe-2 supercomputer in China has 16,000 computing nodes with 5 CPUs each [19]) and sufficient to break BSAFE and SChannel in less than one second.

6 Passive TLS server fingerprinting

In many contexts, including exploitation of the Dual EC backdoor, it is useful to identify, or fingerprint, the implementation used by a TLS server. Existing tools for TLS fingerprinting use active techniques (requesting a page to get an error message and analyzing the result), but our investigations of TLS implementations suggest that the session ID field, in particular, admits a passive fingerprinting mechanism useful to an attacker observing network traffic or even one attacking recorded connections from years ago.

Data collection. We collected a large dataset of TLS session information from servers listening on port 443 in the IPv4 address space. We executed a ZMap scan [7] of port 443 over the entire IPv4 address space (excluding ZMap's default blacklist). The ZMap scan netted 38.9 million services responding on port 443. For 37.1 million of these services, we used a modified version of OpenSSL v1.0.1e s_client to connect to the service, and attempt to perform a TLS handshake up through receiving the ServerHello message (containing the session ID, server random value, and TLS server extensions), and then sent a TCP RST to the server. Of these attempts, 21.8M servers responded with a ServerHello message.

We investigated a number of candidate fingerprints based on observable behavior to a passive adversary. For each server that exhibited the RSA BSAFE fingerprint, we made an HTTP GET request on port 443 in an attempt to determine what software the server uses via the self-reported `Server` field of the HTTP header. We repeated this for 1,000 randomly selected IP addresses exhibiting the SChannel fingerprint. We consider an observable behavior to be a *selective fingerprint* if $\geq 95\%$ of the servers from which we received HTTP headers identify themselves as the same implementation.

6.1 Fingerprints detected

We detected many different types of fingerprints by examining server random values, session IDs, and TLS server extensions (all unencrypted values to a passive observer). In addition to the fingerprints on BSAFE and SChannel discussed in Sections 4.1 and 4.2, we identified five selective fingerprints from unique combinations of supported extensions, 2 selective fingerprints corresponding to session ID values with fewer than 32 bytes, and seven selective fingerprints corresponding to fixed subsequences in the session ID.

In sum, 4 million of the servers we contacted exhibited selective fingerprints. We discuss our findings for BSAFE and SChannel in more detail below.

RSA BSAFE. As described in Section 4.1, by default, BSAFE-Java has a very prominent fingerprint that is enabled by default, and BSAFE-C has a similar fingerprint that is not enabled by default. We found 720 servers with the BSAFE-Java fingerprint, and none with the BSAFE-C fingerprint. Of these servers, 33% self-reported running Apache Coyote 1.1,[8] with the remaining two self-reported implementations ("ADP API" and lighthttpd) appearing on fewer than ten instances. The remaining servers did not return a `Server` field.

Microsoft SChannel. As described in Section 4.2, SChannel exhibits a fingerprint in the first 4 bytes of the session ID. 2.7 million of the servers we contacted exhibited this fingerprint. We requested HTTP headers from 1,000 of these IPs (randomly selected), and 96% of the responses included the string "Microsoft" in the server field, suggesting that this is a selective fingerprint.

7 Conclusions

We provided the first theoretical and practical analysis of the exploitability of Dual EC as used in deployed TLS implementations. We evaluated the viability and performance of recovering TLS session keys for fielded implementations that use Dual EC. Our results demonstrate that

[8] Apache Coyote is a front end that forwards requests to Apache Tomcat, which supports Java Servlets and JavaServer pages; running Tomcat with BSAFE-Java may indicate an effort to provide a FIPS-compliant web application.

otherwise innocuous implementation decisions greatly affect exploitability. For example, RSA BSAFE-C is by far the easiest to exploit due to caching of unused bytes of Dual EC output. On the other end of the spectrum, OpenSSL-fixed uses additional input, which can render attacks significantly more challenging if no or only little information is available about the server.

We developed and successfully tested state-of-the-art parallelized implementations of all attacks against versions of the libraries patched to use Dual EC constants that we generated. Depending on the design choices in the implementations, an attacker can recover TLS session keys within seconds on a single CPU or may require a cluster of more than 100,000 CPUs for the same task if a different library is used. For OpenSSL some parameters might require such a serious cluster for an even longer time.

While there are a number of available mitigations to the vulnerabilities we discuss in this work, the simplest and best is to remove the Dual EC implementation from deployed products. OpenSSL has already initiated the (expensive, due to FIPS certification) process of removing Dual EC from its FIPS version and, in the meantime, is not fixing the bug we discovered that prevents its use [17]. RSA has advised developers to stop using the BSAFE Dual EC implementation [9]. Our work further emphasizes the need to deprecate the algorithm as soon as possible.

Acknowledgements

We would like to thank Bo-Yin Yang's research group at Academia Sinica, Taiwan, for giving us access to their computing cluster for benchmarking. We also thank Steve Marquess and Dr. Stephen Henson of the OpenSSL Foundation for helpful discussions. We thank Kurt Opsahl and Nate Cardozo of the Electronic Frontier Foundation for their legal advice throughout this project. Adam Everspaugh contributed to Section 6 of this paper.

iSeeYou: Disabling the MacBook Webcam Indicator LED

Matthew Brocker
Johns Hopkins University

Stephen Checkoway
Johns Hopkins University

Abstract

The ubiquitous webcam indicator LED is an important privacy feature which provides a visual cue that the camera is turned on. We describe how to disable the LED on a class of Apple internal iSight webcams used in some versions of MacBook laptops and iMac desktops. This enables video to be captured without any visual indication to the user and can be accomplished entirely in user space by an unprivileged (non-root) application.

The same technique that allows us to disable the LED, namely reprogramming the firmware that runs on the iSight, enables a virtual machine escape whereby malware running inside a virtual machine reprograms the camera to act as a USB Human Interface Device (HID) keyboard which executes code in the host operating system.

We build two proofs-of-concept: (1) an OS X application, *iSeeYou*, which demonstrates capturing video with the LED disabled; and (2) a virtual machine escape that launches *Terminal.app* and runs shell commands. To defend against these and related threats, we build an OS X kernel extension, *iSightDefender*, which prohibits the modification of the iSight's firmware from user space.

1 Introduction

Video is ineffably compelling. The (consensual) sharing of video is an act of intimacy as it allows the viewer a glimpse into the life of the sharer. It is no surprise then that the Internet's first "lifecast," Jennifer Ringley's "JenniCam" in 1996 [24], was video and not audio. Similarly, YouTube, the most popular website for sharing user-created videos, predates SoundCloud, a website with similar functionality for audio, by several years even though technological constraints would suggest the opposite order. It is precisely because of the intimacy of video that turning on someone's camera without his or her knowledge or consent is a violation more fundamental than recording audio.

Beyond intentional sharing, video makes for more compelling evidence that an event occurred as claimed than either an after-the-fact eye witness account or audio recording. This is true whether it is a video of a successfully performed feat of skill — e.g., in sports [44] or even video games [49] — video of police brutality [55], video of violent crime [63], or webcam video used for blackmail [15].

Figure 1: The iSight from a 2008 MacBook we studied.

The value of video evidence is so high that The Washington Post recently reported that the US Federal Bureau of Investigation (FBI), has developed surveillance malware, similar to the proof-of-concept described in this paper, which can covertly turn on a victim's webcam [59]. Of course, the threat to privacy from webcams vulnerable to hacking comes not only from law enforcement.

At the beginning of the 2008 school year, the Lower Merion School District provided a MacBook laptop to each enrolled student. These laptops came pre-loaded with the *LANrev* remote administration tool (RAT) which allowed school district officials to, among other things, capture images from the MacBooks' built-in iSight webcam. During the following 18 months, officials captured more than 30 thousand images from these webcams [5, 6]. The first indication that images were being captured was every time the software took a picture, the green indicator LED would briefly illuminate [5, 6, 42]. Some teachers were so concerned by this they they covered the lens of the webcams on their own laptops [6]. Here, the indicator LED worked exactly as it was supposed to and alerted the users that they were being photographed.

The possibility that a webcam could be capturing pictures without the LED illuminating has led to suggestions that owners should tape over the webcam [43] as well as products designed to cover the camera stickers [10, 58].

This incident illustrates the dangers of passive sensors attached to computers like cameras, microphones, and GPS receivers. Unlike active input devices like keyboards and mice that require user actions to provide input, a passive sensor requires no action on the part of the user to capture input. Indeed, a user is typically unaware that input is being captured at all unless specific mechanisms are built into the technology to indicate that the sensor is currently in use. Such mechanisms include camera-use indicator LEDs, shutter sounds on cell phone cameras, and GPS-use indicator icons on mobile devices and laptops.

In the past few years, the ever-expanding set of sensors present in commodity laptops and smart phones has prompted the security and privacy community to begin researching ways to detect and limit the undesired use of sensors [20, 22, 26, 27, 31]. At the same time, researchers have demonstrated attacks exploiting the presence of sensors such as a clickjacking attacks against Adobe Flash to gain access to the camera and microphone [23] from a malicious web page and exfiltrating audio from microphones in modern automobiles [11]. (See Section 2 for more examples.)

Our results in this paper demonstrate that, at least in some cases, people have been correct to worry about malware covertly capturing images and video. We show a vulnerability in the iSight webcam that affects a particular range of Apple computers — including the MacBooks given to the students in the Lower Merion School District — that can be exploited to turn on the camera and capture images and video without the indicator illuminating.

At a high level, our investigation of the iSight revealed that it is designed around a microprocessor and a separate image sensor with an indicator LED sitting between them such that whenever the image sensor is transmitting images to the microcontroller, a hardware interlock illuminates the LED. We show how to reprogram the microcontroller with arbitrary, new firmware. This in turn enables us to reconfigure the image sensor, allowing us to bypass the hardware interlock and disable the LED. We also show a new method of performing a virtual machine escape based on our ability to reprogram the microcontroller.

Specifically, our technical contributions in this paper are five-fold:

1. We describe the architecture of the Apple internal iSight webcam found in previous generation Apple products including the iMac G5 and early Intel-based iMacs, MacBooks, and MacBook Pros until roughly 2008 (Section 3).
2. We demonstrate how to bypass the hardware interlock that the iSight uses to turn on the indicator LED whenever the camera is capturing images or video (Section 4) and provide a proof-of-concept user space application, *iSeeYou*, to do so (Section 6).
3. We demonstrate how to use the capability developed to bypass the hardware interlock to achieve a virtual machine escape (Appendix A[1]).
4. We develop an OS X kernel extension, *iSightDefender*, to defend against these attacks (Section 7).
5. We sketch the design space for building a secure camera module (Section 8).

The ability to bypass the interlock raises serious privacy concerns and the technical means by which we accomplish it raises additional security concerns which we discuss in Section 9.

Threat model. To mount our main attack where we capture video without any external indication to the victim, we assume that an attacker is able to run native code on the victim's computer as an unprivileged user. Further, we assume the code is unencumbered by defenses such as Apple's *App Sandbox* [4] which is used for applications downloaded from the Mac App Store but by little else. This assumption is quite mild and would typically be satisfied by malware such as RATs.

For the virtual machine escape, we assume the attacker has code running locally in the virtual machine and with whatever privileges the guest OS requires to communicate with USB devices. We also assume that the virtual machine monitor has exposed the iSight device to the virtual machine. This second assumption is quite strong as virtual machine monitors typically do not expose USB devices to the guest OS unless the user specifically configures it to do so, for example to use video conferencing software.

Generality of results. We stress that our main result — disabling the iSight LED — only applies to the first generation internal iSight webcams, found in some Apple laptops and desktops, and we make no claims of security or insecurity of later models, including the most recent (renamed) FaceTime cameras. The virtual machine escape described in Appendix A likely holds for other USB devices that use the Cypress EZ-USB chip used in the iSight, but we have not yet tested other devices.

2 Related work

General purpose computers contain a variety of processors designed for performing specialized tasks other than general-purpose computation. Examples include graphics processing units (GPUs) which produce video output; processors in network interface controllers (NICs) which perform network packet processing; microcontrollers in perhipherals such as keyboards, mice, and webcams; microcontrollers in laptop batteries; and, in some systems, baseboard management controllers (BMCs) which en-

[1] Although we regard this as a major contribution, we have moved the details to an appendix to improve the paper's flow

ables out-of-band system management independent of the host computer's CPU.

Security researchers have only recently begun examining these additional processors and the firmware that runs on them. In many cases, the designers of these systems appear not to have appreciated the security implications of their interfaces and implementations.

Perhaps the most well-studied processor apart from the CPU is the GPU. Vasiliadis et al. [60] demonstrate using the GPU to harden malware against detection by using the GPU to implement unpacking and runtime polymorphism. Ladakis et al. [33] use the GPU's direct memory access (DMA) capability to monitor the system's keyboard buffer to build a keylogger. Beyond GPU malware itself, researchers have used the GPU to accelerate malware detection [32] and intrusion detection systems [50].

Duflot and Perez [17] demonstrate exploiting a NIC to achieve arbitrary code execution. In follow up work, Duflot et al. [18] build a NIC malware detection framework.

Miller [39] demonstrates how to communicate with Apple laptop batteries using the System Management Bus, authenticate to the battery to "unseal" it, and change both configuration values and firmware. This enables overcharging the battery resulting in overheating and, potentially, leading to a fire.

Tereshkin and Wojtczuk [57] introduce the concept of a "Ring −3" rootkit which runs on Intel's Active Management Technology (AMT) hardware which has a processor independent of the host CPU with a separate interface to the NIC and DMA access to main memory.

In a very similar vein, Farmer [21] discusses weaknesses and vulnerabilities in the Intelligent Platform Management Interface (IPMI) — the standard interface to the baseboard management controller (BMC). Like AMT, a BMC has direct access to the host system but its operation is completely independent making exploits both extremely powerful and difficult to detect. Moore [41] builds on this work to produce a penetration tester's guide for examining IPMI and BMCs.

A webcam is just a particular type of sensor attached to a computing device. Others include microphones, accelerometers, and GPS receivers. Our work joins an emerging line of research on the security and privacy implications of such sensors. For example, Schlegel et al. [54] show how to use a smartphone's microphone to extract credit card numbers and PINs from spoken and tone-based interfaces. Marquardt et al. [36], Owusu et al. [46] and Miluzzo et al. [40] use smartphone accelerometers to extract information about key presses. Checkoway et al. [11] extract audio and GPS coordinates from automobiles. Templeman et al. [56] use smartphone cameras to covertly take pictures which are then used to create 3D models of physical spaces.

Our virtual machine escape (Appendix A) is not the first to emulate a USB Human Interface Device (HID) such as a mouse or keyboard. Wang and Stavrou [62] use a compromised smart phone to act as a USB HID keyboard and send key presses to the host system. Kennedy and Kelley [30] use a small microcontroller to interact with the Windows Powershell. Pisani et al. [48] similarly describe having USB devices pose as HID keyboards to control the computer. Elkins [19] adds a RF receiver for remote controlling a fake HID keyboard.

3 Internal iSight architecture

This section describes the architecture of the internal iSight webcam in sufficient detail to understand how the multi-step attack described in Section 4 works. Readers who are already familiar with the iSight or the Cypress EZ-USB or who are not interested in the low-level details of the device are encouraged to skip directly to Section 4 and use this section and Figure 2, in particular, as a reference as needed.

The internal iSight consists of a Cypress CY7C68013A EZ-USB FX2LP, a Micron MT9V112 CMOS digital image sensor, a 16 byte configuration EEPROM, and an indicator LED (see Figure 1). A block diagram is given in Figure 2.

3.1 Cypress EZ-USB

The host computer interacts with the iSight entirely through a USB connection to the Cypress EZ-USB. The EZ-USB is responsible for handling all USB requests and sending replies including video data.

The EZ-USB has an internal Intel 8051-compatible microcontroller core and 16 kB of on-chip RAM accessible as both code and data "main" memory[2] but lacks persistent storage [13]. In general, the firmware for the 8051 core can be located in one of three locations: (1) external memory such as flash or EPROM attached to the EZ-USB address/data bus; (2) an I^2C EEPROM; or (3) loaded from USB. The iSight loads its firmware at boot from the host computer over USB (see Section 4.2).

3.2 Micron digital image sensor

The Micron digital image sensor is a low-power system-on-a-chip (SOC) capable of producing an image in several formats. The sensor is configured by the I^2C interface which can read from and write to several hundred configuration registers [37]. In addition to the I^2C interface, several hardware signals influence the operation of sensor.

The most important signals from our perspective are the active-low `#RESET` and active-high `STANDBY` sig-

[2] The standard 8051 is a Harvard architecture which has separate code and data memory differentiated by hardware signals. In the configuration used by the iSight, the signals are combined effectively giving a single main memory address space.

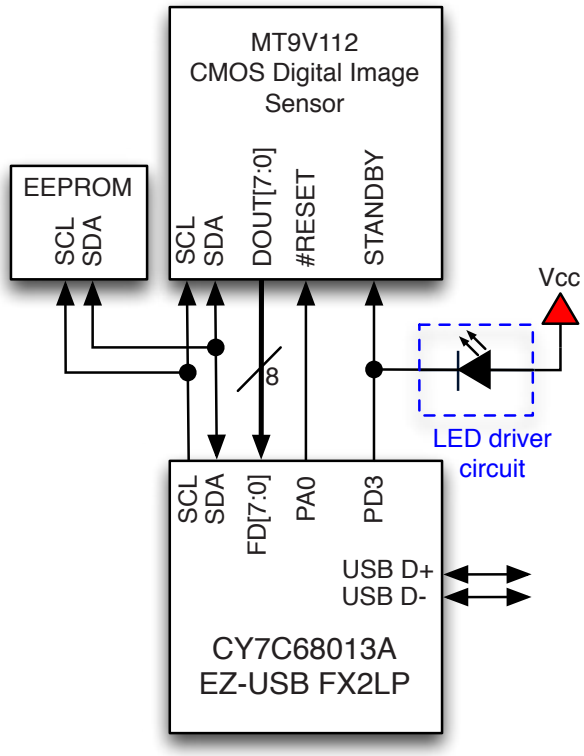

Figure 2: Internal iSight architecture block diagram consisting of a Cypress EZ-USB, a Micron digital image sensor, a 16 byte configuration EEPROM, and an indicator LED. The SCL and SCA lines comprise the I^2C bus.

nals. The corresponding hardware pins are connected directly to the EZ-USB's general purpose I/O (GPIO) pins. As shown in Figure 2, `#RESET` is connected to pin 0 of GPIO port A and `STANDBY` is connected to pin 3 of GPIO port D. The other connection between the image sensor and the EZ-USB shown in Figure 2 `DOUT[7:0]`→`FD[7:0]` is an 8 bit unidirectional bus which transfers pixel data to the EZ-USB's FIFO interface. Other, less important, control signals are omitted from the diagram.

The `#RESET` signal performs a hardware reset, resetting all configuration registers to their default value. The `STANDBY` signal controls output enable and power down functions. That is, when `STANDBY` is asserted, the image sensor stops producing data on `DOUT[7:0]` which enters the high impedance state as well as allowing the image sensor to transition to a low-power state.

3.3 Configuration EEPROM

The first byte of the 16 byte EEPROM controls whether the EZ-USB loads its firmware from USB or from the EEPROM itself. When set to load firmware from USB, as the iSight does, the EEPROM contains the USB vendor ID (VID), product ID (PID), device release number, and a configuration byte for the initial device enumeration. Once the EZ-USB has enumerated using the VID, PID, and release values, software on the host computer can load the firmware. The iSight initially enumerates with vendor ID `0x05ac` (Apple, Inc.) and product ID `0x8300` (Built-in iSight (no firmware loaded)).

Table 1: Relation between the `PD3` GPIO, the `STANDBY` signal, and the LED.

PD3	STANDBY	LED
High	Asserted	Off
Low	Deasserted	On

3.4 Indicator LED

Since the purpose of the indicator LED is to illuminate whenever the camera is capturing video, a LED driver circuit is connected directly to the `STANDBY` input of the image sensor (see Figure 2). In this way, whenever `PD3` is high — that is, `STANDBY` is asserted — the LED is off and whenever `PD3` is low — so `STANDBY` is deasserted and the image sensor is producing output — the LED is on. Since the LED is controlled by the same output that controls `STANDBY`, there is no danger that firmware on the EZ-USB could deassert `STANDBY` *and* turn the LED off (see Table 1). However, as we demonstrate in Section 4, we can bypass the `STANDBY` signal such that changing `PD3` allows us to control the LED without affecting the operation of the image sensor.

4 Disabling the indicator LED

Disabling the indicator LED on the iSight entails two requirements. First, as described in Section 3, the indicator LED is directly connected to the `STANDBY` pin on the image sensor. In order to disable the LED, we need to keep `STANDBY` asserted. Since asserting `STANDBY` will disable the image sensor output, we need to configure the image sensor to ignore `STANDBY` before we assert this signal. Second, we need a way to modify the firmware on the EZ-USB to in order to configure the image sensor appropriately as well as keep `STANDBY` asserted whenever we want the LED to stay off.

4.1 Bypassing the `STANDBY` signal

The Micron image sensor has a 16 bit configuration register, RESET (which is distinct from the `#RESET` power-on-reset signal). RESET is addressable from the I^2C interface at address `0x0D` in register page 0 [37]. The most significant 8 bits control hardware clocks and how bad frames should be handled which are of no interest to us and can be left as 0. The least significant 8 bits have the following functionality as described in the image sensor

data sheet [37, Table 13]:

- Bit 7. Prevent `STANDBY` from affecting entry to or exit from the low-power state if set.
- Bit 6. Prevent `STANDBY` from contributing to output enable control if set.
- Bit 5. Reset the SOC (but not the sensor) if set.
- Bit 4. Disable pixel data output if set.
- Bit 3. Chip enable. Normal operation if set, no sensor readout otherwise.
- Bit 2. Software standby if set, otherwise normal operation.
- Bit 1. Restart reading an image frame.
- Bit 0. Reset the sensor to its default state if set, normal operation otherwise.

Bits 0, 1, and 5 are of no interest and can be set to 0 but the remaining 5 bits enable us to bypass the `STANDBY` signal while still maintaining normal operation. This includes entering a (software) standby state and disabling output when appropriate.

When the iSight is first powered up (or, more precisely, when `#RESET` becomes deasserted), the RESET register has value `0x0008`; that is, normal operation and `STANDBY` affects the low-power state and output enable. If RESET is set to `0x00c8`, then the camera has normal operation but `STANDBY` is effectively bypassed. When it becomes desirable for the camera to enter the standby state, RESET can be set to `0x00d4` which disables output and enters the software standby state.

With RESET set to either `0x00c8` or `0x00d4`, the hardware `STANDBY` signal is ignored. This enables the use of the EZ-USB `PD3` output to control the LED independent of the standby state of the image sensor.

4.2 Programming the EZ-USB

When the iSight is first powered, it checks the configuration EEPROM and then waits for programming over USB (see Section 3.3). The *AppleUSBVideoSupport* I/O Kit driver matches the vendor ID (VID) and product ID (PID). The driver loads and the `AppleUSBCamera::start()` function downloads the camera's firmware (stored in the `gTheFirmware` array) to the EZ-USB using a series of vendor-specific USB "Firmware Load" device requests [13, Section 3.8]. The camera will then reenumerate and function as a webcam.

One approach to change the firmware on the camera is to modify the *AppleUSBVideoSupport* driver to contain different firmware. A second approach would be to provide a new driver that matches the VID/PID and provides a higher probe score [2]. The new driver would run at system start up instead of Apple's driver and download the new firmware to the camera. These approaches have two major drawbacks. The first drawback is that they rely on programming the iSight when it is in its unprogrammed state which only happens when the camera is first powered by the USB bus. The second drawback is that root access is required in order to modify the existing driver or load a new driver.

A third approach overcomes both drawbacks by letting the iSight be programmed with the legitimate firmware when it is first powered. Once the firmware has been loaded onto the camera, it can be reprogrammed at any time using "Firmware Load" requests. Furthermore, it can be reprogrammed from any user space process.

5 Finding the vulnerability

The information described in Sections 3 and 4 was discovered by a combination of reverse engineering, experimentation, and reading data sheets once individual components were identified. We started by ordering camera modules from a variety of Apple computers on eBay. Coincidentally, the modules were all from the original iSight camera, although the camera boards for the MacBook and iMac had different forms. Figure 1 shows the MacBook board.

A cursory examination of the board reveals that the camera microprocessor is a Cypress EZ-USB. The EZ-USB Technical Reference Manual [13] describes the procedure to download code to EZ-USB. We reverse engineered the *AppleUSBVideoSupport* driver using IDA [25] to determine the format of the firmware stored in the driver. (Section 6.1 describes the firmware in more detail.) We then extracted the firmware as it would appear in memory and analyzed it using IDA.

Our initial hypothesis was that the LED would be controlled by one of the EZ-USB GPIO pins via the firmware. To test this, we mapped out the connections on the board using a digital multimeter with a specific focus on connections from the microcontroller to the indicator LED. A connection was found between the microcontroller, image sensor, and the LED driver circuit. Since the microcontroller pin connected to the LED was set as an output, we constructed new firmware to toggle this output and examined the results. When the LED was turned on, the camera functioned correctly. When the LED was turned off, the camera ceased operating (see Table 1).

Since the output controlling the LED was also connected to the image sensor, we examined it next. When the legitimate camera firmware is downloaded to the camera, it identifies itself as "Apple, Inc. Built-in iSight [Micron]" suggesting that the image sensor was manufactured by Micron Technology. There is no visible part number that can be used to identify the model (see Figure 1). Rather than decapping the chip, we used the Wayback Machine[3] to view the Micron website for 2005, the year the camera board was copyrighted. Data sheets for the

[3] `https://archive.org/web/`

image sensors that matched the publicly known specs for the iSight camera on Micron's website indicate that the image sensor communicates over an I^2C bus. One of the I^2C-addressable registers identifies the chip version. We identified the I^2C bus and read the register which revealed the particular image sensor.

We examined the relevant data sheet for the image sensor and noticed the `STANDBY` pin with functionality consistent with our experiments toggling the LED-controlling output pin. After reading the data sheet in more detail, we discovered the I^2C-addressable register which enables a software override for the `STANDBY` pin. Further experiments with modified firmware were performed to verify that the LED driver circuit was indeed connected to `STANDBY` and that it could be bypassed.

6 Proof of concept

The discussion in Section 4 shows that, in principle, it is possible to modify the legitimate firmware to disable the LED. In this section, we describe the proof-of-concept application, *iSeeYou* we created which reprograms the iSight to add the capability to enable or disable the LED using a new vendor-specific USB device request.

6.1 Modifying the firmware

Although one could reimplement the camera functionality, we opted to create new firmware by appending new binary code to the legitimate firmware and patching it to call our new code. The first step is to extract the legitimate firmware from the *AppleUSBVideoSupport* device driver.[4]

The firmware consists of an 8 byte header followed by a sequence of triples: a 2 byte size, a 2 byte address, and size-bytes of data. This format corresponds exactly to the "C2 Load" format of the EEPROM for loading firmware directly from the EEPROM [13, Table 3-6]. Each triple specifies the data that should be written to the EZ-USB's main memory at a given address. By stripping off the header and the final triple,[5] we can construct the "raw" firmware image. The raw firmware can then be analyzed using IDA.

The raw firmware is structured similarly to sample code provided in the Cypress EZ-USB FX2LP Development Kit [14] including a hardware initialization function and USB events that are serviced by a main loop based on state bits set by interrupt handlers.

To the legitimate firmware, we add two bits of state, "is the sensor in software standby or running" and "is the LED enabled or disabled," as well as four new functions, `reset_sensor`, `enter_standby`, `exit_standby`, and `handle_led_control`.

When the LED is enabled, the behavior of the camera is indistinguishable from the normal behavior. That is, when the camera is in its standby state the LED is off and when the camera is in its running state, the LED is on.

The legitimate firmware contains a function to reset and configure the image sensor. This is called both from the hardware initialization function and the handler for the USB set interface request. It begins by deasserting the `STANDBY` signal and asserting the `#RESET`. After a short spin loop, it deasserts `#RESET` and, depending on the function argument, deasserts `STANDBY`. It then proceeds to configure the image sensor. We patch the firmware to call `reset_sensor` instead of this configuration function in both locations. The `reset_sensor` function reimplements the reset functionality but adds a call to the function which writes to the I^2C bus to program the RESET register to bypass the `STANDBY` signal (see Section 4.1). At this point, if the LED has been disabled or the argument indicates that it should enter the standby state, the `STANDBY` signal is asserted to turn off the LED which will have momentarily illuminated during the reset sequence. Otherwise, the sensor is left running and the LED is enabled so `STANDBY` remains deasserted and the LED stays on. Finally, the `reset_sensor` function jumps into the middle of the configuration function, just past the `#RESET` and `STANDBY` manipulating code, in order to perform the rest of the configuration.

The `enter_standby` and `exit_standby` functions update the bit of state which records if the image sensor is running or in standby. Then, based on whether the LED is enabled or not, they deassert (resp. assert) `STANDBY` as needed to turn the LED on (resp. off). Finally, these functions use I^2C to program the RESET register to enter or exit software standby. Each location in the legitimate firmware which sets the state of the `STANDBY` signal is patched to call its new, corresponding standby function instead.

The final function, `handle_led_control` is responsible for handling a new vendor-specific USB device request. The main loop in the legitimate firmware which handles USB device request "setup" packets is patched to instead call `handle_led_control`. If the `bRequest` field of the request does not match the new vendor-specific value, then it jumps to the legitimate handler. Otherwise, based on the `wValue` field of the request, the LED is enabled or disabled. As with the other functions, the LED is then turned on if it has been enabled and the image sensor is running. Otherwise, it is turned off.

6.2 Demonstration application: *iSeeYou*

iSeeYou is a simple, native OS X application; see Figure 3. When *iSeeYou* starts, it checks for the presence of

[4] There are several open source tools to perform this task, e.g., iSight Firmware Tools [7], several of which include binary patching to fix bugs in the USB interface descriptors.

[5] The final triple stores a single `0x00` byte to address `0xE600` which takes the Intel 8051 core out of reset so that it can begin executing instructions.

Figure 3: *iSeeYou* running on a white MacBook "Core 2 Duo" capturing video from the internal iSight with the LED (the black dot to the right of the square camera at the top, center of the display bezel) unilluminated.

a built-in iSight using the appropriate vendor and product IDs. If the iSight is found, *iSeeYou* initiates the reprogramming process using the modified firmware described above. Once the camera has been reprogrammed and has reenumerated, the start/stop button begins/ends capturing and displaying video. The `LED Enable`/`LED Disable` control sends USB device requests with the new vendor-specific value to enable/disable the indicator LED while video is being captured. Finally, when the user quits *iSeeYou*, the camera is reprogrammed with the legitimate firmware.

7 Defenses

There are several approaches one can envision to defend the iSight against the attacks described in the previous sections. One can change (1) the hardware, (2) the firmware on the EZ-USB (unfortunately this is not effective, see below), or (3) the software on the host system. See Table 2 for an overview of possible defenses and their efficacy.

The most comprehensive defense would be to change the hardware used in the iSight. See Section 8 for several secure hardware designs. Of course, changing the hardware is not a deployable solution for existing devices.

Table 2: Overview of possible defenses.

Defense	Deployable	User	Root
Change hardware	No	Yes	Yes
Change firmware	Yes	No	No
App Sandbox	Yes	Some	No
iSightDefender	Yes	Yes	No

A "Yes" in the Deployable column indicates that the defense could be deployed to existing computers. A "Yes" in the User (resp. Root) column indicates that the defense would prevent an unprivileged (resp. root) process from reprogramming the iSight. A "Some" indicates that some reprogramming attempts would be prevented but others allowed.

If the hardware must remain the same, then if the firmware on the camera could be changed to disallow future reprogramming, then the camera would be secure against our attacks. Unfortunately, the "Firmware Load" USB device request used to reprogram the 8051 core is handled entirely by the EZ-USB device itself and cannot be blocked or handled by the 8051 itself [13, Section 3.8].

Thus no matter how one programs the device's firmware, it can be reprogrammed by an attacker who can send basic USB messages to the camera.

Apple deploys sandboxing technology called the *App Sandbox*[6] [4] which can prevent applications inside the sandbox from accessing the iSight. Specifically, the `com.apple.security.device.camera` entitlement enables an application to capture still images and video from cameras, including the internal iSight. The `com.apple.security.device.usb` entitlement enables applications to access USB devices.

Any *App Sandbox*–protected application lacking the `usb` entitlement would be prohibited from reprogramming the iSight and thus prohibited from disabling the indicator LED. Although an application with the `usb` entitlement but lacking the `camera` entitlement would be prohibited from using the high-level APIs for accessing the camera, such as the QTKit API [3], it could easily reprogram the camera to not appear as a USB video class (UVC) device and instead transfer the frames of video using a custom protocol.

The major drawback to using the *App Sandbox* to protect the camera is that applications need to opt into the protection, something malware is unlikely to do. Worse, the *App Sandbox* has, at times, been broken allowing applications to escape from the restrictions [12, 38].

Perhaps the best way to defend against reprogramming the iSight without changing the hardware is to modify the operating system to prevent particular USB device requests from being sent to the camera. We have built such a defense structured as an OS X kernel extension called *iSightDefender*.

When iSight is powered for the first time, it enumerates with vendor ID `0x05ac` and product ID `0x8300` and is programmed with the legitimate firmware via the *AppleUSBVideoSupport* kernel extension as described in Sections 3.3 and 4.2. When it reenumerates with product ID `0x8501` the kernel matches and loads the normal drivers as well as *iSightDefender*.

I/O Kit kernel drivers are written in a subset of C++ and each USB device is represented by an object of class `IOUSBDevice` which is responsible for communicating with the hardware by sending messages to objects in lower layers of the USB stack. When *iSightDefender* is started, it overwrites the C++ virtual method table of its "provider" `IOUSBDevice` to point to the virtual method table of a subclass of `IOUSBDevice`.[7] The subclass overrides the four `DeviceRequest` member functions. The overridden implementations check if the device request is for the "Firmware Load" vendor-specific request and, if so, log the attempt in the system log and block the request.

iSightDefender is able to block all user space reprogramming attempts,[8] including those mounted from within a virtual machine. The latter requires some care as the normal drivers that match against the `IOUSBDevice` are unloaded and the virtual machine monitor's own driver is loaded in their place.

Using *iSightDefender* raises the bar for attackers by requiring the attacker to have root privileges in order to reprogram the iSight. In some sense, this is the strongest possible software-based defense. Since malware running as root would have the ability to replace or modify kernel code, any defense implemented in the kernel can, theoretically, be bypassed. Despite this limitation, we believe it is a step in the right direction and encourage its use.

iSightDefender, and its source code, is freely available.[9]

8 Secure camera designs

When designing a secure camera, there are two main considerations. First, for sensors such as cameras and microphones, an indicator that the sensor is recording is essential to prevent surreptitious recording. (Although laptop microphones do not, in general, have indicators, it is common for stand alone USB microphones; see [29] for an example.) For the highest level of assurance that the indicator cannot be bypassed, the indicator should be controlled completely by hardware.

Second, as with any peripheral connected to the computer, a vulnerability in the firmware running on the peripheral or the ability to reprogram the firmware enables an attacker to leverage all of the capabilities of the peripheral. Section 2 contains numerous examples of this. The virtual machine escape in Appendix A is another example where an attacker leverages the USB connection and the ability of the EZ-USB to mimic any USB device to the host computer. Apple's most recent FaceTime cameras in its 2013 MacBook Air model eschews USB 2.0. Instead, the camera is connected to the host computer over PCIe [35]. Vulnerabilities in the camera would potentially enable an attacker to have DMA access to the host system. This is a significantly stronger capability than USB access.

8.1 Secure indicators

Laptop cameras are typically constructed by pairing a CMOS image-sensor-on-a-chip (e.g., the Mi-

[6] Formerly codenamed *Seatbelt*.

[7] There seems to be no supported mechanism for interposing on USB device requests. The authors appreciate the irony of using virtual table hijacking — a common hacker technique — for defending against attack.

[8] In fact, *iSightDefender* worked so well that one author spent more than an hour attempting to diagnose (nonexistent) problems with *iSeeYou* before noticing the tell-tale lines in the system log indicating that *iSightDefender* had been loaded by a computer restart and it was blocking reprogramming requests.

[9] `https://github.com/stevecheckoway/iSightDefender`

cron MT9V112 found in the iSight or the Toshiba TCM8230MB(A)) with a separate microcontroller that handles communication with the host computer (e.g., the EZ-USB FX2LP found in the older MacBooks or the Vimicro VC0358 [61] found in more recent MacBook Pros [28]. There are, of course, many possible combinations of image sensors and microcontrollers one could use.

Image-sensors-on-a-chip tend to have a number of common features that can be used to build a secure indicator.

1. Separate power connection for CMOS sensor itself. For example, `VAAPIX` on the MT9V112 powers its pixel array and `PVDD` on the TCM8230MB(A) powers its photo diode. A GPIO pin on the microcontroller can be connected to both the LED driver circuit and the CMOS sensor power supply circuit. Whenever images are to be captured, the microcontroller sets its GPIO pin appropriately, power is supplied to the sensor and the LED turns on.
2. `#RESET` pins. The LED driver circuit can be connected to the `#RESET` pin and a GPIO pin on the microcontroller. The microcontroller would hold the image sensor in reset whenever it was not capturing images. Compared to the power connection for CMOS sensor, holding the entire sensor-on-a-chip in reset means that before images could be captured, the sensor would need to be reconfigured. Reconfiguring typically means sending a few dozen bytes over an I^2C or SPI bus. This introduces a slight delay.
3. Output clocks and synchronization signals. Image sensors typically latch outputs on one edge of an output clock signal and image consumers are expected to read the data on the other edge of the clock. In addition, there are signals used to indicate which part of the image the latched data represents. For example, the MT9V112 has `FRAME_VALID` and `LINE_VALID` signals indicating when it's outputting a frame or a line within the frame, respectively, whereas the TCM8230MB(A) has `VD` and `HD` for vertical and horizontal synchronization. These pins can also be used to control the LED by adding some simple hardware that drives the LED if it has seen one of these signals change in the past few milliseconds.

   Depending on the specifics of the image sensor output signal, a retriggerable, monostable multivibrator can be used to drive the LED as long as its input changes sufficiently often. The multivibrator's output pulse width needs to be set appropriately such that it is triggered frequently enough to continuously drive the LED while images are being recorded.

   Some care must be taken when using these output signals. The exact meanings of the signals can frequently be changed by configuring the sensor. This is analogous to the situation with the iSight where we changed the meaning of the `STANDBY` signal.

An all-in-one design where the image sensor is integrated with the microcontroller which communicates to the host computer is likely to have fewer options for a secure design. A dedicated output pin which could drive an indicator LED would suffice. However, hardware designers are typically loathe to dedicate pins to specific functions, instead a variety of functions tend to be multiplexed over a single pin.

It is likely that, even in this case, there would be a separate power connection for the CMOS sensor. As with the two-chip design above, the LED driver circuit and a power supply circuit could be driven by a GPIO.

8.2 Secure firmware

Although using one of the secure indicator designs described above will ensure the LED will turn on when the camera turns on, it does nothing to protect against reprogramming attacks.

For this, we make four concrete recommendations which, taken together, can secure the firmware on the camera. These apply more generally to any peripheral or embedded system connected to a host computer.

1. Store the firmware in nonvolatile storage on the camera module. Most commercial off-the-self (COTS) microcontrollers contain some amount of nonvolatile storage, such as flash memory, to hold firmware.[10] By programming the firmware at the factory, one avoids the possibility that the legitimate firmware will be replaced by an attacker on the host system before being downloaded to the microcontroller.

   Depending on the specific requirements of the system, the factory programming could be the complete firmware or a secure loader designed to load cryptographically signed firmware from the host (see below).
2. Use a microcontroller which can block unwanted firmware reprogramming attempts. It is essential that trusted code running on the microcontroller is able to block reprogramming attempts for illegitimate firmware.
3. Firmware updates, if necessary, should be cryptographically signed and the signature verified before applying the update. This requires both nonvolatile storage for the code to verify the signature and a microcontroller which can block reprogramming attempts. Since microcontrollers are typically resource constrained devices, choosing an appropriate signature scheme which can be implemented within the

[10] Microcontrollers without nonvolatile storage can be paired with external nonvolatile storage, such as flash or an EEPROM, to the same effect.

constraints is important. Scheme selection is outside the scope of this paper but we note that recent microcontrollers have started to contain specialized crypto instructions which can reduce code size and increase efficiency. For example, Rohde et al. [53] use specialized AES instructions in some Atmel ATxmega microcontrollers to implement the Merkle signature scheme.

4. Require root/administrator privileges to send reprogramming requests. Strictly as a matter of defense in depth, software running on the host system should restrict reprogramming attempts. Thus, even if the hardware and firmware defenses prove inadequate, this added layer of protection can still defend against some attacks.

   Adding this sort of restriction typically involves a device-specific kernel module (our *iSightDefender* is an example). This may be more difficult for plug and play devices expected to conform to standard protocols and interact with generic drivers such as USB video class (UVC) or USB human interface device (HID) class devices.

The inability of the EZ-USB to block reprogramming attempts indicates that this widely-used microcontroller is inappropriate for use in any system where security is a consideration.

Secure physical user interface Orthogonal to secure indicators and secure software is a secure physical user interface. Most webcams in laptops are controlled by software: Software tells the camera when to power up, when to capture video, and when to power down. A simple solution to the problem is to provide a physical switch similar to the switches found on laptop network adapters which controls power to the camera. A second simple solution is to provide a lens cover which the user must physically move aside to use the camera. This would be similar in spirit to the original external iSight and similar in form to the amusingly named iPatch [58].

9 Discussion

Although some webcams, such as the Logitech QuickCam Pro 9000, come with an explicit "LED control" that can disable the LED [64], such controls are not the norm and, in fact, are a very bad idea from both a security and a privacy stand point. Giving the user the ability to disable a privacy feature is tantamount to giving malware the same capability.

This work concerns the technical challenge of hardware exploitation; however, we would be remiss if we did not discuss the (frequently unpleasant) real-world consequences of vulnerabilities in privacy technology.

A particularly unsavory element of the hacker culture, "ratters," install malware bundled with remote administration tools (RATs) on victims' computers. There are several popular RATs, including Blackshades and DarkComet, which come with a variety of features such as keyloggers, the ability to install additional malware, and the ability to record video and sound using the webcam. Rats are often installed with the goal of spying on women.

RATs and the ratters who use them have recently come under public scrutiny after a recent Miss Teen USA's webcam was used by ratter Jared Abrahams to capture her naked images without her knowledge [15]. Abrahams arrest and guilty plea came on the heels of an ars technica exposé on ratters [1].

A commonly asked question on forums devoted to ratting, such as the *Hack Forums* "Remote Administrator Tools" forum, is how can one disable the webcam's LED. In one representative thread, forum user "Phisher Cat" asks

> So as all of you know, newer laptops have a light when a laptop webcam turns on, and so this scares the slave.
>
> Is it theoretically possible for a RAT to disable this light? [47]

disturbingly referring to his victim as "the slave," as is common in this subcommunity. The first response by "Jabaar" notes that "[p]eople have been trying to figure this out for a very long time. The light won't be able to be disabled as it is built into the hardware." Others agree: "Capital Steez" writes that there is "no way to disable it," and "FBI™" concurs "there [i]s no way to do" it. Still others suggest using social engineering in an attempt to convince the victim that the LED is normal, for example, "Orochimaru" writes, "You can't physically turn it off but you **can** use social engineering to fool them. Maybe send an error or warning msgbox that says 'Camera is now updating, please do not disturb' or something." There are many such threads on Hack Forums alone, all expressing similar sentiments: disabling LEDs is a capability the ratters *really* want to have but do not think is possible.

Unfortunately, the implications of surreptitiously capturing video do not end with privacy violations like law enforcement, school officials, and ratters spying on people. As part of the general trend of growing frustration with passwords as an authentication mechanism, some companies are moving to biometric identification; in particular, using facial recognition on video taken with webcams. For example, BioID is software-as-a-service which provides biometric identification to online service providers using a webcam [8]. Luxand's *FaceSDK* is a cross-platform software development kit that uses the webcam to identify the user [34].

In principle, this sort of facial recognition is trivially defeated by providing the expected picture or video to the software performing the authentication. Malware that

can capture video of the victim can replay that video to authenticate to the given service. This is not a new attack. The Android *Face Unlock* system was defeated shortly after being released by holding a picture of the face in front of the camera [9]. Duc and Minh [16] describes weaknesses of several facial recognition authentication systems in the presence of pictures. By disabling the indicator LED before capturing video, the victims have no way of knowing that their accounts may be compromised.

Although the ability to disable the LED can lead to serious privacy and security problems, there are at least two legitimate use cases. The first is that some people really do not want the LED on while they are recording. We do not find this to be a compelling use as the benefit does not seem to outweigh the potential cost; however, others may value this more than we do.

The second use case is significantly more compelling: laptop recovery. For example, the OS X version of *Adeona* software captures pictures using the laptop's internal iSight to aid in recovery of a laptop that has been stolen by taking a picture of the thief [51, 52]. The *LANrev* software used in the Lower Merion School District incident discussed in the introduction had a similar "Theft Track" feature which is how the school officials were able to obtain pictures of students. For this use, one does not want the thief to know he is being observed.

10 Responsible disclosure

The authors followed responsible disclosure practices by disclosing the LED disabling vulnerability to Apple product security team on July 16, 2013 and the virtual machine escape on August 1, 2013. The disclosures included the source code for *iSeeYou* and the virtual machine escape as well as directions for mounting both attacks. Apple employees followed up several times but did not inform us of any possible mitigation plans. The *iSightDefender* code was also provided to Apple and is now publicly available.[11]

11 Conclusions and future work

Engineering details of privacy technologies can have real-world consequences. As discussed in Sections 1 and 9, a computer user today potentially faces a variety of adversaries — from law enforcement and school officials to criminals — who want to capture images or video clandestinely. Currently, the only technological barrier standing in their way is the camera-on indicator LED. We have shown that, at least in some cases, the barrier can be overcome.

In particular, we have shown that being able to reprogram the iSight from user space is a powerful capability. Coupled with the hardware design flaw that allows the indicator LED hardware interlocks to be bypassed, malware is able to covertly capture video, either for spying purposes or as part of a broader scheme to break facial recognition authentication. Although the *iSightDefender* defense described in Section 7 raises the barrier for malware, including RATs, to take control of the camera without being detected by requiring root privileges, the correct way to prevent disabling the LED is a hardware solution.

In this paper, we have examined only a single generation of webcams produced by a single manufacturer. In future work, we plan to expand the scope of our investigation to include newer Apple webcams (such as their most recent high-definition FaceTime cameras) as well as webcams installed in other popular laptop brands.

The virtual machine escape described in Appendix A demonstrates the danger that reprogrammable peripheral devices such as keyboards and mice pose. We plan to undertake a much broader examination of these devices in an attempt to understand the security implications of connecting one device to a computer which can, under attacker control, pretend to be a wide range of devices. One particularly promising direction is to study how drivers react to malformed or malicious responses from devices. In the worst case, a user space program could reprogram a peripheral device which in turn exploits a poorly written driver to inject code into the kernel.

A Virtual machine escape

The reprogramability of the iSight firmware can be exploited to effect a virtual machine escape whereby malware running in a guest operating system is able to escape the confines of the virtual machine and influence the host operating system.

One method is to reprogram the iSight from inside the virtual machine to act as a USB Human Interface Device (HID) such as a mouse or keyboard. Once the iSight reenumerates, it would send mouse movements and clicks or key presses which the host operating system would then interpret as actions from the user.

To demonstrate the feasibility of a virtual machine escape from a VirtualBox virtual machine, we implemented a USB HID keyboard which, once loaded, performs the following actions in order:

1. send a "host key" press;
2. send command-space to open *Spotlight*;
3. send the key presses for "Terminal.app" one at a time;
4. wait a few seconds, send a return key press, and wait a few more seconds for the *Terminal* to open;
5. send the key presses for a shell command followed by a return key press;
6. disconnect from the USB bus and modify its USB device descriptor to use the product ID `0x8300` — the PID for the iSight in its unprogrammed state; and
7. reenumerate.

The VirtualBox host key, which defaults to the left command key on a Mac host, releases keyboard ownership, causing the rest of the key presses to go to the host operating system rather than to the guest operating system [45, Chapter 1].

Figure 4 shows an iSight that has been reprogrammed from inside a VirtualBox virtual machine sending key presses to *Spotlight*, instructing it to open *Terminal.app*.

When a new keyboard is first plugged into the computer, the *Keyboard Setup Assistant* asks the user to press several keys in order to determine the keyboard layout. This behavior appears to be controlled by the vendor ID, product ID, and device release number. By using the appropriate values for an Apple USB keyboard, the assistant

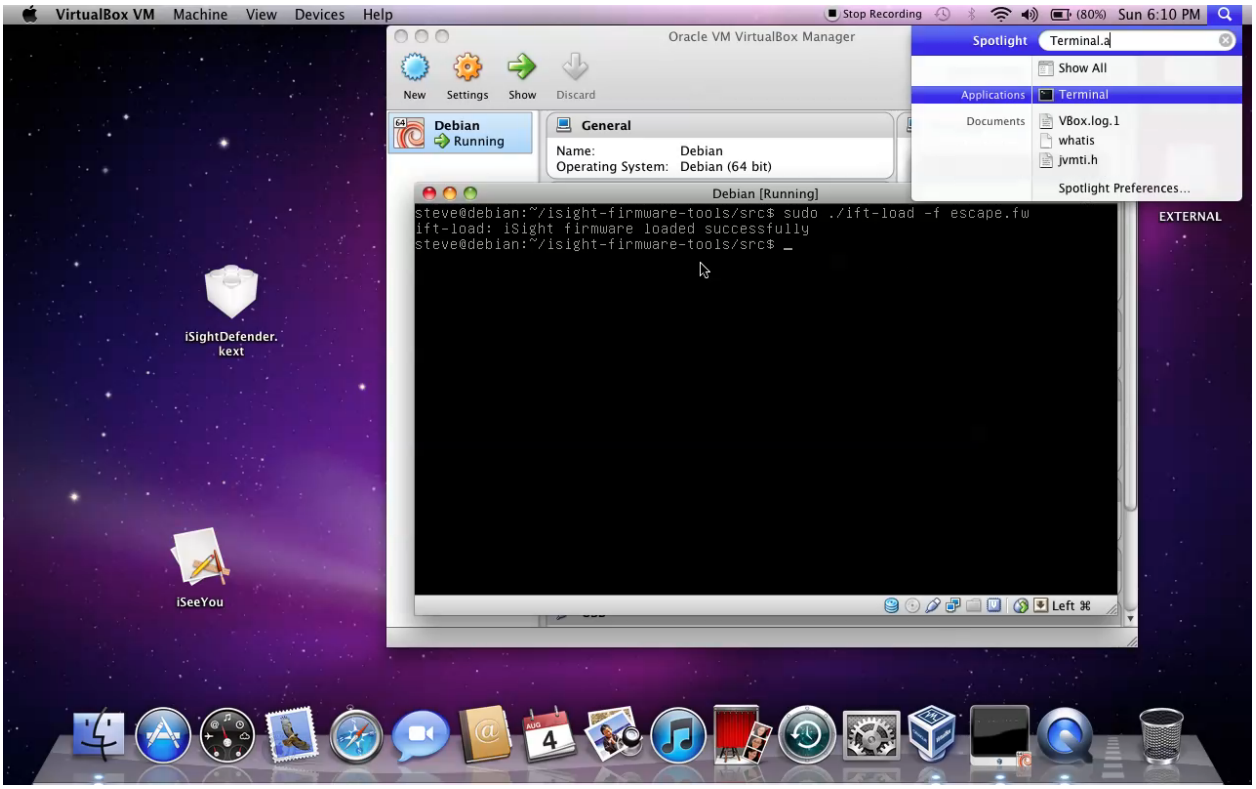

Figure 4: Virtual machine escape. The iSight has been reprogrammed to act as a USB keyboard from inside a VirtualBox virtual machine and it is sending key presses to the host operating system. It is in the middle of entering "Terminal.app" into *Spotlight*.

does not appear and there is no visual indication that the operating system believes a new keyboard has connected.

The shell command entered into the *Terminal* is unconstrained and could, for example, use *curl* to download arbitrary, new code and run it.

After the iSight has finished typing commands, it reenumerates as an unprogrammed iSight which causes the *AppleUSBVideoSupport* driver to reprogram it with the legitimate iSight firmware, removing evidence that the iSight was the infection vector.

Although we use the iSight to escape from the virtual machine, in theory, any EZ-USB device which is accessible from inside the virtual machine can be reprogrammed to behave as a HID keyboard.

The one major limitation is that the USB device must be connected to virtual machine before the attack is possible. By default, virtual machine monitors do *not* provide this connection for most devices and thus malware would need to coerce the user into establishing the connection.

Even with the device connected to the virtual machine, there is no feedback to the firmware that the attack is proceeding as planned. All it can do is send key presses in response the USB polling. If the user is sitting in front of the computer, the key presses sent by the iSight may be apparent and the user can interfere by performing an action such as typing or clicking the mouse. One way to partially compensate is to decrease the USB polling interval by changing the USB endpoint descriptors in the firmware allowing the iSight to send key presses more quickly.

Each operating system has its own policy which governs a process's ability to send USB device requests. On Linux, this is controlled by *udev*. In Figure 4, we used *sudo* inside the virtual machine to bypass the access controls of the guest operating system. Alternatively, the appropriate permissions could be granted to the user. One of these steps is required even though the host operating system, OS X, imposes no restrictions on the use of USB device requests. Since each guest operating system controls access to the USB device once it has been connected to the virtual machine, to perform an escape, malware must first acquire sufficient privileges in the guest operating system to reprogram the camera — a potentially nontrivial feat.

From the Aether to the Ethernet – Attacking the Internet using Broadcast Digital Television

Yossef Oren, Angelos D. Keromytis
Columbia University

25th May 2014

Abstract

In the attempt to bring modern broadband Internet features to traditional broadcast television, the Digital Video Broadcasting (DVB) consortium introduced a specification called Hybrid Broadcast-Broadband Television (HbbTV), which allows broadcast streams to include embedded HTML content which is rendered by the television. This system is already in very wide deployment in Europe, and has recently been adopted as part of the American digital television standard.

Our analyses of the specifications, and of real systems implementing them, show that the broadband and broadcast systems are combined insecurely. This enables a large-scale exploitation technique with a localized geographical footprint based on radio frequency (RF) injection, which requires a minimal budget and infrastructure and is remarkably difficult to detect. Despite our responsible disclosure to the standards body, our attack was viewed as too expensive and with limited pay-off to the attackers.

In this paper, we present the attack methodology and a number of follow-on exploitation techniques that provide significant flexibility to attackers. Furthermore, we demonstrate that the technical complexity and required budget are low, making this attack practical and realistic, especially in areas with high population density – in a dense urban area, an attacker with a budget of about $450 can target more than 20,000 devices in a single attack. A unique aspect of this attack is that, in contrast to most Internet of Things/Cyber-Physical System threat scenarios where the attack comes from the data network side and affects the physical world, our attack uses the physical broadcast network to attack the data network.

1 Introduction

The battle for the living room is in full swing. After being used for decades as purely passive terminals, our television sets have become the subject of intense, competitive attention. Technology companies wish to use the Internet to create a viewing experience which is more engaging, interactive, and personalized, and in turn maximize their ad revenue by offering advertising content which is better targeted at the user. As the result of this trend, most US and European households with broadband Internet access now have at least one television set which is also connected to the Internet [37, 27], either directly or through a set-top box or console. In technical terms, a device which has both a **broadcast** TV connection and a **broadband** Internet connection is called a **hybrid terminal**. The specification that defines how to create and interact with "hybrid content" (which combines both broadcast and broadband elements) is called **Hybrid Broadcast-Broadband Television**, or *HbbTV*.

At its core, HbbTV combines broadcast streams with web technologies. The broadcast channel, augmented with the notion of separate digital streams, allows the transmission of distinct yet intertwined types of content that enable rich-interaction experience to the user. However, this enhanced interaction introduces new vulnerabilities to what was until now a conceptually simple network (TV broadcasting) and media-presentation device.

This paper examines the security impact of emergent

properties at the intersection of digital video broadcasting and web technologies. The work presented here is based both on analysis of the HbbTV standard and on experimentation with actual DVB hardware. The attacks were crafted using low-cost hardware devices using open-source software, and they are extremely easy to replicate.

While the impact of many of these attacks is exacerbated by poor implementation choices, for most attacks the core of the problem lies with the overall architecture, as defined in the specification itself. Thus, our findings are significantly broader than the specific devices that we used in our analysis; indeed, *any* future device that follows these specifications will contain these same vulnerabilities. Exploiting these vulnerabilities, an attacker can cause many thousands of devices to interact with any website, even using any credentials stored in the TV sets for accessing services such as social networks, webmail, or even e-commerce sites. This capability can be leveraged to perform "traditional" attack activities: perform click-fraud, insert comment or voting spam, conduct reconnaissance (within each home network or against a remote target), launch local or remote denial of service attacks, and compromise other devices within the home network or even elsewhere. Beyond these, the attacker can also control the content displayed on the TV, to craft phishing and other social engineering attacks that would be extremely convincing, especially for TV viewers who are educated to (and have no reason not to) trust their screens. Finally, the attacker can use the broadcast medium to effectively distribute exploits that completely take over the TV set's hardware. Most of these attacks require no user knowledge or consent – the victims are only required to keep watching their televisions. The unique physical characteristics of the broadcast TV medium allow these attacks to be easily amplified to target tens of thousands of users, while remaining **completely undetectable**. Remarkably, the attacker does not even require a source IP address.

Today's smart TVs are already very complex devices which include multiple sensors such as cameras and microphones and store considerable amounts of personal data. Equipment manufacturers are busy adding more hardware and software capabilities to these devices, with the aim of turning them into the center of the user's digital life. Obviously, as smart TVs become more capable, and as users use them for more sensitive applications, the impact of the attacks described here will only grow.

One interesting, perhaps unique aspect of the problem space we are examining here is the reversal of attack source and destination domains: in typical attacks against Internet-connected physical systems, large-scale device compromise through the data network can lead to physical exploitation with a large (perhaps global) geographical footprint. With HbbTV, a physical attack with a relatively large geographical footprint can lead to large-scale data network compromise, at least in areas with high population density. The essence of the problem we address lies in that the hybrid TV now connects the broadcast domain, which has no authentication or protection infrastructure, to the broadband Internet domain. This allows the attacker to craft a set of attacks which uniquely do not **attack the TV** itself, but instead **attack through the TV**.

1.1 Disclosure and response

Our work addresses a security risk in a specification which is already in very wide use in Europe, and is on the verge of expanding to the US and to the rest of the world. We thus made an effort to responsibly disclose our work to the relevant standards bodies. In December 2013, we provided a description of our RF-based attack, together with a video recording of an attack in progress, to the HbbTV Technical Group. In January 2014 we were informed that the HbbTV Technical Group discussed our disclosure, but did not consider the impact or severity of these attacks sufficient to merit changes to the standard. There were two main criticisms raised by the HbbTV Technical Group. The first criticism was that it would be very difficult for the attacker to reach a large number of systems; the second was that, even when an attack is carried out, a Smart TV has a very limited attack surface, so attacks would not be cost-effective. We explicitly structured this paper to address both of these criticisms – we quantitively demonstrate how a low cost attack can reach thousands of systems, and we show how attacks can cause a considerable amount of damage and provide a real financial gain for the attacker.

Document Structure: The rest of the document is arranged in the following manner: Section 2 provides a high-level overview of digital video broadcasting. In Section 3, we describe the fundamental weaknesses of the protocol which enable our attack and propose an attack

setup designed to exploit them. Next, in Section 4 we describe a series of possible attacks based on these weaknesses. We continue in Section 5, where we quantitatively analyze the impact potential of our attack, based on the power and propagation characteristics of the attack setup and on actual demographic information. In Section 6 we experimentally verify several of our proposed attacks. In Section 7 we analyze the financial impact our attacks and evaluate several possible countermeasures. Finally, we conclude in Section 8.

2 Fundamentals

The vision of an Internet-powered living room brings to mind products such as on-demand video streaming or cloud-delivered gaming. However, the masters of the living room are still the incumbent operators of existing television broadcast networks, who broadcast their content to billions of viewers worldwide. In order to compete with the new generation of entertainment content, the operators of these broadcast networks are also looking for ways to add Internet-based functionality to their traditional content. For example, a broadcast television channel might use Internet functionality to ask its viewers to participate in an online poll, or to vote for a candidate in a game show. The broadcast channel might also invite the viewer to learn more about an advertised product using interactive web content, or even replace regular broadcast advertisements with custom-delivered Internet ads personalized to the particular user. In this form of content delivery enhances traditional broadcast content with an interactive HTML overlay, rendered by the TV together with the normal broadcasted channel. This content is commonly called "**Red Button Content**", since pressing the red button on the TV remote is (by convention) the standard way of interacting with it.

The specification defining this behavior is called **Hybrid Broadcast-Broadband Television**, or HbbTV, and it is maintained by the European standards body ETSI [10]. The current generation of the specification, version *1.2.1*, is enjoying very rapid adoption and is in active deployment or in advanced stages of testing in most of Europe. In December 2013, the Advanced Television Systems Committee (ATSC), which defines the digital video standards in the US, Canada, South Korea and several other countries, published a candidate standard for hybrid TV in America [6]. This candidate standard shares much of its structure with the European HbbTV standard, and is specifically equivalent to the European standard with respect to the attacks described in this paper.

HbbTV is designed to work on top of a standard Digital Video Broadcasting (DVB) system. While DVB can be delivered over cable, satellite or standard terrestrial signal, each with its unique radio frequency (RF) modulation and transmission scheme, the underlying digital stream is essentially the same for all delivery methods. This stream takes the form of an MPEG-2 **Transport Stream** [23], which multiplexes together multiple data streams named MPEG-2 **Elementary Streams**. Each elementary stream carries an individual element of a television channel, such as video, audio or subtitles. Special **metadata streams,** which the specification refers to as **information tables,** are then used to group together multiple elementary streams into an individual TV channel and provide additional information about the channel such as its name, its language and the list of current and upcoming programs. A single radio physical frequency may thus carry multiple channels.

2.1 Mixing broadcast and broadband

The HbbTV specification extends standard DVB by introducing additional metadata formats which mix broadband Internet content into the digital television channel. While the specification proposes multiple ways in which web content can be used in a TV, this article will focus on the most common form of content, **autostart broadcast-dependent applications**. This form of content starts running automatically when the user tunes into a particular TV channel, and terminates when the user moves to another channel. To create an autostart broadcast-dependent application, the broadcaster includes in the MPEG transport stream an additional **application information table** (AIT) describing the broadband-based application, then references this table in the **program mapping table** (PMT) describing a certain TV channel. The HbbTV specification defines two possible ways of providing the application's actual web content (*i.e.,* HTML pages, images, and scripts). One way is to have the AIT include a URL that points to a web server hosting the application. Another possible way is to create an additional data

stream which includes the HbbTV application's HTML files, deliver this additional elementary stream over the broadcast transport, and finally have the AIT point to this data stream. The way in which the latter embedding method was realized leads to a serious security problem, as we discuss later.

Regardless of the delivery method, Internet content is rendered by the TV using a specially-enhanced web runtime, described in the HbbTV standard as a Data Execution Environment (DAE) [14]. In addition to the document object model (DOM) elements available to normal HTML environments such as XmlHttpRequest, the DAE exposes additional DOM elements which are specific to the television world (for example, information about the running program and the current channel). The DAE also allows programatic access to the live TV broadcast window. Thus, it is possible for an HbbTV application to render content on top of the TV broadcast, resize the broadcast window or even completely replace the broadcasted content with its own content. On the other extreme, it is also possible for an HbbTV application to run without displaying any indication to the user. Practically speaking, most "benign" applications typically display a small overlay inviting the user to press the Red Button, then disappear to run transparently in the background.

2.2 Security in HbbTV

Smart TVs are built with some consideration of security, since they are often used to display content protected by digital rights management (DRM) schemes. Indeed, the HbbTV specification dedicates an entire chapter to security, but the discussion is mainly focused on protecting DRM content and not on other aspects of security. To that effect, the HbbTV specification describes trusted and untrusted applications, and restricts "sensitive functions of the terminal" only to trusted applications. Examples of such "sensitive functions" include downloading and playing back DRM-protected downloaded content (actions which may incur a cost on the viewer), as well as configuring and activating the terminal's scheduled recording (time-shifting) capabilities.

The attacks described in this work make use of capabilities which are available both to trusted and untrusted applications. None of the attacks described in this work are restricted in any way by HbbTV's security mechanisms. Furthermore, since the specification does not strictly define how an application can become trusted, it might be possible to inject an attack into a trusted application without changing its trusted status.

3 Attack Characterization

Several unique properties of HbbTV make it potentially prone to attack. These security weaknesses can all be considered **emergent** properties, which exist on the boundary between the broadband and broadcast systems, and stem from the different expectations and guarantees which exist in each system.

First and foremost, HbbTV applies a very problematic security model to web content embedded into the broadcast data stream. This is, in our opinion, the most serious security flaw in HbbTV, and one which has not been discussed in any previous work. One of the cornerstones of modern web security is the Same-Origin Policy [1], which essentially serves to isolate content retrieved from different origins and prevent content from one web site from interfering with the operation of another web site. Under the same origin policy, each piece of web content is provided with an origin consisting of a tuple of scheme, host and port, and two resources are limited in their communications unless they share the same origin.

When an HbbTV application is downloaded from the Internet via URL, the origin of the web content is clearly defined by the URL, appropriately isolating HbbTV applications to their own domain and preventing them from interfering with Internet at large. However, when the content is embedded in the broadcast data stream it is not linked to any web server and, as such, has no implicitly defined origin. The HbbTV specification suggests [10, S 6.3] that in this case the broadcast stream should **explicitly define its own web origin** by setting the `simple_application_boundary_descriptor` property in the AIT to any desired domain name.

The security implications of this design decision are staggering. Allowing the broadcast provider control over the purported origin of the embedded web content effectively lets a malicious broadcaster inject **any script of his choice** into **any website of his choice**.

An illustrative example of such an attack is presented in Figure 1. In this attack, which we dis-

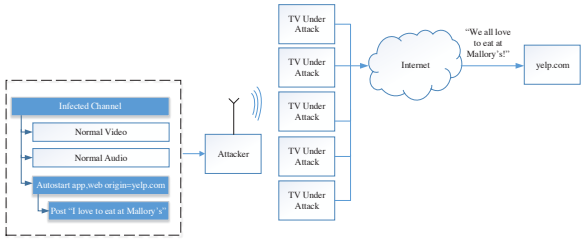

Figure 1: A practical attack based on a malicious HbbTV application. In this attack the malicious player forces multiple infected TVs to interact with a rating site and leave a favourable review for his restaurant.

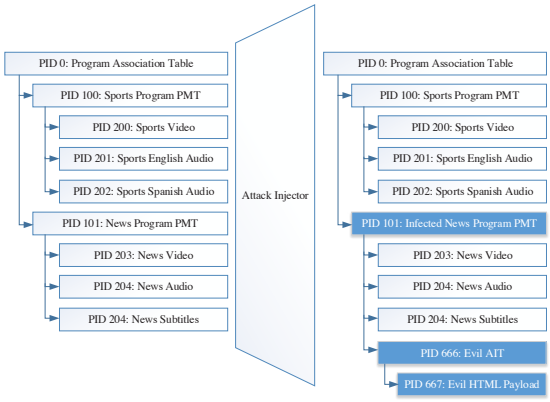

Figure 2: Injecting a malicious appication into a DVB stream. Note that only the program mapping table is modified, while the audio and video content is left untouched.

cuss more extensively in Subsection 4.2, the adversary delivers a malicious Javascript payload over HbbTV, and furthermore indicates by the `simple_application_boundary_descriptor` property in the AIT that this payload's web origin is a rating site. Next, the attacker has the TV render a simple HTML page which embeds the real rating site's home page (downloaded from the broadband Internet), as well as this script, in a zero-sized frame. The malicious script now has full programmatic access to the content delivered by the rating site, since it is running within the same web origin. To make matters worse, if the user has previously logged on to the site, this attack allows the attacker to fully interact with the website on the user's behalf. While the innocent viewers enjoy their normal television content, the malicious application causes their infected TVs to interact with the rating site over the Internet to leave favourable reviews for the attacker's restaurant or to harrass his competitors.

3.1 General Principle of Operation

We now describe how an attacker can use the vulnerability described above to launch a series of large-scale attacks. Our setup targets digital terrestrial television (DTT), which is the most common way in which television is received in many parts of the world [11]. In Subsection 7.2 we discuss how this attack can also be applied to other delivery methods such as cable or satellite.

Our attack works by creating a television broadcast which includes, together with the normal audio and video streams, a malicious HbbTV application. To maximize the effectiveness of our attack, we would like this as many users as possible to tune into this broadcast. The best way to do so is to carry out a form of **man-in-the-middle attack**, in which the attacker transparently modifies a popular TV channel to include a malicious payload.

Our attack module follows the general design illustrated in Figure 2. Following the notation of Subsection 2.1, the attacker adds into the intercepted stream a new **Application Information Table**, as well as a **data stream containing a malicious HbbTV application**, which the new AIT points to. The attacker then modifies one or more existing **Program Mapping Tables** to reference the new malicious application, while leaving the audio and video contents of the channel unmodified. It is important to note that the attacker does not have any form of control or cooperation with the radio tower itself.

The physical attack setup required by the attacker is illustrated in Figure 3. The attacker's uses a **receive antenna** connected to a **DVB tuner** to intercept a legitimate television signal, **modifies the content** of the DVB stream to add its malicious payload, and finally uses a **DVB modulator** connected through a **power amplifier** to a **transmit antenna** to re-transmit the modified signal to the **TV under attack** using the same frequency as the original broadcast. The TV under attack is, in turn, connected to the Internet.

Our attack works because in a certain geographic area

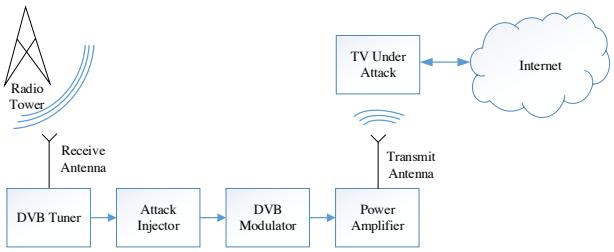

Figure 3: Attack Setup

around the attacker the malicious modified signal will be stronger than the original signal transmitted by the tower. This will cause any televisions in the area to immediately fall victim to the attacks described below. We note that since in digital broadcasting multiple TV channels are sent from the radio tower using the same radio frequency, a single attack setup is capable of injecting attack code into several channels simultaneously.

The characteristics and estimated cost of each of the components in Figure 3 are presented below:

Receive antenna and DVB tuner – a USB-powered DVB tuner and a short passive antenna can be purchased online for about $15. The open-source VLC media player [33] is capable of interfacing with many of these tuners and sending the demodulated stream extracted from an entire RF channel to a file or a network socket.

Content modification – the demodulated stream is modified to contain a malicious application (either as a URL, or as a full application delivered via data stream), and the PMTs of all TV channels in the demodulated stream are modified to auto-start this application as soon as the user tunes into the channel. Since the video and audio streams in the channel are forwarded without any modification, this operation is not particularly computation intensive, and any low-cost computer with USB 2.0 support can be used for this purpose. A software suite named Avalpa OpenCaster [8] provides a set of open-source command-line tools which can be used to modify a multiplexed DVB stream in real time.

DVB modulator – this hardware component takes a multiplexed MPEG stream and converts it into an RF signal suitable for transmission. While these devices were once massive and expensive, modern DVB modulators are remarkably small and easy to use – a full-featured USB-powered modulator which can interface with OpenCaster can be purchased online for less than $200.

Power amplifier and transmit antenna – the attacker needs to create a signal that is stronger than the original TV tower's signal and transmit it toward the target televisions. An attacker with a higher transmit power can affect more television sets, but a high-power setup is generally less portable, giving the attacker a higher probability of being detected and arrested. In Section 5 we formally analyze the power requirements of the attacker and show that, under the right conditions, a remarkably high amount of television sets can be affected with a moderate-to-low powered amplifier.

3.2 Additional Security Weaknesses

3.2.1 Attacks are untraceable

In traditional Internet-borne attacks, it is always assumed that the attacker is himself present on the Internet before he can deliver a malicious payload to his victims. The attacker's IP and DNS entries can then be used by intrusion protection services and law enforcement agencies to protect against the attack as it occurs, and to trace and prosecute its perpetrators after it has concluded. In contrast, our attacker needs no such infrastructure to deliver its malicious payload. It is surprisingly simple and inexpensive to build a digital terrestrial television (DTT) transmitter and use it to reach thousands of potential hosts. After the attack concludes, the attacker leaves no trace of his activities in the form of IP or DNS transactions.

Operating an unlicensed TV transmitter is illegal in many countries. Law enforcement agencies capture these illegal transmitters by **triangulation** methods, which involve sending multiple car-mounted receivers to the vicinity of the attack, then using the differences in received signal strengths between receivers to locate the rogue transmitter. A sensitive receiver can also "fingerprint" the rogue transmitter's RF envelope and help recognize it in the future. While this defense mechanism can potentially trace our radio attacker, mobile triangulation is a **reactive** defense step, which requires a considerable expense of time and resources from the defender's side. Considering that the attack we describe has a very limited geographical signature, operates for a very limited time (potentially only a few minutes), and causes no visible adverse effects

to the user, it is highly unlikely that the attacker will be caught by these methods.

3.2.2 Attacks are invisible and unstoppable

HbbTV content is not required by standard or convention to offer any visual indication that it is running. Depending on the choice of the application creator, HbbTV content can run invisibly in the background, side by side with the broadcast content, or even take over part or all the user's entire screen. At one extreme, this makes it possible for HbbTV applications to run completely in the background without the knowledge or consent of the user. In [21] Herfurt discovered that many German broadcasters are using this functionality of HbbTV to invisibly track the viewing habits of users by periodically "phoning home" while the TV is tuned to a particular channel. At the other extreme, it is possible for an HbbTV application to take over part or all of the user's screen without his knowledge. Herfurt used this functionality to demonstrate a proof-of-concept application that replaces the news ticker of a German news channel with headlines from a satire website.

Another related weakness is the weak control the user has over the life-cycle of HbbTV applications. As described in Subsection 2.1, an application can start running automatically as soon as the user starts viewing a certain channel. More troubling is the fact that, once an HbbTV application has started running, there is no standard way of **stopping** it, short of switching a channel, turning off the television, or completely disabling HbbTV support.

4 Attacks

The attacks proposed in this Section are based upon our analysis of the HbbTV standards, as well as upon personal communications with the HbbTV technical group, who have confirmed that our attacks are possible given the current specification. Some of these attacks described below can be applied even to perfectly secure Smart TV implementations with no known exploits; Other attacks allow the attacker to transform local vulnerabilities on the Smart TV into automatic, large-scale distributed exploits. With the exception of the attack described in Subsection 4.5, all of these attacks take place without the user's knowledge or consent, requiring the user to do nothing more than keep his TV turned on and tuned to his favourite channel.

4.1 Distributed Denial of Service

To carry out this attack, the attacker creates a simple Red Button application which repeatedly accesses a target website with high frequency, using a simple mechanism such as a zero-sized `iframe` element or through repetitive calls to `XmlHttpRequest`. All TVs tuned to the infected channel will immediately start running the application, potentially overwhelming the target website. Due to the design of the HbbTV specification, the owners of TVs who are carrying out this attack have no knowledge that they are participating in this attack, nor do they have any way of stopping it.

This attack is the simplest abuse of the HbbTV protocol, and was also considered by [21], albeit in a different attacker model. As scary as this attack sounds, we note in Subsection 7.1 that there are far less expensive and risky ways of DDoSing a website.

4.2 Unauthenticated Request Forgery

This attack is similar to the previous attack, but this time the infected users do not blindly access the site under attack, but instead attempt to interact with it in a meaningful manner. For example, such an attack could skew the results of an online poll or competition, "spam" a forum with comments to the point of unreadability, falsely promote another website by "liking" or "upvoting" it, or falsely obtain ad revenue by programmatically clicking on an ad (a.k.a. "click fraud"). This attack venue is especially painful for the designers of HbbTV, since the entire point of the specification is to allow this type of interaction between TV viewers and websites.

This attack is a variant of traditional cross-site request forgery (CSRF) attacks, which are well-known to the security community [2]. However, one unique advantage of the HbbTV attack vector is that the attack is not "blind" – due to the unique way same-origin is implemented for HbbTV, the attack script can fully interact with the static and dynamic content of the page with the full permissions of a human user accessing the webpage. This defeats many of the state-of-the-art defenses against CSRF, which operate by embedding session and authentication

tokens in locations which are only accessible within the same origin as the protected web page.

4.3 Authenticated Request Forgery

An interesting twist on the previous attack, this attack assumes that the user has previously authenticated to a certain website using another application on his Smart TV, and that the TV now holds a cookie, an HTML5 local storage element, or any other authentication token for this website[1]. When the infected application accesses the website, it will now automatically do so with the full credentials of the logged-in user, a fact which dramatically increases the damage potential of the previous attack. An infected application using this attack vector can, for example, post links to malware to the legitimate user's friends over Twitter or Facebook, purchase DRM-protected content whose royalties are pocketed by the attacker, or call a premium number using a VoIP application. As the usage scenarios of Smart TVs grow and users begin using them for more applications such as e-commerce and health, the damage potential of this attack will grow rapidly.

4.4 Intranet Request Forgery

This attack makes use of the fact that the Smart TV is most likely connected to a home wireless network shared with other devices such as wireless routers, personal computers and printers. Instead of attacking the whole Internet, the attacker instead mounts his attacks on those local intranet devices. The most basic attack would be a port scan to discover which devices are present on the home network (this can assist in planning a burglary). If vulnerable devices are discovered on the network, the attacker can also try and exploit them using the Smart TV. For example, the attacker can identify a vulnerable wireless router and a Windows PC, then proceed to modify the DNS settings of the router so that the PC is directed to a phishing website when it attempts to connect to a banking website. This attack, which again has been investigated in other works such as [26], is particularly effective due to the way same-origin is implemented on HbbTV. Remarkably, the attacker's code can freely interact with the device under attack and observe the results of its interaction, without requiring additional steps such as DNS rebinding.

[1] While the smart TV platform we evaluated had two separate "web runtimes" – one for the TV and one for the HbbTV stack – and thus kept credentials isolated, this behavior was probably caused by engineering concerns (two independent teams may have written the two runtimes, with no time for integration) and is in no way required by the standard.

4.5 Phishing/Social Engineering

As described in Subsection 3.2.2, HbbTV content is displayed on the user's television without any warning or notification, and the user cannot turn it off without turning off the TV itself. HbbTV content can completely overlay the user's TV broadcast and can programmatically interact with many of the buttons on the user's remote control. This direction, also investigated by Herfurt in [21], makes HbbTV content a natural vector for attacks which mislead the user into divulging sensitive information or otherwise acting in a harmful manner.

For example, a malicious HbbTV payload can notify the user that he must enter his credit card information to view some restricted content, compel the user to change the configuration of their network in a form that compromises their security (for example, instruct the user to press the WPS button on their wireless router, thus allowing a malicious device to join the network), or even encourage "real world" risky behavior, such as notifying the user that a "cable technician" is due to visit their house at a certain time and date, or that the TV needs to be "recalled" and physically delivered to the attacker. This attack is different than the other attacks described in this paper since it requires user interaction and, as such, is more likely to be detected or simply ignored. Obviously, the damage potential of this attack will increase in the future as more users are trained to interact with their TVs for applications other than passive content consumption.

4.6 Exploit Distribution

A modern smart TV is essentially a personal computer with a very limited user interface, running a highly modified version of Linux or Android. Just like normal PCs, security exploits are occasionally discovered in Smart TVs – either in the vendor's proprietary software, or in the device's various open-source underlying components. Just like normal PCs, Smart TVs also have automatic software update mechanisms which are generally successful

in keeping the TVs running smoothly and securely. However, the vulnerability-to-patch cycle for these devices is typically much longer than that of a desktop operating system, due to the additional steps required by the equipment vendor to implement, test and deploy security updates for this nonstandard platform. Whenever an exploit is discovered for a Smart TV platform, the combination of HbbTV's invisibility and undetectability make it a remarkably efficient method of distributing this exploit and compromising the TVs.

Assume, for example, that a Smart TV uses an open-source image processing library as part of its code. Assume now that a patch is released to fix a vulnerability in the upstream version of this component. While the equipment vendor is busy porting, testing and deploying a patch specifically tailored for the smart TV, an attacker can immediately craft an exploit corresponding to this vulnerability, embed it in a malicious Red Button application, then immediately deploy it to thousands of Smart TVs.

5 Scale Considerations

As stated in Subsection 1.1, one of the main criticisms directed at our work was the claim that it is very difficult for the attacker to infect large numbers of television sets. This Section quantitatively demonstrates how a low-budget attacker can modify and then overwhelm a TV tower's transmissions in a limited geographical area.

We first determine the approximate area an attacker can cover for a fixed transmit power. We assume that the **attack frequency** is approximately 500MHz, corresponding to the DVB-T UHF band. We assume that the unamplified signal exiting the attacker's modulator has a signal level of 0 dBm, and that the attacker uses an **omnidirectional antenna** which is in free space and on a level plane with the targeted devices. Thus, the attacker's output power is equal to the gain of his power amplifier G.

We further assume that the radio tower's original transmission is received by all targeted devices with a signal level T of -50 dBm, corresponding to a moderate to high signal level (digital television receivers can function at signal levels as low as -112 dBm, while the FCC defines the "City Grade" signal level for digital television at -61 dBm [5]).

Our final assumption is that, when receiving two competing DVB-T signals with the same frequency (a condition technically referred to as co-channel interference), the receiver will demodulate and display the stronger signal while ignoring the weaker signal. This assumption, which does not hold for analog transmission systems, is valid for DVB signals as long as the stronger signal overwhelms the weaker signal by some minimal amount (the International Telecommunications Union recommends in [24, Table 15] a power difference of 6 to 8 dB between the stronger station and the interfering weaker station, but a practical attacker who is not neccessarily standards compliant can get away with a much smaller margin).

The decay in decibels of a radio signal with frequency f (in Hz) over a distance d (in meters) is described by the Free Space Path Loss equation [30]:

$$FSPL = 20\log_{10}(d) + 20\log_{10}(f) - 147.55$$

We require that the attacker's signal will be more powerful than the radio tower's original signal:

$$G - FSPL > T$$

Assigning values to f and T we obtain that for a successful attack

$$G - 20\log_{10}(d) - 20\log_{10}\left(5 \cdot 10^8\right) + 147.55 > -50$$

Solving for d we obtain that

$$d < 10^{\frac{G}{20}+1.18}$$

Using this formula shows that with a 1 W (30 dBm) amplifier, whose cost is approximately $250, the attacker will be able to cover a region with radius of 477 m, or an area of 1.4 km^2. With a more powerful 25 W (44 dBm) amplifier, whose cost is approximately $1500, the attack can cover a region with radius 2385 m, or an area of 35 km^2. The attacker might have an incentive to use a lower-powered amplifier to reduce his risk of being detected by mobile triangulation methods (see Subsection 3.2.1).

Our next step was to demonstrate quantitatively that there exist densely-populated urban areas in which popular digital TV stations are received with a sufficiently low power level as to allow such an attack to be carried out.

Our analysis was based on the NASA SEDAC Metropolitan Statistical Areas dataset [35], which records

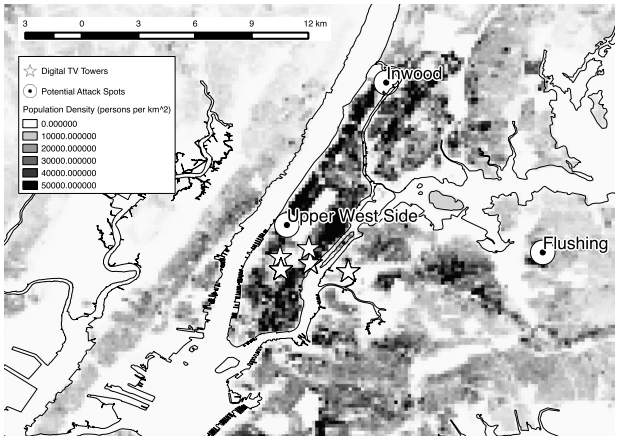

Figure 4: Attack potential – New York City. White stars identify digital TV towers. Bulls-eyes identify locations where an attack would be particularly effective.

demographic and socioeconomic data for 50 US cities, with a spatial resolution of approximately 250 square meters. We cross-correlated this dataset with the FCC database of digital TV towers in the United States and with station coverage maps supplied by TV Fool [13]. The TV Fool maps use 3D propagation modeling algorithms, and consider transmitter power, terrain obstructions and Earth curvature. Our objective was to find densely-populated areas in which a popular channel is received with a power of between -50 and -61 dBm. As a case study, we present our results for New York City in Figure 4 (more maps will be available in the extended version of this paper). The map shows the high-resolution population density of New York City, with the location of radio towers marked with white stars, and potential attack spots marked with bulls-eyes. Flushing, Queens, with a population density of 71,000 persons per km^2, is one example. There are 7 DTV stations with the desired characteristics in this location, most notably the Home Shopping Network. HSN can also be attacked in the Upper West Side, with a population density of over 80,000 persons per km^2. In certain locations in the Inwood area, where the population density is 50,000 persons per km^2, the attacker can infect 10 different stations, including CBS, NBC, Fox and the Spanish language Telemundo.

There are several limitations to this attack. The attacker obviously has to be physically present at the attacked location, and to have a line of sight both to the transmitter tower and to the antennas of the televisions under attack. In an urban setting this condition can be realised if the attack is carried out from the roof of an appropriately located tall building. To reduce the attacker's risk of capture and thus increase the effectiveness of the attack, the attacker can install the relay equipment on a remote controlled-drone and fly it to an appropriate location, similar to the work of [34].

The attacker would also need to prevent his receive antenna from picking up his own signal. This can be achieved by using a directional receive antenna directed toward the radio tower, together with a directional transmit antenna directed toward the TVs under attack, and finally locating the receiver setup in one of the transmitter's "dead zones". Using a directional antenna setup will change the shape, but not the general area, of the location under attack.

6 Experimental Validation

To show the validity of our claims, we created a test setup and experimentally reproduced a few of the attacks proposed in this paper. Our attacks were carried out on a modern Smart TV, manufactured in 2012 and running the latest software version supplied by the vendor. Our DVB demodulator was an OEM DVB-T stick based around the highly popular Afatech AF9015 chipset. The broadcast DVB stream was captured using VLC Player [33] running on Linux. Our DVB modulator was a DekTec DTU-215 unit, which was connected via USB to a low-cost laptop computer running Linux. For safety reasons our test setup did not include a power amplifier and transmitter antenna – instead, the DVB modulator was directly connected to the TV's antenna input through a 10 dB RF attenuator. The signal sent to the TV included different malicious HbbTV payloads created using the open-source OpenCaster package [8], version 3.2.1, and were played back to the TV using the DekTec StreamXpress software utility.

Using our test setup, we were able to create HbbTV applications which ran invisibly in the background, as well as applications which completely took over the TV screen. Using HbbTV, we were able to deploy the

Browser Exploitation Framework (BeEF) Toolkit [7] on the TV and use it to port scan the TV's intranet, examine the TV's runtime environment and display fraudulent login messages on the TV. We were able to crash the TV by having it render a malformed image file – a precursor for exploit distribution. Finally, we were able to craft a denial of service attack on an external web server, which ran as long as the user was tuned in to a particular channel. We verified that we were able to access servers both on the Internet at large and on the local intranet.

7 Discussion

7.1 Risk Assessment Analysis

Table 1 summarizes the attacks described in this paper and assigns each one with a qualitative complexity and damage potential. The justification for each qualitative complexity and damage assessment grade is provided below. In our analysis we assume the attack setup costs $450 in fixed costs, and that each attack costs an additional $50 per hour in variable costs (including equipment running costs and compensation for the risk taken by the attacker, who has to be physically close to the attacked location). We conservatively assume that the attack impacts 10,000 hosts – as we showed in Subsection 3.1, the attack can be easily scaled by one or more orders of magnitude by using a higher-powered amplifier.

The **denial of service** attack is the attack with the lowest complexity, since it requires no research on the side of the attacker, neither of the TV nor of the site under attack. However, its damage potential is also low, especially since it is not cost effective. As anecdotally shown in [3], a DDoS attack involving more than 20,000 hosts costs approximately $5 per hour. However, it must be noted that since the TV-based DDoS attack described here is localized to a single area, it can overwhelm a single edge node on a Content Distribution Network and thus deny service to other users in the same physical area.

The **unauthenticated request forgery** attack (in which an attacker uses HbbTV to vote in a poll, promote an article, or click an advertisement) also has low complexity, since it only requires minimal reverse engineering of the target web page. However, it has a higher damage potential than the DDoS attack, since it is much easier to monetise due to the possibility of click fraud [19]. According to Google's official figures, the average cost per click to advertisers in 2013 was $0.94, out of which 25% goes to the fraudulent advertiser [22]. This means the attacker can expect an income of around $2500 per attack even if every compromised host clicks only a single ad. In addition, since the interactive abilities abused by this attack are the main selling points of HbbTV, this attack has a wider area chilling effect of scaring advertisers and limiting the adoption of HbbTV.

The **authenticated request forgery** attack has a higher complexity than the previous two attacks, since it requires the attacker to discover and exploit a situation in which credentials are shared between the HbbTV runtime and other applications running on the Smart TV. However, this attack has a higher damage potential, since webmail and social network accounts are easier to monetise – according to [38] a verified Facebook account can retail for as much as $1.50, giving the attacker a potential income of $15,000 per attack. Once users begin using their Smart TVs for additional activities such as shopping the impact of this attack will only grow.

The **intranet request forgery** attack has medium complexity, since it involves compromising and exploiting not only the TV but also an intranet-connected device such as a router or a printer. However, there are existing intranet attacks which can be reused for this purpose. The damage potential of this attack is understandably high, since it lets the attacker compromise the user's personal computer.

The **phishing/social engineering** attack may be technically easy to launch, but it has external factors which make it more complex to carry out. First, the user's cooperation is required for this attack to succeed, raising the chance that the attack is ignored or, in the worst case, reported to law enforcement. In addition, the attack requires the attacker to set up additional attack infrastructure (e.g. a web server for collecting credentials), raising the risk of capture. The damage potential of this attack, however, is the highest of all attacks described here, since it risks the user's personal safety.

The **exploit distribution attack** may appear to be technically the most complex attack described here. However, since Smart TVs are commonly built using open-source components, an aspiring attacker can use an exploit patched in the most recent version of the component and not yet updated in the Smart TV. This attack has a

Attack Type	Complexity	Damage Potential	Overall Risk
Denial of Service	Low	Low	Medium
Unauthenticated Request Forgery	Low	Medium	High
Authenticated Request Forgery	Medium	High	High
Intranet Request Forgery	Medium	High	High
Phishing/Social Engineering	High	High	Medium
Exploit Distribution	Medium	High	High

Table 1: Risk assessment matrix of suggested attacks

high damage potential, since it results in total compromise of the TV.

7.2 Attacking cable and satellite

The physical attack setup described in the previous sections assumed a digital terrestrial television (DTT) broadcast system. According to [11], this is the most common delivery method for digital television across Europe. However, there are several areas of the world, most notably the USA, where this form of delivery is less common than cable or satellite communications. While splicing into cable connections or hijacking satellite signals is more expensive and risky than transmitting a low-power UHF signal, it might still be possible to attack such systems if they use microwave RF links for part of their (non-broadcast) transmission networks. Setting up a relay system which adds malicious applications to such a relay link is possible using fundamentally the same technique as the one described in this paper, with the limitation that the relay device must be physically located along the line of sight of the microwave link. High-budget adversaries such as crime syndicates or state players might also like to directly attack cable or satellite distribution centers to launch truly massive large scale attacks using HbbTV, gaining control over hundreds of millions of connected devices.

7.3 Countermeasures

As stated in Section 3.2, there are three main security weaknesses in HbbTV: the fact that attacks are invisible and unstoppable, the fact that the attacker cannot be detected, and most significantly the problematic implementation of the same origin policy. This subsection proposes several approaches which can be used to address these weaknesses. Some of these defenses "break the standard" and make existing use cases for HbbTV applications (such as tracking cookies) impractical. Other defenses are less disruptive and can be independently deployed by security-minded equipment vendors and even marketed as differentiating features of their TV sets.

7.3.1 Crowdsource detection of RF attacks

Acting alone, an individual television set can do little to detect that its broadcast TV signal is suddenly coming from a malicious source. However, multiple television sets in the same area can aggregate their statuses, making it possible to use this information for detecting radio-based attacks. For example, if the Receive Signal Strength Indication (RSSI) in a certain geographic area has rapidly and suddenly changed, it might mean these TV sets are now receiving a signal from the attacker and not from the original radio tower. The RSSI information can even be used as a form of triangulation, to help pinpoint the exact location of the attacker and aid in his capture. Similarly, if multiple television sets are tuned to the same broadcast frequency, but a certain subset is receiving a different HbbTV application associated with this channel than the other TVs, this can indicate that an attack is in progress. It would be interesting to find a way of achieving this without compromising the privacy of the viewers.

7.3.2 Tighten control over app life cycle

The attacks described here are especially effective since they turn on automatically and without the knowledge of the user, and have no standard way of being disabled. The obvious way of addressing this limitation would be

to guarantee the user's informed consent before active HTML content is rendered by the television. A good analogue to this behavior be found in the WHATWG's recommended implementation of the HTML5 full-screen API [39], which specifies that "User agents should ensure, e.g. by means of an overlay, that the end user is aware something is displayed fullscreen. User agents should provide a means of exiting fullscreen that always works and advertise this to the user." In this spirit, the TV should prompt the user to press the red button **before** rendering any form of HbbTV content for the first time for a given channel, then periodically remind the user that content is running (for example by displaying a brief notification overlay whenever the user switches back to the channel). Users should also have a way of stopping HbbTV rendering for a particular channel.

This countermeasure is perhaps the most intuitive and can be immediatly implemented by individual hardware makers. Sadly, it was shown that users do not react productively to warning messages which interfere with their browsing (or TV watching) [36]. In addition, there are already several established market players who will resist any change to this behaviour, as they already use invisible HbbTV applications for user tracking and analytics.

7.3.3 Prevent broadcast-delivered HTML content from accessing the Internet

It is risky to allow unauthenticated broadcast content to define its own web origin. It seems tempting, then, to create a special restricted origin for broadcasted content, which is distinct from all other Internet domains. Another possible countermeasure is **content signing**. With this proposed defense, all HTML content delivered inside the DVB stream will be accompanied by a signed certificate attesting to its web origin. A malicious adversary cannot sign web pages on behalf of the website under attack, and thus cannot claim these sites as its origin. Unfortunately, even if all broadcast content was properly assigned to a restricted web origin, many attacks would still be possible via "blind" CSRF or PuppetNet attacks [29]. These attacks can cause considerable damage, even if the same-origin principle is upheld, by the sheer virtue of being able to access the Internet using somebody else's computer.

The HbbTV specification conceived the embedding of web content into the DVB data stream as a redundancy method, designed to allow the delivery of interactive content to the 30% of smart TV owners who do not, in fact, plug them into the Internet. This reasoning can be turned into an brutal, but effective, way to secure HbbTV. We recommend to **completely cut off Internet access** to all broadcast-delivered HTML content. Under this model, broadcast-delivered applications will be able to interact only with broadcast-delivered resources, while the only way of getting the television to access the Internet would be through an application delivered in URL form and fetched from the Internet itself. We note that the Google Chrome browser applies a very similar security policy to its browser extensions [17].

7.3.4 Ineffective countermeasures

There are several defensive steps which appear at first to protect against the attack, but whose practical effectiveness is very limited. The first is **content encryption**. Rights-managed DVB content is commonly encrypted, or scrambled, and this encryption appears to be a way of preventing an attack which modifies the television channel. DVB encryption is, however, only applied to individual transport streams such as audio or video. The DVB specification [9] dictates that and not to the program management table (PMT), which points to the HbbTV application, is always sent in the clear. This makes it possible for an adversary to inject a malicious application into any channel, even one with encrypted video and audio.

It will also be inffective to protect against this attack using **Internet proxies**. As suggested by Tews in [16], these "green button" proxies can deliver "sanitised" versions of HbbTV applications to users, after applying modifications which protect the security and privacy of the users. Unfortunately, these proxies are only effective as long as the HbbTV application itself lives on the Internet. Our attack deals with a different form of delivery, where the application resides inside the broadcast television stream.

7.4 Related Work

Works investigating other security issues with Smart TVs were published by Grattafiori and Yavor in [18] and by Lee and Kim in [31]. The first academic work to deal with security weaknesses in HbbTV was published by Tews et al. in [16, 15]. This work focused on potential

privacy leaks resulting from the use of HbbTV. The authors showed how an adversary sniffing encrypted traffic generated by HbbTV on a user's wireless network can infer which program the user is currently watching, even without decrypting the packets. This work also suggests a proxy-based method for blocking autostart applications from running on the television without user permissions.

Another series of works on HbbTV was published by Martin Herfurt [21, 20]. Herfurt surveyed the HTML applications used by German HbbTV providers, discovering that many of them use HbbTV to periodically "phone home" and notify that the user is tuned to the station. Since this was done without the user's consent, these behaviours were considered a breach of German privacy laws. Herfurt additionally suggested a series of attacks which might be possible using HbbTV, including content spoofing, intranet attacks and even bitcoin mining. Finally, Herfurt also implemented a DNS-based privacy protection method called HbbTV Access Limiter (HAL).

Our work significantly contributes to that of of Herfurt and Tews et al. in two aspects. First, our work is the first to present and evaluate a cost-effective method of injecting malicious content into HbbTV systems, by using an RF-based man-in-the-middle attack. Second, our work is the first to call attention to the flawed specification of the same-origin policy for embedded HTML content, and to the devastating cross-domain attacks made possible by this flaw. It is the combination of a feasible attack model and a faulty security model which makes the attacks described in this paper so practical and so dangerous.

The most troubling attacks we discuss result from a flawed implementation of the Same-Origin Policy. As described by Johns et al. in [25], there have been several historical compromises of this policy, starting from 1996 [12], with each compromise resulting in serious consequences for web security. This work can be viewed as a particular instance of this case, made even more powerful due to the broadcast nature of the attack. Our work can also be viewed as a form of **cross-mechanism vulnerability**, in which the combination of perfectly benign broadcast and broadband systems create a system-of-systems with an **emergent property** which allows it to be compromised. Similar properties have previously been demonstrated in voice over IP systems which which combine Internet and PSTN networks [28].

There have been several previous works which exploit a broadcast radio frequency channel to attack a multitude of computers. Notable are the work of Nighswander et al. which attacks GPS software stacks [32], and the work of Checkoway et al. which attacks car computers via the broadcast FM RDS channel [4].

8 Conclusion

We have described a series of novel attacks on Smart TVs – a widely deployed device whose significance in our life is only likely to grow. The key enabling factor of this attack was the fact that the device can render Internet content whose source is outside the Internet. This makes it possible for a physical attacker to cause a large-scale compromise of the Internet. We qualitatively and quantitively demonstrated that the attacks we described can be cost-effectively distributed to many thousands of users, and that they have a large damage potential. The attacks described in this paper are of high significance, not only because of the very large amount of devices which are vulnerable to them, but because they exemplify the complexity of securing systems-of-systems which combine both Internet and non-Internet interfaces. Similar cyber-physical systems will become increasingly more prevalent in the future Internet of Things, making it especially important to analyze the weaknesses in this system, as well as the limitations of its proposed countermeasures.

Abstract

Advanced imaging technologies are a new class of people screening systems used at airports and other sensitive environments to detect metallic as well as nonmetallic contraband. We present the first independent security evaluation of such a system, the Rapiscan Secure 1000 full-body scanner, which was widely deployed at airport checkpoints in the U.S. from 2009 until 2013. We find that the system provides weak protection against adaptive adversaries: It is possible to conceal knives, guns, and explosives from detection by exploiting properties of the device's backscatter X-ray technology. We also investigate cyberphysical threats and propose novel attacks that use malicious software and hardware to compromise the the effectiveness, safety, and privacy of the device. Overall, our findings paint a mixed picture of the Secure 1000 that carries lessons for the design, evaluation, and operation of advanced imaging technologies, for the ongoing public debate concerning their use, and for cyberphysical security more broadly.

1 Introduction

In response to evolving terrorist threats, including nonmetallic explosive devices and weapons, the U.S. Transportation Security Administration (TSA) has adopted advanced imaging technology (AIT), also known as whole-body imaging, as the primary passenger screening method at nearly 160 airports nationwide [50]. Introduced in 2009 and gradually deployed at a cost exceeding $1 billion, AIT provides, according to the TSA, "the best opportunity to detect metallic and non-metallic anomalies concealed under clothing without the need to touch the passenger" [48].

AIT plays a critical role in transportation security, and decisions about its use are a matter of public interest. The technology has generated considerable controversy, including claims that the devices are unsafe [40], violate privacy and civil liberties [27, 41], and are ineffective [8, 21]. Furthermore, AIT devices are complex cyberphysical systems — much like cars [23] and implantable medical devices [13] — that raise novel computer security issues. Despite such concerns, neither the manufacturers nor the government agencies that deploy these machines have disclosed sufficient technical details to facilitate rigorous independent evaluation [40], on the grounds that such information could benefit attackers [48]. This lack of transparency has limited the ability of policymakers, experts, and the public to assess contradicting claims.

Figure 1: The Rapiscan Secure 1000 full-body scanner uses backscattered X-rays to construct an image through clothing. Naïvely hidden contraband, such as the handgun tucked into this subject's waistband, is readily visible to the device operator.

To help advance the public debate, we present the first experimental analysis of an AIT conducted independently of the manufacturer and its customers. We obtained a Rapiscan Secure 1000 full-body scanner — one of two AITs widely deployed by the TSA [32] — and performed a detailed security evaluation of its hardware and software. Our analysis provides both retrospective insights into the adequacy of the testing and evaluation procedures that led up to TSA use of the system, and prospective lessons about broader security concerns, including cyberphysical threats, that apply to both current and future AITs.

The Secure 1000 provides a unique opportunity to investigate the security implications of AITs in a manner that allows robust yet responsible public disclosure. Although it was used by the TSA from 2009 until 2013, it has recently been removed from U.S. airports due to changing functional requirements [34]. Moreover, while the Secure 1000 uses backscatter X-ray imaging, current TSA systems are based on a different technology, mil-

limeter waves [11], so many of the attacks we present are not directly applicable to current TSA checkpoints, thus reducing the risk that our technical disclosures will inadvertently facilitate mass terrorism. However, while Secure 1000 units are no longer used in airports, they still are in use at other government facilities, such as courthouses and prisons (see, e.g., [15, 29]). In addition, other backscatter X-ray devices manufactured by American Science and Engineering are currently under consideration for use at airports [34]. To mitigate any residual risk, we have redacted a small number of sensitive details from our attacks in order to avoid providing recipes that would allow an attacker to reliably defeat the screening process without having access to a machine for testing.

In the first part of our study (Section 3), we test the Secure 1000's effectiveness as a physical security system by experimenting with different methods of concealing contraband. While the device performs well against naïve adversaries, fundamental limitations of backscatter imaging allow more clever attackers to defeat it. We show that an adaptive adversary, with the ability to refine his techniques based on experiment, can confidently smuggle contraband past the scanner by carefully arranging it on his body, obscuring it with other materials, or properly shaping it. Using these techniques, we are able to hide firearms, knives, plastic explosive simulants, and detonators in our tests. These attacks are surprisingly robust, and they suggest a failure on the part of the Secure 1000's designers and the TSA to adequately anticipate adaptive attackers. Fortunately, there are simple procedural changes that can reduce (though not eliminate) these threats, such as performing supplemental scans from the sides or additional screening with a magnetometer.

Next, we evaluate the security of the Secure 1000 as a cyberphysical system (Section 4) and experiment with three novel kinds of attacks against AITs that target their effectiveness, safety features, and privacy protections. We demonstrate how malware infecting the operator's console could selectively render contraband invisible upon receiving a "secret knock" from the attacker. We also attempt (with limited success) to use software-based attacks to bypass the scanner's safety interlocks and deliver an elevated radiation dose. Lastly, we show how an external device carried by the attacker with no access to the console can exploit a physical side-channel to capture naked images of the subject being scanned. These attacks are, in general, less practical than the techniques we demonstrate for hiding contraband, and their limitations highlight a series of conservative engineering choices by the system designers that should serve as positive examples for future AITs.

Finally, we attempt to draw broader lessons from these findings (Section 5). Our results suggest that while the Secure 1000 is effective against naïve attackers, it is not able to guarantee either efficacy or privacy when subject to attack by an attacker who is knowledgeable about its inner workings. While some of the detailed issues we describe are specific to the scanner model we tested, the root cause seems to be the failure of the system designers and deployers to think adversarially. This pattern is familiar to security researchers: past studies of voting machines [4], cars [23] and medical devices [13] have all revealed cyberphysical systems that functioned well under normal circumstances but were not secure in the face of attack. Thus, we believe this study reinforces the message that security systems must be subject to adversarial testing before they can be deemed adequate for widespread deployment.

Research safety and ethics. Since the Secure 1000 emits ionizing radiation, it poses a potential danger to the health of scan subjects, researchers, and passers by. Our institutional review board determined that our study did not require IRB approval; however, we worked closely with research affairs and radiation safety staff at the university that hosted our device to minimize any dangers and assure regulatory compliance. To protect passers by, our device was sited in a locked lab, far from the hallway, and facing a thick concrete wall. To protect researchers, we marked a 2 m region around the machine with tape; no one except the scan subject was allowed inside this region while high voltage was applied to the X-ray tube. We obtained a RANDO torso phantom [33], made from a material radiologically equivalent to soft tissue cast over a human skeleton, and used it in place of a human subject for all but the final confirmatory scans. For these final scans we decided, through consultation with our IRB, that only a PI would be used as a scan subject. Experiments involving weapons were conducted with university approval and in coordination with the campus police department and all firearms were unloaded and disabled. We disclosed our security-relevant findings and suggested procedural mitigations to Rapiscan and the Department of Homeland Security ahead of publication.

Online material. Additional resources and the most recent version of this report are available online at `https://radsec.org/`.

2 The Rapiscan Secure 1000

The Secure 1000 was initially developed in the early 1990s by inventor Steven W. Smith [42, 44]. In 1997, Rapiscan Systems acquired the technology [43] and began to produce the Rapiscan Secure 1000. In 2007, the TSA signed a contract with Rapiscan to procure a customized version of the Secure 1000 for deployment in airport passenger screening [47].

We purchased a Rapiscan Secure 1000 from an eBay seller who had acquired it in 2012 at a surplus auction

from a U.S. Government facility located in Europe [17]. The system was in unused condition. It came with operating and maintenance manuals as well as detailed schematics, which were a significant aid to reverse engineering. The system consists of two separate components: the scanner unit, a large enclosure that handles X-ray generation and detection under the control of a special purpose embedded system, and the user console, a freestanding cabinet that contains a PC with a keyboard and screen. The two components are connected by a 12 m cable.

The system we tested is a dual pose model, which means that the subject must turn around in order to be scanned from the front and back in two passes. TSA screening checkpoints used the Secure 1000 single pose model [32], which avoids this inconvenience by scanning from the front and back using a pair of scanner units. Our system was manufactured in about September 2006 and includes EPROM software version 2.1. Documents obtained under the Freedom of Information Act suggest that more recent versions of the hardware and software were used for airport screening [45, 52], and we highlight some of the known differences below. Consequently, we focus our analysis on fundamental weaknesses in the Secure 1000 design that we suspect also affect newer versions. A detailed analysis of TSA models might reveal additional vulnerabilities.

2.1 Backscatter Imaging

X-ray backscatter imaging exploits the unique properties of ionizing radiation to penetrate visual concealment and detect hidden contraband. The physical process which generates backscatter is Compton scattering, in which a photon interacts with a loosely bound or free electron and scatters in an unpredictable direction [7]. Other interactions, such as the photoelectric effect, are possible, and the fraction of photons that interact and which particular effect occurs depends on each photon's energy and the atomic composition of the mass. For a single-element material, the determining factor is its atomic number Z, while a compound material can be modeled by producing an "effective Z," or Z_{eff} [46].

Under constant-spectrum X-ray illumination, the backscattered intensity of a given point is largely determined by the atomic composition of matter at that location, and to a lesser extent its density. Thus, organic materials, like flesh, can be easily differentiated from materials such as steel or aluminum that are made from heavier elements.

The Secure 1000 harnesses these effects for contraband screening by operating as a "reverse camera," as illustrated in Figure 2. X-ray output from a centrally-located tube (operating at 50 kVp and 5 mA) passes through slits in shielding material: a fixed horizontal slit directly in front of a "chopper wheel," a rapidly spinning disk with four radial slits. This results in a narrow, collimated X-ray beam, repeatedly sweeping across the imaging field. During a scan, which takes about 5.7 s, the entire X-ray assembly moves vertically within the cabinet, such that the beam passes over every point of the scene in a series of scan lines.

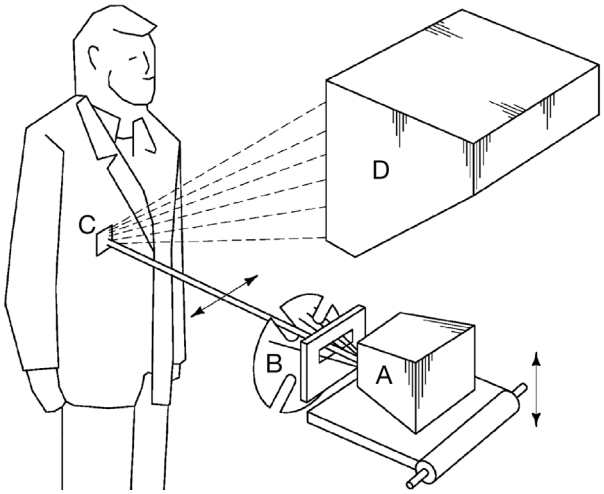

Figure 2: Backscatter Imaging — An X-ray tube (A) mounted on a platform travels vertically within the scanner. The X-rays pass through a spinning disk (B) that shapes them into a horizontally scanning beam. Some photons that strike the target (C) are backscattered toward detectors (D) that measure the reflected energy over time. Adapted from U.S. Patent 8,199,996 [16].

As the beam sweeps across the scene, a set of 8 large X-ray detectors measures the intensity of the backscattered radiation at each point, by means of internal photomultiplier tubes (PMTs). The Secure 1000 combines the output of all 8 detectors, and sends the resulting image signal to the user console, which converts the time-varying signal into a 160×480 pixel monochrome image, with the intensity of each pixel determined by the Z_{eff} value of the surface of the scan subject represented by that pixel location.

2.2 Subsystems

Operator interface. The operator interacts with the Secure 1000 through the user console, a commodity x86 PC housed within a lockable metal cabinet. With our system, the user console is connected to the scanner unit via a serial link and an analog data cable. Documents released by the TSA indicate that airport checkpoint models were configured differently, with an embedded PC inside the scanner unit linked to a remote operator workstation via a dedicated Ethernet network [45, 52].

On our unit, the operator software is an MS-DOS application called SECURE65.EXE that launches automatically when the console boots. (TSA models are apparently Windows-based and use different operator software [45, 47].) This software is written in a BASIC vari-

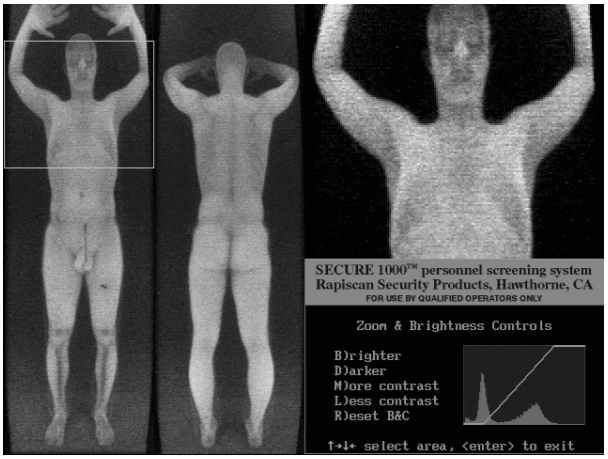

Figure 3: Operator View — The user console displays front and back images and offers basic enhancements and 2 × zoom. It also allows the operator to print images or save them to disk.

ant, and the main user interface is a 640×480 pixel, 4-bit grayscale screen, as shown in Figure 3. The operator invokes a scan by pressing a hand switch. After image acquisition, the operator can inspect the scan by means of a 2× zoom and interactive brightness and contrast controls. The image can also be saved to disk or printed. Further, the software contains several calibration functions that can only be accessed by entering a 4 digit numeric password. The password is hard-coded and is printed in the maintenance manual.

Scanner unit. The scanner unit contains an assortment of electrical and mechanical systems under the control of an embedded computer called the System Control Board (SCB). The SCB houses an Intel N80C196KB12 microcontroller, executing software contained on a 32 KiB socketed ROM. It interacts with the user console PC over a bidirectional RS-232 serial link using simple ASCII commands such as `SU` for "scan up" and `SD` for "scan down." In turn, the SCB uses digital and analog interfaces to direct and monitor other components, including the X-ray tube, PMTs, and chopper wheel. It also implements hardware-based safety interlocks on the production of X-rays, which we discuss further in Section 4.2.

To control vertical movement of the X-ray tube, the scanner unit uses an off-the-shelf reprogrammable servo motor controller, the Parker Gemini GV6. In normal operation, the servo controller allows the SCB to trigger a movement of the X-ray tube, initially to a "home" position and subsequently to scan up and down at predefined rates. There is no command to move the tube to a specific intermediate position.

3 Contraband Detection

As the Secure 1000 is intended to detect prohibited or dangerous items concealed on the body of an attacker, the first and most obvious question to ask is how effectively the Secure 1000 detects contraband.

To make the discussion concrete, we consider the machine as it was typically used by the TSA for airport passenger screening. Under TSA procedures, subjects were imaged from the front and back, but not from the sides. A trained operator inspected the images and, if an anomaly was detected, the passenger was given a manual pat down to determine whether it was a threat [45]. The Secure 1000 was used in place of a walk-through metal detector, rather than both screening methods being employed sequentially [48]. We focus our analysis on threats relevant to an airport security context, such as weapons and explosives, as opposed to other contraband such as illicit drugs or bulk currency.

To replicate a realistic screening environment, we situated our Secure 1000 in an open area, oriented 2.5 m from a concrete wall sufficient to backstop X-ray radiation. This distance accords with the manufacturer's recommendation of at least 2 m of open area "for producing the best possible images" [35]. For typical tests, we arranged the subject at a distance of about 38 cm in front of the scanner using the foot position template provided with the machine.

Naïve adversary. First, we consider the scanner's effectiveness against a naïve adversary, an attacker whose tactics do not change in response to the introduction of the device. Although this is a weak attacker, it seems to correspond to the threat model under which the scanner was first tested by the government, in a 1991 study of a prototype of the Secure 1000 conducted by Sandia National Laboratories [22]. Our results under this threat model generally comport with theirs. Guns, knives, and blocks of explosives naïvely carried on the front or back of the subject's body are visible to the scanner operator.

Three effects contribute to the detectability of contraband. The first is *contrast*: human skin appears white as it backscatters most incident X-ray radiation, while metals, ceramics, and bone absorb X-rays and so appear dark gray or black. The second is *shadows* cast by three-dimensional objects as they block the X-ray beam, which accentuate their edges. The third is *distortion* of the subject's flesh as a result of the weight of the contraband or the mechanics of its attachment. The naïve adversary is unlikely to avoid all three effects by chance.

A successful detection of hidden contraband can be seen in Figure 1. The subject has concealed a .380 ACP pistol within his waistband. The X-ray beam interacts with the gun metal significantly differently than the surrounding flesh, and the sharp contrast in backscatter intensity is immediately noticeable.

Adaptive adversary. Of course, real attackers are not entirely ignorant of the scanner. The TSA announced

(a) Subject with .380 ACP pistol taped above knee.

(b) Subject with .380 ACP pistol sewn to pant leg.

Figure 4: Concealing a Pistol by Positioning — The Secure 1000 cannot distinguish between high Z_{eff} materials, such as a metal handgun, and the absence of a backscatter response. Carefully placed metallic objects can be invisible against the dark background.

that it would be used at screening checkpoints [12, 48], the backscatter imaging mechanism is documented in patents and manufacturer reports [16, 24, 36], images captured with the device have appeared in the media [12, 25], and the physics of backscatter X-rays are well understood [2, 7, 22]. We must assume that attackers have such information and adapt their tactics in response.

To simulate an adaptive adversary, we performed experiments in the style of white-box penetration testing commonly employed in the computer security field. We allowed ourselves complete knowledge of how the scanner operates as well as the ability to perform test scans, observed the resulting images, and used them to adjust our concealment methods.

Such interactive testing is not strictly necessary to develop clever attacks. Indeed, researchers with no access to the Secure 1000 have proposed a number of concealment strategies based only on published information [21], and we experimentally confirm that several of these attacks are viable. However, the ability to perform tests substantially increases the probability that an attack will succeed on the first attempt against a real deployment. A determined adversary might acquire this level of access in several ways: by buying a machine, as we did; by colluding with a dishonest operator; or by probing the security of real installations over time.

In the remainder of this section, we describe experiments with three adaptive concealment techniques and show that they can be used to defeat the Secure 1000. We successfully use them to smuggle firearms, knives, and explosive simulants past the scanner.

3.1 Concealment by Positioning

The first concealment technique makes use of a crucial observation about X-ray physics: backscatter screening machines emitting X-rays in the 50 keV range, such as the Secure 1000, cannot differentiate between the absence of matter and the existence of materials with high Z_{eff} (e.g., iron and lead). That is, when the scanner emits probing X-rays in a direction and receives no backscatter, it can

either be because the beam interacted with nothing, i.e., traveled unimpeded past the screening subject, or because the beam shone directly upon a material which absorbed it entirely and thus did not backscatter. In either case, the resulting pixels will be dark.

These facts lead directly to a straightforward concealment attack for high Z_{eff} contraband: position the object such that it avoids occluding the carrier's body with respect to the X-ray beam. This technique was first suggested on theoretical grounds by Kaufman and Carlson [21]. In limited trials, a TSA critic used it to smuggle small metal objects through airport checkpoints equipped with the Secure 1000 and other AITs [8]. Note that this attack is not enabled by a poor choice of image background color; as discussed above, the scanner cannot differentiate between the metal objects and the absence of material.

To more fully investigate this attack, we obtained a set of weapons: both knives and firearms, ranging from a .380 ACP pistol to an AR-15 semi-automatic rifle. When we scanned the weapons against a dark backdrop, most of the firearms were readily visible due to the presence of nonmetallic parts. After testing a number of firearms, we settled on our .380 ACP pistol as the most suitable candidate for concealment.

We performed several trials to test different placement and attachment strategies. In the end, we achieved excellent results with two approaches: carefully affixing the pistol to the outside of the leg just above the knee using tape, and sewing it inside the pant leg near the same location. Front and back scans for both methods are shown in Figure 4. In each case, the pistol is invisible against the dark background, and the attachment method leaves no other indication of the weapon's presence.

In a similar test, we concealed an 11 cm metal folding knife, in its closed position, along our test subject's side. In this case, too, front and back scans were completely unable to detect the weapon.

Fortunately, simple procedural changes can thwart these attacks. Instead of performing only front and back scans, every subject could also be made to undergo scans from the left and right sides. Under these scans, a high Z_{eff} weapon positioned on the side of the body would be as obvious as the one in Figure 1. Unfortunately, these additional scans would nearly halve the maximum throughput of the checkpoint, as well as double each person's radiation dose. Another possible mitigation would be to screen each subject with a magnetometer, which would unequivocally find metallic contraband but would fail to uncover more exotic weapons, such as ceramic knives [50, 54]. We note that the attacker's gait or appearance might be compromised by the mass and bulk of the firearm or knife, and this might be noticeable to security personnel outside of the backscatter X-ray screening.

3.2 Concealment by Masking

The second object concealment techniques we attempted are similarly based on X-ray physics: the brightness of a material in the image is directly correlated to its backscatter intensity, which in turn is determined by the Z_{eff} and density of the matter in the path of the beam. Therefore, any combination of substances which scatter incoming X-rays at the same approximate intensity as human flesh will be indistinguishable from the rest of the human.

One consequence of this fact is that high-Z_{eff} contraband can be concealed by masking it with an appropriate thickness of low-Z_{eff} material. We experimented with several masking materials to find one with a Z_{eff} value close to that of flesh. We obtained good results with the common plastic PTFE (Teflon), although due to its low density a significant thickness is required to completely mask a metallic object.

To work around this issue, we took advantage of the Secure 1000's ability to see bones close to the skin. Figure 5 demonstrates this approach: an 18 cm knife is affixed to the spine and covered with 1.5 cm of PTFE. As the X-rays penetrate through the material, they backscatter so that the knife outline approximates our subject's spine. While this mask arrangement creates hard edges and shadows which render it noticeable to screening personnel these effects could be reduced by tapering the edges of the mask.

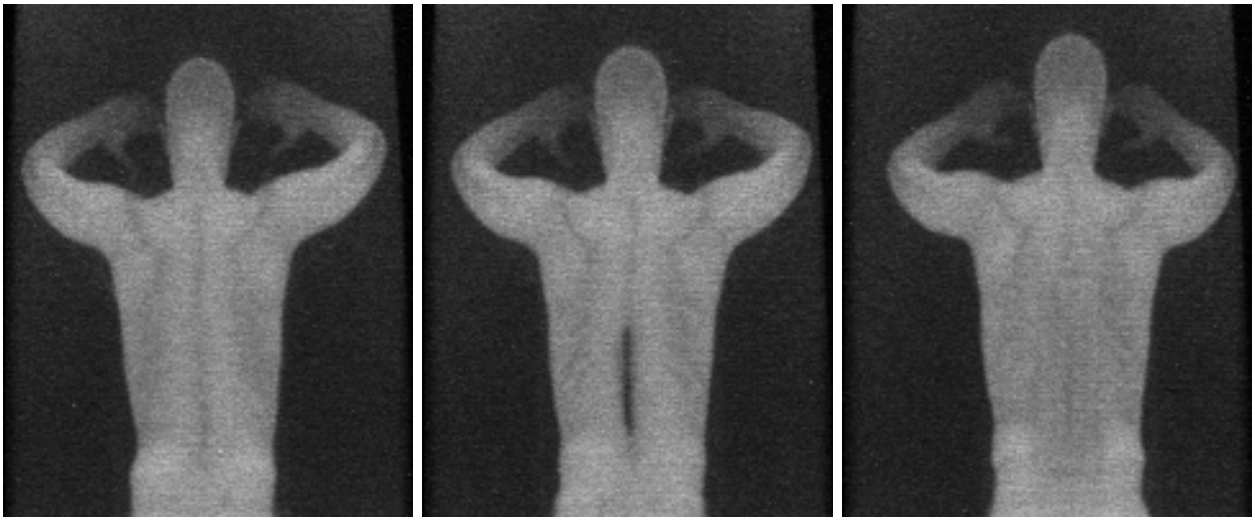
A more difficult challenge for the attacker is taking into account the anatomy of the specific person being imaged. Shallow bones and other dense tissue are visible to the scanner under normal conditions, and a poorly configured mask will stand out against these darker areas of the scan. We conclude that masking can be an effective concealment technique, but achieving high confidence of success would require access to a scanner for testing.

3.3 Concealment by Shaping

Our third and final concealment technique applies a strategy first theorized in [21] to hide malleable, low-Z_{eff} contraband, such as plastic explosives. These materials produce low contrast against human flesh, and, unlike rigid weapons, the attacker can reshape them so that they match the contours of the body.

To experiment with this technique, we acquired radiological simulants for both Composition C-4 [56] and Semtex [57], two common plastic high explosives. These simulants are designed to emulate the plastic explosives with respect to X-ray interactions, and both are composed of moldable putty, similar to the actual explosive materials. We imaged both C-4 and Semtex simulants with the Secure 1000, and found that they appear very similar. We selected the C-4 simulant for subsequent tests.

Our initial plan was to modify the simulants' Z_{eff} to better match that of flesh, by thoroughly mixing in fine metallic powder. To our surprise, however, a thin pancake



(a) No contraband **(b)** 18 cm knife taped to spine **(c)** Knife behind 1.5 cm plastic block

Figure 5: Concealing a Knife by Masking — We find that high-Z_{eff} materials can be hidden by covering them with lower Z_{eff} materials, such as the common plastic PTFE (Teflon). For example, a metal knife is clearly visible when naïvely concealed, but when covered with a thin plastic block it approximates the color of the spine. Tapering the block's edges would reduce the visible outline.

(about 1 cm) of unmodified C-4 simulant almost perfectly approximated the backscatter intensity of our subject's abdomen.

We affixed the pancake with tape (which is invisible to the Secure 1000), and faced two further problems. First, the pancake covered our subject's navel, which is normally clearly visible as a small black area in the scans. Second, by design, plastic explosives are almost completely inert without a matching detonator. These problems neatly solve each other: we attached a detonator, consisting of a small explosive charge in a metal shell, directly over our subject's navel. Since the detonator is coated in metal, it absorbs X-rays quite well and mimics the look of the navel in the final image.

Figure 6 shows a side-by-side comparison of our test subject both carrying no contraband and carrying 200 g of C-4 explosive and attached detonator. To put this amount in perspective, "Shoe Bomber" Richard Reid reportedly carried about 280 g of explosive material [6], and the bomb that destroyed Pan Am Flight 103 is thought to have contained 350 g of Semtex [55].

These scans indicate that plastic explosives can be smuggled through a Secure 1000 screening, since thin pancakes of these materials do not contrast strongly with flesh. While a metal detector would have been sufficient to detect the detonator we used, not all detonators have significant metal components.

In summary, an adaptive adversary can use several attack techniques to carry knives, guns, and plastic explosives past the Secure 1000. However, we also find that multiple iterations of experimentation and adjustment are likely necessary to achieve consistent success. The security of the Secure 1000, then, rests strongly on the adversary's inability to acquire access to the device for testing. However, since we were able to purchase a Secure 1000, it is reasonable to assume that determined attackers and well-financed terrorist groups can do so as well. We emphasize that procedural changes — specifically, performing side scans and supplementing the scanner with a magnetometer — would defeat some, though not all, of the demonstrated attacks.

4 Cyberphysical Attacks

The Secure 1000, like other AITs, is a complex cyberphysical system. It ties together X-ray emitters, detectors, and analog circuitry under the control of embedded computer systems, and feeds the resulting image data to a traditional desktop system in the user console. In this section, we investigate computer security threats against AITs. We demonstrate a series of novel software- and hardware-based attacks that undermine the Secure 1000's efficacy, safety features, and privacy protections.

4.1 User Console Malware

The first threat we consider is malware infecting the user console. On our version of the Secure 1000, the user console is an MS-DOS–based PC attached to the scanner unit via a proprietary cable; TSA models apparently used Windows and a dedicated Ethernet switch [47, 49]. Although neither configuration is connected to an external network, there are several possible infection vectors. If the operators or maintenance personnel are malicious, they could abuse their access in order to manually install malware.

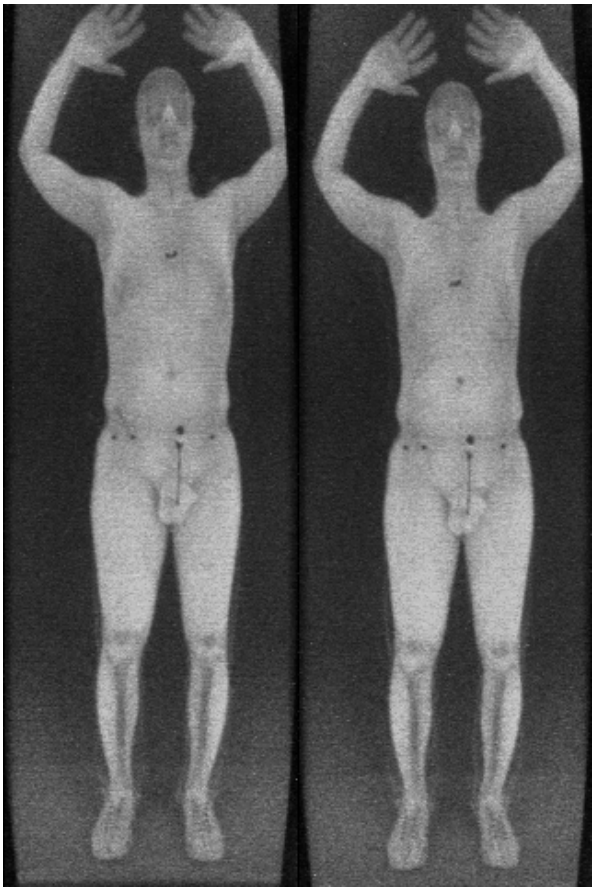


Figure 6: Concealing Explosives by Shaping — *Left:* Subject with no contraband. *Right:* Subject with more than 200 g of C-4 plastic explosive simulant plus detonator, molded to stomach.

The software on our machine lacks any sort of electronic access controls (e.g., passwords) or software verification. While the PC is mounted in a lockable cabinet, we were able to pick the lock in under 10 seconds with a commercially available tool. Therefore, even an outsider with temporary physical access could easily introduce malicious code. TSA systems may be better locked down, but sophisticated adversaries have a track record of infecting even highly secured, airgapped systems [26, 31].

We implemented a form of user console malware by reverse engineering SECURE65.EXE, the front-end software package used by the Secure 1000, and creating a malicious clone. Our version, INSECURE.EXE, is a functional, pixel-accurate reimplementation of the original program and required approximately one man-month to create.

In addition to enabling basic scanning operations, INSECURE.EXE has two malicious features. First, every scan image is saved to a hidden location on disk for later exfiltration. This is a straightforward attack, and it demonstrates one of many ways that software-based privacy protections can be bypassed. Of course, the user could also take a picture of the screen using a camera or smartphone — although operators are forbidden to have such devices in the screening room [39].

Second, INSECURE.EXE selectively subverts the scanner's ability to detect contraband. Before displaying each scan, it applies a pattern recognition algorithm to look for a "secret knock" from the attacker: the concentric squares of a QR code position block. If this pattern occurs, INSECURE.EXE replaces the real scan with a preprogrammed innocuous image. The actual scan, containing the trigger pattern and any other concealed contraband, is entirely hidden.

To trigger this malicious substitution, the subject simply wears the appropriate pattern, made out of any material with a sufficiently different Z_{eff} than human tissue. In our experiments, we arranged lead tape in the target shape, attached to an undershirt, as shown in Figure 7. When worn under other clothing, the target is easily detected by the malware but hidden from visual inspection.

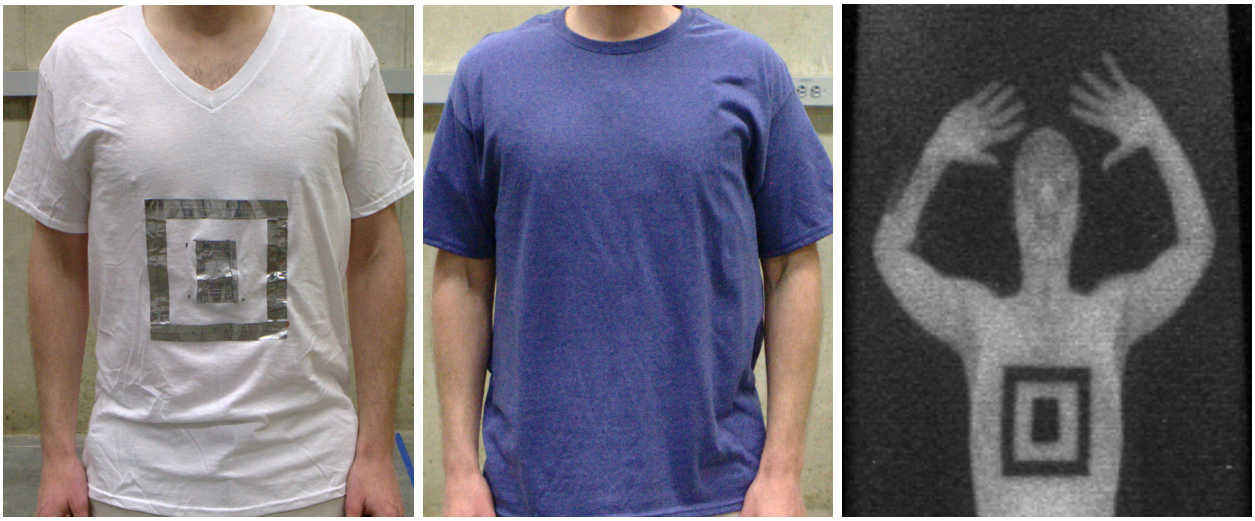
Recently, in response to privacy concerns, the TSA has replaced manual review of images with algorithmic image analysis software known as automated target recognition (ATR) [51]. Instead of displaying an image of the subject, this software displays a stylized figure, with graphical indicators showing any regions which the software considers suspect and needing manual resolution. (Delays in implementing this algorithm led the TSA to remove Secure 1000 machines from airports entirely [1].) If malware can compromise the ATR software or its output path, it can simply suppress these indicators — no image replacement needed.

4.2 Embedded Controller Attacks

The System Control Board (SCB) managing the physical scanner is a second possible point of attack. While the SCB lacks direct control over scan images, it does control the scanner's mechanical systems and X-ray tube. We investigated whether an attacker who subverts the SCB firmware could cause the Secure 1000 to deliver an elevated radiation dose to the scan subject.

This attack is complicated by the fact that the Secure 1000 includes a variety of safety interlocks that prevent operation under unexpected conditions. Circuits sense removal of the front panel, continuous motion of the chopper wheel and the vertical displacement servo, X-ray tube temperature and supply voltage, X-ray production level, key position ("Standby" vs. "On"), and the duration of the scan, among other parameters. If any anomalous state is detected, power to the X-ray tube is immediately disabled, ceasing X-ray emission.

While some of these sensors merely provide inputs to the SCB software, others are tied to hard-wired watchdog circuits that cut off X-ray power without software mediation. However, the firmware can *bypass* these hardware interlocks. At the beginning of each scan, operational



(a) Lead tape pattern **(b)** Pattern concealed **(c)** Scan as captured

Figure 7: A Secret Knock — We demonstrate how malware infecting the Secure 1000 user console could be used to defeat the scanner. The malware is triggered when it detects a specific pattern in a scan, as shown here. It then replaces the real image (c) of the attacker, which might reveal hidden contraband, with an innocuous image stored on disk. Pattern recognition occurs in real time.

characteristics such as tube voltage and servo motion fluctuate outside their nominal ranges. To prevent immediate termination of every scan, SCB software temporarily asserts a bypass signal, which disables the hardware interlocks. This signal feeds a "bypass watchdog" circuit of its own, meant to prevent continual interlock bypass, but the SCB can pet this watchdog by continuously toggling the bypass signal, and cause all hardware interlocks to be ignored. Thus, every safety interlock is either directly under software control or can be bypassed by software.

We developed replacement SCB firmware capable of disabling all of the software and hardware safety interlocks in the Secure 1000. With the interlocks disabled, corrupt firmware can, for instance, move the X-ray tube to a specific height, stop the chopper wheel, and activate X-ray power, causing the machine to deliver the radiation dose from an entire dose to a single point. Only the horizontal displacement of this point is not directly under firmware control — it depends on where the chopper wheel happens to come to rest.

Delivering malicious SCB firmware presents an additional challenge. The firmware is stored on a replaceable socketed EPROM inside the scanner unit, which is secured by an easily picked wafer tumbler lock. Although attackers with physical access could swap out the chip, they could cause greater harm by, say, hiding a bomb inside the scanner. For SCB attacks to pose a realistic safety threat, they would need to be remotely deployable.

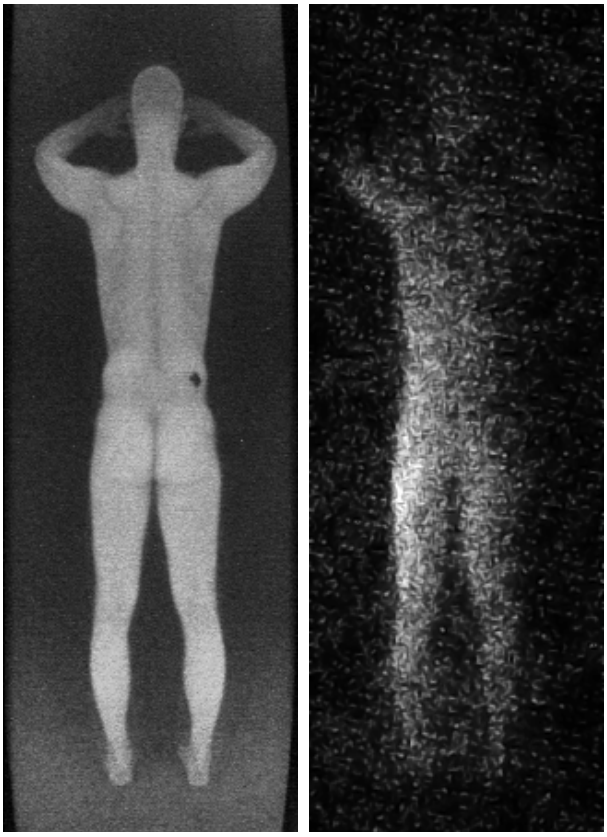
Due to the scanner's modular design, the only feasible vector for remote code execution is the serial link between the user console and the SCB. We reverse engineered the SCB firmware and extensively searched for vulnerabilities. The firmware is simple (<32 KiB) and appears to withstand attacks quite well. Input parsing uses a fixed length buffer, to which bytes are written from only one function. This function implements bounds checking correctly. Data in the buffer is always processed in place, rather than being copied to other locations that might result in memory corruption. We were unable to cause any of this code to malfunction in a vulnerable manner.

While we are unable to remotely exploit the SCB to deliver an elevated radiation dose, the margin of safety by which this attack fails is not reassuring. Hardware interlocks that can be bypassed from software represent a safety mechanism but not a security defense. Ultimately, the Secure 1000 is protected only by its modular, isolated design and by the simplicity of its firmware.

4.3 Privacy Side-Channel Attack

AIT screening raises significant privacy concerns because it creates a naked image of the subject. Scans can reveal sensitive information, including anatomical size and shape of body parts, location and quantity of fat, existence of medical conditions, and presence of medical devices such as ostomy pouches, implants, or prosthetics. As figures throughout the paper show, the resulting images are quite revealing.

Recognizing this issue, the TSA and scanner manufacturers have taken steps to limit access to raw scanned images. Rapiscan and DHS claim that the TSA machines had no capacity to save or store the images [27, 45]. The TSA also stated that the backscatter machines they used had a "privacy algorithm applied to blur the image" [50]. We are unable to verify these claims due to software dif-



(a) From scanner **(b)** From external detector

Figure 8: Attacking Privacy — An attacker could use a detector hidden in a suitcase to capture images of the subject during scanning. As a proof of concept, we used a small external PMT to capture images that are consistent with the scanner's output. A larger detector would produce more detailed images.

ferences between our machine and TSA models. Our Secure 1000 has documented save, recall (view saved images), and print features and does not appear to have a mechanism to disable them. In fact, using forensic analysis software on the user console's drive, we were able to recover a number of stored images from test scans that were incompletely deleted during manufacturing.

These software-based defenses aim to safeguard privacy in images that are constructed by the machine, but they do not address a second class of privacy attacks against AITs: an outsider observer could try to reconstruct scanned images by using their own external detector hardware. The most mechanically complex, dangerous, and energy intensive aspects of backscatter imaging are related to X-ray illumination; sensing the backscattered radiation is comparatively simple. Since X-rays scatter off the subject in a broad arc, they create a kind of physical side channel that potentially leaks a naked image of the subject to any nearby attacker. To the best of our knowledge, we are the first to propose such an attack; the privacy threat model for AITs appears to have been focused almost entirely on concerns about the behavior of screening personnel, rather than the general public.

In the scenario we envision, an attacker follows a target subject (for instance, a celebrity or politician) to a screening checkpoint while carrying an X-ray detector hidden in a suitcase. As the victim is scanned, the hardware records the backscattered X-rays for later reconstruction.

We experimented with the Secure 1000 to develop a proof-of-concept of such an attack. The major technical challenge is gathering enough radiation to have an acceptable signal/noise ratio. The Secure 1000 uses eight large photomultiplier tubes (PMTs) — four on either side of the X-ray generator — in order to capture as much signal as possible. For best results, an attacker should likewise maximize observing PMT surface area, and minimize distance from the subject, as radiation intensity falls off quadratically with distance. To avoid arousing suspicion, an attacker may be limited to only one PMT, and may also be restricted in placement.

To determine whether external image reconstruction is feasible, we used a small PMT, a 75 mm Canberra model BIF2996-2 operated at 900 V, with a 10 cm $\times$ 10 cm NaI crystal scintillator. We placed this detector adjacent to the scanner and fed the signal to a Canberra Model 1510 amplifier connected to a Tektronix DPO 3014 oscilloscope. After capturing the resulting signal, we converted the time varying intensity to an image and applied manual enhancements to adjust levels and remove noise.

Figure 8 shows the results from the scanner and from our corresponding reconstruction. While our proof-of-concept results are significantly less detailed than the scanner's output, they suggest that a determined attacker, equipped with a suitcase-sized PMT, might achieve satisfactory quality. A further concern is that changes in future backscatter imaging devices might make this attack even more practical. Since the PMTs in the Secure 1000 are close to the maximum size that can fit in the available space, further improvements to the scanner's performance — i.e., better resolution or reduced time per scan — would likely require increased X-ray output. This would also increase the amount of information leaked to an external detector.

5 Discussion and Lessons

The Secure 1000 appears to perform largely as advertised in the non-adversarial setting. It readily detected a variety of naïvely concealed contraband materials. Our preliminary measurements of the radiation exposure delivered during normal scanning (Appendix A) seem consistent with public statements by the manufacturer, TSA, and the FDA [5, 18, 38, 54]. Moreover, it seems clear that the manufacturer took significant care to ensure that predictable equipment malfunctions would not result in un-

safe radiation doses; in order for this to happen a number of independent failures would be required, including failures of safety interlocks specifically designed to prevent unsafe conditions.

However, the Secure 1000 performs less well against clever and adaptive adversaries, who can use a number of techniques to bypass its detection capabilities and to attempt to subvert it by cyberphysical means. In this section, we use the device's strengths and weaknesses to draw lessons that may help improve the security of other AITs and cyberphysical security systems more generally.

The effectiveness of the device is constrained by facts of X-ray physics . . . As discussed in Section 2.1, Compton scattering is the physical phenomenon which enables backscatter imaging. As the tight beam of X-rays shines upon the scene, it interacts with the scene material. The intensity and energy spectrum of the backscattered radiation is a function of both the X-ray spectrum emitted by the imaging device and the atomic composition of the material in the scene.

The Secure 1000 emits a single constant X-ray spectrum, with a maximum energy of 50 keV, and detects the intensity of backscatter to produce its image. Any two materials, no matter their actual atomic composition, that backscatter the same approximate intensity of X-rays will appear the same under this technology. This physical process enables our results in Section 3.3. This issue extends beyond the Secure 1000: any backscatter imaging device based upon single-spectrum X-ray emission and detection will be vulnerable to such attacks.

By contrast, baggage screening devices (such as the recently studied Rapiscan 522B; see [37]) usually use transmissive, rather than backscatter, X-ray imaging. These devices also often apply dual-energy X-ray techniques that combine information from low-energy and high-energy scans into a single image. To avoid detection by such systems, contraband will need to resemble benign material under two spectra, a much harder proposition.

. . . but physics is irrelevant in the presence of software compromise. In the Secure 1000, as in other cyberphysical screening systems, the image of the object scanned is processed by software. If that software has been tampered with, it can modify the actual scan in arbitrary ways, faking or concealing threats. Indeed, the ability of device software to detect threats and bring them to the attention of the operator is presumed in the "Automated Target Recognition" software used in current TSA millimeter-wave scanners [51]. Automatic suppression of threats by malicious software is simply the (easier to implement) dual of automatic threat detection. As we show in Section 4.1, malware can be stealthy, activating only when it observes a "secret knock."

Software security, including firmware updates, networked access, and chain-of-custody for any physical media, must be considered in any cyberphysical scanning system. Even so, no publicly known study commissioned by TSA considers software security.

Procedures are critical, but procedural best practices are more easily lost than those embedded in software. As early as 1991, Sandia National Labs recommended the use of side scans to find some contraband:

> A metallic object on the side of a person would blend in with the background and be unobserved. However, a side scan would provide an image of the object. There are other means of addressing this which IRT is considering presently [22, page 14].

Yet TSA procedures appear to call for only front and back scans, and the device manual characterizes side scans as an unusual practice:

> The Secure 1000 can conduct scans in four subject positions, front, rear, left side and right side. Most users only conduct front and rear scans in routine operations and reserve the side scans for special circumstances [35, page 3-7].

Omitting side scans makes it possible to conceal firearms, as we discuss in Section 3.1.

Since side scans are necessary for good security, the device's design should encourage their use by default. Yet, if anything, the scanner user interface nudges operators away from performing side scans. It allows the display of only two images at a time, making it poorly suited to taking four scans of a subject. A better design would either scan from all sides automatically (the Secure 1000 is already sold in a configuration that scans from two sides without the subject's turning around) or encourage/require a four-angle scan.

Adversarial thinking, as usual, is crucial for security. The Sandia report concludes that both C-4 and Detasheet plastic explosives are detected by the Secure 1000. Attached to their report is an image from one C-4 test (Figure 9), wherein a 0.95 cm thick C-4 block is noticeable only by edge effects — it is outlined by its own shadow, while the intensity within the block almost exactly matches the surrounding flesh. This suggests a failure to think adversarially: since plastic explosives are, by design, moldable putty, the attacker can simply gradually thin and taper the edges of the mass, drastically reducing edge effects and rendering it much less noticeable under X-ray backscatter imaging. We describe precisely such an attack in Section 3.3.

The basic problem appears to be that the system, while well engineered, appears not to have been designed, documented, or deployed with adaptive attack in mind. For

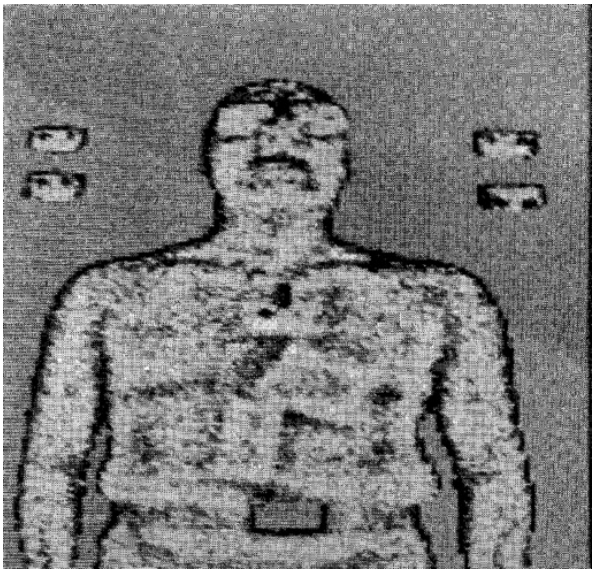


Figure 9: Naïve Evaluation — In an evaluation by Sandia National Labs, a Secure 1000 prototype successfully detects blocks of C-4 plastic explosive and Lucite attached to the subject's chest. Observe that the detection is based almost entirely on the X-ray shadow surrounding each rectangular block, which can be reduced or eliminated by an adaptive adversary through clever shaping and positioning of contraband. Reproduced from [22].

instance, attaching contraband to the side of the body as described in Section 3.1 is a straightforward attack that is enabled by scanning only straight-on rather than from all angles. However, the operator's manual shows only example images where the contraband is clearly at the front or the back.

The other attacks we describe in Sections 3 and 4, which allow us to circumvent or weaken the advertised efficacy, privacy, and security claims, again show that the system's designers failed to think adversarially.

Simplicity and modular design are also crucial for security. The system control board implements simple, well-defined functionality and communicates with the operator console by means of a simple protocol. We were unable to compromise the control board by abusing the communication protocol. This is in contrast to the scanner console, whose software runs on a general-purpose COTS operating system.

Simplicity and modular design prevented worse attacks, but do other AITs reflect these design principles? Modern embedded systems tend towards greater integration, increased software control, and remote network capabilities, which are anathema to security.

Components should be designed with separation of concerns in mind: each component should be responsible for controlling one aspect of the machine's operation. Communication between components should be constrained to narrow data interfaces. The Secure 1000 gets these principles right in many respects. For example, the PC software does not have the ability to command the X-ray tube to a particular height. Instead, it can only command the tube to return to its start position or to take a scan.

Our main suggestion for improving the Secure 1000's cyberphysical security is to remove the ability for the control board firmware to override the safety interlocks (something currently needed only briefly, at scan initialization). As long as this bypass functionality is in place, the interlocks can serve as safety mechanisms but not as a defense against software- or firmware-based attacks.

Keeping details of the machine's behavior secret didn't help . . . Published reports about the Secure 1000 have been heavily redacted, omitting even basic details about the machine's operation. This did not stop members of the public from speculating about ways to circumvent the machine, using only open-source information. In an incident widely reported in the press, Jonathan Corbett suggested that firearms hanging off the body might be invisible against the dark background [8], an attack we confirm and refine in Section 3.1. Two physicists, Leon Kaufman and Joseph Carlson, reverse engineered the Secure 1000's characteristics from published scans and concluded that "[i]t is very likely that a large (15–20 cm in diameter), irregularly-shaped, [one] cm-thick pancake [of plastic explosive] with beveled edges, taped to the abdomen, would be invisible to this technology" [21], an attack we confirm and refine in Section 3.3. Keeping basic information about the device secret made an informed public debate about its use at airports more difficult, but did not prevent dangerous attacks from being devised.

. . . but keeping attackers from testing attacks on the machine might. To a degree that surprised us, our attacks benefited from testing on the device itself. Our first attempts at implementing a new attack strategy were often visible to the scanner, and reliable concealment was made possible only by iteration and refinement. It goes without saying that software-replacement attacks on the console are practical only if one has a machine to reverse engineer. As a result, we conclude that, in the case of the Secure 1000, keeping the machine out of the hands of would-be attackers may well be an effective strategy for preventing reliable exploitation, even if the details of the machine's operation were disclosed.

The effectiveness of such a strategy depends critically on the difficulty of obtaining access to the machine. In addition to the device we purchased, at least one other Secure 1000 was available for sale on eBay for months after we obtained ours. We do not know whether it sold, or to whom. Also, front-line security personnel will always have some level of access to the device at each deployment

installation (including at non-TSA facilities) as they are responsible for its continued operation. Given these facts, imposing stricter purchase controls on backscatter X-ray machines than those currently enacted may not be enough to keep determined adversaries from accessing, studying, and experimenting with them.

6 Related work

Cyberphysical devices must be evaluated not only for their safety but also for their security in the presence of an adversary [19]. This consideration is especially important for AITs, which are deployed to security checkpoints. Unfortunately, AIT manufacturers and TSA have not, to date, allowed an unfettered independent assessment of AITs. Security evaluators retained by a manufacturer or its customers may not have an incentive to find problems [30]. In the case of a backscatter X-ray AIT specifically, an evaluation team may be skilled in physics but lack the expertise to identify software vulnerabilities, or vice versa.

Ours is the first study to consider computer security aspects of an AIT's design and operation, and the first truly independent assessment of an AIT's security, privacy, and efficacy implications informed by experimentation with an AIT device.

Efficacy and procedures. In 1991, soon after its initial development, the Secure 1000 was evaluated by Sandia National Laboratories on behalf of IRT Corp., the company then working to commercialize the device. The Sandia report [22] assessed the device's effectiveness in screening for firearms, explosives, nuclear materials, and drugs. The Sandia evaluators do not appear to have considered adaptive strategies for positioning and shaping contraband, nor did they consider attacks on the device's software. Nevertheless, they observed that side scans were sometimes necessary to detect firearms.

More recently, the Department of Homeland Security's Office of Inspector General released a report reviewing TSA's use of the Secure 1000 [10]. This report proposed improvements in TSA procedures surrounding the machines but again did not consider adversarial conditions or software vulnerabilities.

Working only from published descriptions of the device, researchers have hypothesized that firearms can be concealed hanging off the body [8] and that plastic explosives can be caked on the body [21]. We confirm these attacks are possible in Section 3 and refine them through access to the device for testing.

Health concerns. The ionizing radiation used by the Secure 1000 poses at least potential health risks. Studies performed on behalf of TSA by the Food and Drug Administration's Center for Devices and Radiological Health [5] and by the Johns Hopkins University Applied Physics Laboratory [18] attempted to quantify the overall radiation dose delivered by the device. Both studies saw public release only in heavily redacted form, going so far as to redact even the effective current of the X-ray tube.

In 2010, Professors at the University of California, San Francisco wrote an open letter to John P. Holdren, the Assistant to the President for Science and Technology, expressing their concern about potential health effects from the use of backscatter X-ray scanners at airports [40]. The letter writers drew on their radiological expertise, but did not have access to a Secure 1000 to study. The FDA published a response disputing the technical claims in the UCSF letter [28], as did the inventor of the Secure 1000, Steven W. Smith [43]. Under dispute was not just the total radiation dose but its distribution through the skin and body. In independent work concurrent with ours, a task group of the American Association of Physicists in Medicine [2] explicitly considered skin dose. The task group's measurements are within an order of magnitude of our own, presented in Appendix A.

7 Conclusion

We obtained a Rapiscan Secure 1000 and evaluated its effectiveness for people screening. Ours was the first analysis of an AIT that is independent of the device's manufacturer and its customers; the first to assume an adaptive adversary; and the first to consider software as well as hardware. By exploiting properties of the Secure 1000's backscatter X-ray technology, we were able to conceal knives, firearms, plastic explosive simulants, and detonators. We further demonstrated that malicious software running on the scanner console can manipulate rendered images to conceal contraband.

Our findings suggest that the Secure 1000 is ineffective as a contraband screening solution against an adaptive adversary who has access to a device to study and to use for testing and refining attacks. The flaws we identified could be partly remediated through changes to procedures: performing side scans in addition to front and back scans, and screening subjects with magnetometers as well as backscatter scanners; but these procedural changes will lengthen screening times.

Our findings concerning the Secure 1000 considered as a cyberphysical device are more mixed. Given physical access, we were able to replace the software running on the scanner console, again allowing attackers to smuggle contraband past the device. On the other hand, we were unable to compromise the firmware on the system control board, a fact we attribute to the separation of concerns embodied in, and to the simplicity of, the scanner design.

The root cause of many of the issues we describe seems to be failure of the system designers to think adversarially. That failure extends also to publicly available evaluations of the Secure 1000's effectiveness. Additionally, the secrecy surrounding AITs has sharply lim-

ited the ability of policymakers, experts, and the general public to assess the government's safety and security claims.

Despite the flaws we identified, we are not able to categorically reject TSA's claim that AITs represent the best available tradeoff for airport passenger screening. Hardened cockpit doors may mitigate the hijacking threat from firearms and knives; what is clearly needed, with or without AITs, is a robust means for detecting explosives. The millimeter-wave scanners currently deployed to airports will likely behave differently from the backscatter scanner we studied. We recommend that those scanners, as well as any future AITs — whether of the millimeter-wave or backscatter [34] variety — be subjected to independent, adversarial testing, and that this testing specifically consider software security.

Acknowledgments

We are grateful to the many people who contributed to the preparation of this report, including Michael Bailey, Nate Cardozo, Cindy Cohn, Prabal Dutta, Jennifer Granick, Nadia Heninger, Daniel Johnson, Daniel Kane, Brian Kantor, Falko Kuester, Sarah Meiklejohn, Kurt Opsahl, Stefan Savage, Daniel Scanderberg, Alex Snoeren, Geoff Voelker, Kai Wang, and the anonymous reviewers. We also thank the outstanding staff members at UCSD and the University of Michigan who helped us navigate the legal and regulatory landscape and made studying the device possible. This material is based in part upon work supported by the National Science Foundation Graduate Research Fellowship Program.

A Radiation Dose Assessment

The Secure 1000 generates low-energy X-rays (50 kVp at 5 mA tube accelerating potential) to construct its images. Although this output is low, the machine still produces ionizing radiation, and careful assessment is necessary to ensure public safety.

The imparted dose has been scrutinized recently by various agencies applying a number of experimental designs [2, 14, 53]. These findings have been consistent with manufacturer claims [38] that per-scan radiation exposure to subjects is nonzero, but is near natural background levels. Additionally, there have been claims and counterclaims surrounding the distribution of dose within the body, with some groups raising concerns that the scanner might impart a minimal deep dose but an overly large skin dose to the subject [5, 40, 43].

To shed light on this question, we executed a brief assessment of the radiological output of the scanner using Landauer Inc.'s InLight whole body dosimeters. These dosimeters give a shallow dose equivalent (SDE), a deep dose equivalent (DDE), and an eye lens dose equivalent. They are analyzed using optically stimulated luminescence (OSL), an established dosimeter technology [9, 20]. We read the results using Landauer's proprietary MicroStar dosimeter reader.

We used a simple experimental design to quantify the dose output: we arranged 21 dosimeters on a RANDO chest phantom positioned upright on a wooden table with a neck-to-floor distance of 144 cm and a source-to-detector distance of 66 cm, approximating the conditions of a normal scan. The dosimeters give a more accurate dose representation if the incident beam is perpendicular to the detector material. In this case, the dosimeters were attached to the chest phantom without regard for beam angle, and so no correction factors were implemented; geometry issues were expected in the results.

The InLight dosimeters require a total dose of at least 50 µSv to be accurate. To irradiate them sufficiently, we performed 4033 consecutive single scans in the machine's normal operating mode. (Each screening consists of at least two such scans: one front and one rear.) A scan was automatically triggered every 12 s and lasted 5.7 s, for a total beam-on time of 6 h 23 min.

We read the dosimeters the following day. A small loss of dose due to fade is expected, but for the purpose of this study we regard this decrease as negligible. We applied the standard low-dose Cs-137 calibration suggested by Landauer. Initially, we were concerned that the low energy output of the scanner (50 kVp tube potential emits an X-ray spectrum centered roughly in 16 keV–25 keV) would lead to inaccurate readings on the InLights, but since the dosimeters are equipped with filters, the dose equation algorithm in the MicroStar reader can deduce beam energy without a correction factor applied to the 662 keV energy from the original calibration.

The average DDE per scan for all the dosimeters was calculated to be 73.8 nSv. The average SDE per scan was 70.6 nSv, and the average eye-lens dose per scan was 77.9 nSv. The standard deviation (σ) and the coefficient of variation (CV) value of all the dosimeters for the DDE were 0.75 and 0.10 (generally low variance) respectively. For the SDE and lens dose, σ and the CV were 1.26 and 0.16, and 2.08 and 0.29, respectively.

An unexpected aspect of our results is that the measured DDE is higher than the SDE, and this occurrence is worth further examination. The irradiation geometry of the dosimeters could possibly explain this irregularity. It might be productive to conduct further experiments that account for this effect.

The doses we measured are several times higher than those found in the recent AAPM Task Group 217 report [2], but they still equate to only nominal exposure: approximately equal to 24 minutes of natural background radiation and below the recommendation of 250 nSv per screening established by the applicable ANSI/HPS standard [3]. A person would have to undergo approximately 3200 scans per year to exceed the standard's annual exposure limit of 250 µSv/year, a circumstance unlikely even for transportation workers and very frequent fliers.

ROP is Still Dangerous: Breaking Modern Defenses

Nicholas Carlini David Wagner
University of California, Berkeley

Abstract

Return Oriented Programming (ROP) has become the exploitation technique of choice for modern memory-safety vulnerability attacks. Recently, there have been multiple attempts at defenses to prevent ROP attacks. In this paper, we introduce three new attack methods that break many existing ROP defenses. Then we show how to break kBouncer and ROPecker, two recent low-overhead defenses that can be applied to legacy software on existing hardware. We examine several recent ROP attacks seen in the wild and demonstrate that our techniques successfully cloak them so they are not detected by these defenses. Our attacks apply to many CFI-based defenses which we argue are weaker than previously thought. Future defenses will need to take our attacks into account.

1 Introduction

The widespread adoption of DEP, which ensures that all writable pages in memory are non-executable, has largely killed classic code injection attacks. In its place, Return Oriented Programming (ROP) has become the attack technique of choice for nearly all modern exploits of memory-safety vulnerabilities. In a ROP attack, the attacker does not inject new code; instead, the malicious computation is performed by chaining together existing sequences of instructions (called *gadgets*) [27].

In response to this, there has been a large effort to find defenses that protect against ROP attacks. Defenses fall in to two broad categories. The first category of defenses relies on recompilation to remove potential gadgets from the program binary or to enforce the Control-Flow Integrity (CFI) [4] of the binary. The other category of defenses attempts to transparently protect legacy binaries using runtime protections.

In this paper, we present three attack methods that can be combined to break many existing ROP defenses from both of these categories. Our first method breaks the conventional wisdom that it is difficult to mount attacks in a fully *call-preceded* manner, that is, where the instruction before each gadget is a `call`. Many CFI-based defenses rely upon policies similar to this. Next, we show that while most existing ROP attacks consist entirely of *short* gadgets, it is possible to mount attacks which consist of long gadgets as well. Therefore, defenses that distinguish a ROP attack from normal execution by looking for a sequence of short gadgets are not secure. Finally, we examine defenses that record a limited history of the execution state of a process. We show it is possible to effectively clear out any history kept by these defenses, rendering them ineffective.

We use these attacks to break two recent state-of-the-art runtime defenses, kBouncer [23] and ROPecker [11]. These defenses are particularly interesting because they can be deployed on existing hardware, have nearly zero performance overhead, and do not require binary rewriting. kBouncer [23] takes advantage of hardware support for recording indirect branches and examines this history at each system call in order to prevent ROP attacks from issuing any malicious syscalls. ROPecker [11] extends kBouncer in novel ways. In addition to checking for any signs of a ROP attack at each system call, ROPecker additionally checks for attacks at various points throughout program execution.

We show that both of these schemes are broken. While they may detect existing ROP attacks, we give ways of modifying a ROP attack so it will not be detected by either of these defenses. The attacks we develop in breaking these defenses are also applicable to many recent CFI-based approaches, and discuss how our work can be applied to four in particular.

This paper makes three contributions:

1. We introduce three novel ROP attacks methods that demonstrate weaknesses in multiple defenses.

2. We demonstrate these attacks on kBouncer and ROPecker, two state-of-the-art ROP defenses. We modify real-world exploits, which these defenses were shown to prevent, to bypass them.

3. Our attacks provide a baseline set of attacks that can be used to evaluate future ROP defenses.

2 Introduction to ROP Attacks

Return Oriented Programming (ROP) [27] is a generalization of return-into-libc [24] attacks where an attacker causes the program to return to arbitrary points in the program's code. This allows one to perform malicious computation without injecting any new malicious code by only controlling the program's execution flow. It has been shown that ROP can perform Turing-complete computation [30]. We provide a very brief overview of return oriented programming in this section. For a more complete introduction, we refer the reader to [7, 25, 27].

A ROP exploit consists of multiple *gadgets* that are chained together. Each gadget performs some small computation, such as loading a value from memory into a register or adding two registers. In a ROP attack, the attacker finds gadgets within the original program text and causes them to be executed in sequence to perform a task other than what was intended.

Gadget chaining is achieved by influencing indirect jumps executed by the program. Each gadget begins with some useful instructions (e.g., `mov rax, rbx`) and ends with an indirect jump (e.g., `ret` or `jmp *rcx`). The attacker chains gadgets together by controlling the target of a gadget's indirect jump to point to the beginning of the next gadget in the sequence. In a classic ROP attack, gadgets end with the `ret` instruction and the attacker chains gadgets by writing appropriate values over the stack.

Many ROP attacks use *unintended* instruction sequences. Because x86 instructions are variable-width, it is possible that a potentially useful gadget sequence exists when starting at an offset that was not intended to be the beginning of an instruction. Our attacks do not rely on unintended instructions.

In Figure 1, we give an example ROP exploit that adds 0x32400 to the value stored at address 0x4a304120. This exploit begins by initializing two registers. It then reads the value stored at address `eax`, stores it into `eax`, adds `ebx` to `eax`, and stores this value back into memory.

Address Space Layout Randomization (ASLR). One common defense for ROP attacks is ASLR which works by randomly moving the segments of a program (including the text segment) around in memory, preventing the attacker from predicting the address of useful gadgets. Despite ASLR, ROP attacks are still common in the wild for two reasons. First, if even a single module has ASLR disabled, a ROP attack may be formed around only the code in that module. Second, an attacker may use an *information disclosure vulnerability* to de-randomize some module [29].

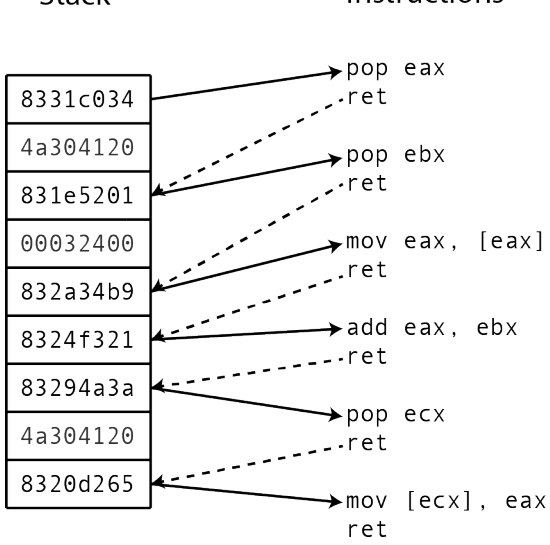

Figure 1: An example ROP exploit which adds the constant 0x32400 to the word at address 0x4a304120. At the left is the stack of the process with the addresses of the gadgets and the values to initialize the registers. At right are the instructions at those addresses.

3 Our Three Attack Primitives

We have identified three building blocks that are useful in attacking ROP defenses:

- *Call-Preceded ROP.* Normally, in a well-structured program, every `ret` instruction returns back to an instruction that immediately follows a corresponding `call`. ROP attacks deviate from this pattern. Therefore, many ROP defenses ensure that every `ret` instruction always targets an instruction that immediately follows some `call`. Our attack demonstrates that this policy is not sufficient: ROP attacks are still possible even when returns are restricted in this way.

- *Evasion Attacks.* It is common for defenses that monitor program execution at runtime to have a method of classifying execution as either "normal execution" or "gadget". Evasion attacks involve using gadgets that the defense classifies as "normal."

- *History Flushing.* Some defenses maintain only a limited amount of history about execution and inspect this history periodically. We can bypass defenses with this property by flushing the true history (cleansing the history of all signs of the ROP attack) and then presenting a new, fake view of history that the defense will not classify as an attack.

Each of these three attack primitives bypasses a common defense mechanism. This section gives more detail about each of these three primitives. We then combine them in different ways to mount our full attacks on kBouncer [23] and ROPecker [11] in the following sections.

3.1 Call-Preceded ROP

The call-preceded policy. We say that an instruction is *call-preceded* if the instruction immediately preceding it is a `call` instruction. Many ROP defenses [6, 23, 32, 34] apply the following policy: any time a `ret` instruction is executed, its target must be a call-preceded instruction.

This policy seems helpful for defending against ROP attacks. In well-structured programs, calls and returns usually come in pairs. Any address that is returned to was almost always pushed by a `call` instruction previously. In a ROP attack, gadgets use the `ret` instruction to chain gadgets together, so this policy dramatically limits the space of candidate addresses where gadgets can be chosen from. For instance, one evaluation found that only 6% of gadgets are call-preceded [23]. Thus, one might intuitively expect the call-preceded policy to significantly increase the difficulty of mounting a ROP attack.

Using only call-preceded gadgets. Despite this intuition, we find that it is possible to mount ROP attacks in a fully call-preceded manner, where all gadgets start at a call-preceded address. The key idea is we allow gadgets to be more complex. This increases the space of candidate gadgets enough to find many call-preceded gadgets. By allowing our gadgets to be long and contain direct jumps or even conditional jumps, we find many more useful gadgets. In our experiments (see § 8.2), 70KB of binary code was sufficient to mount fully call-preceded ROP attacks.

3.2 Evasion Attacks

Classification-based defenses. Other ROP defenses work by monitoring the runtime behavior of a process and try to detect ROP attacks by classifying segments of execution as either "gadget" or "non-gadget", using some signature that is intended to characterize attributes of ROP gadgets. One of the most common approaches used to classify execution, as used in [11, 23], uses a length-based classifier. Existing ROP attacks tend to consist of long sequences of short gadgets, and so these defenses use this as their heuristic to classify gadgets.

These defenses separate the execution trace into segments of ordinary instructions, separated by indirect instructions (e.g., returns, indirect jumps). A length-based defense classifies each segment as gadget or non-gadget by examining its length: a short segment is classified as a gadget and a long segment as a non-gadget. If the defense observes too many short segments within some window, it reports a ROP attack.

Using gadgets that look like benign execution. A powerful attack on such defenses is to look for instruction sequences that would be classified by the defense as a non-gadget, but that perform some useful computation. These can then be used as stealthy gadgets in a ROP attack.

Length-based classifiers are particularly easy to evade. A simple attack is to use long gadgets, since these will be incorrectly classified by the defense as non-gadget. We demonstrate that it is possible to mount a ROP attack that contains a mixture of both short and long gadgets, thus evading many published detectors.

More generally, one could imagine future ROP defenses that rely on other heuristics for distinguishing ROP attacks from normal program execution. An *evasion attack* is one that will be classified by the defense as normal, but in reality allows the attacker to mount a ROP attack.

3.3 History Flushing

History inspection defenses. There are many runtime defenses that inspect program execution at different points throughout its execution. Typically, these defenses keep only a limited amount of history about the program's execution, and so must decide whether an attack is occurring or not based upon information saved in the recent past. Usually, performance considerations rule out constantly monitoring all execution, so this inspection process is only invoked at certain points (e.g., when the application issues a system call).

Using gadgets to hide history. Such defenses can be fooled by preventing them from seeing any evidence of a ROP attack. We perform the ROP attack when they are not watching, periodically performing enough innocuous actions to wipe the history clean of any evidence of the past ROP attack before the defender's inspection process is invoked. While the defender is running, we do not attempt to make progress towards our attack goal. Instead, we insert effective no-op instructions so that the defender does not see any evidence of attack.

Though similar, this attack is different from an evasion attack. An evasion attack attempts to make progress in the attack while being *continuously* monitored by the defender. In a history flushing attack, there is a period of time when the defender is not running, when we make forward progress. Before the defender runs, we clear out this history so it is not visible to the defender, but do not attempt to make forward progress while the defender is watching. After the defender has made its observation, we continue with our attack.

For instance, kBouncer uses the Last Branch Record, a

hardware feature that records the 16 most recent indirect jumps. Our history-flushing attack on kBouncer performs the bulk of the ROP attack, then performs 16 innocuous indirect jumps to remove the evidence of the ROP attack from the Last Branch Record. As we show (§ 8.3), this prevents kBouncer from detecting the ROP attack.

4 Attack Goal & Threat Model

Attack Goal. The goal of each of our attacks, without loss of generality, is to issue a single syscall. It is usually enough to issue a `mprotect` (on Linux) or `VirtualProtect` (on Windows) system call to make a page in memory both writable and executable; after that, exploitation is trivial.[1]

This is not the only possible goal an attacker may have. There are other methods of attack that do not involve issuing system calls [10]. We do not consider them in this work, although our results suggest these attacks are equally possible, and in some cases even trivial.

Threat Model. At a minimum, we assume that an attacker has a known exploit that allows control of the instruction pointer in the future. A stack overflow is sufficient; a heap overflow that allows an arbitrary memory write to a function pointer is also sufficient; as is directly overwriting other function pointers. We assume the attacker knows that the defense is present and knows how it works. We assume that DEP is enabled, so no page is both writable and executable. We focus on the case where the program contains at least one library whose executable region has not been randomized with ASLR, or where all modules have ASLR enabled but there exists a memory disclosure vulnerability, as this is the situation that modern ROP attacks typically exploit.

We also assume that there exists some way of running arbitrary code if the new defenses were not present. We do not claim to create attacks that allow running arbitrary code in all situations; we only hope to show that if it is possible to mount a ROP attack when the defense is not present, then it is possible when it is present.

5 Defeating kBouncer

5.1 Overview of kBouncer

Pappas et al. introduced kBouncer [23], a scheme that uses indirect branch tracing to detect ROP attacks. At a high level, kBouncer periodically pauses execution of the program, inspects recent execution history, and then either allows the process to proceed or kills it.

[1] Alternatively, if we can execute the `execve` syscall, we can spawn a second process running an arbitrary program.

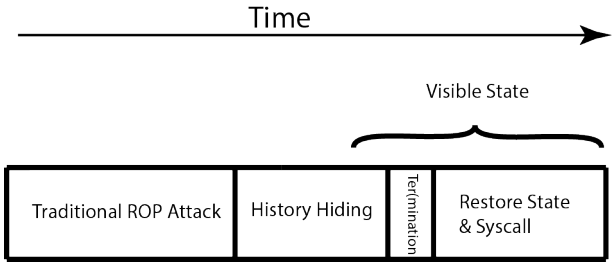

Figure 2: Overview of our history hiding attack on kBouncer. We mount a traditional ROP attack, insert a number of innocuous gadgets to hide this from kBouncer, and finally restore registers and issue the desired syscall.

kBouncer uses the Last Branch Record (LBR), a feature of modern Intel CPUs, to inspect the last 16 indirect branches taken each time the program invokes a system call. kBouncer checks two properties of the history stored in the LBR. First, it verifies that all `ret` instructions in the LBR returned to a call-preceded address. Second, if the eight most recent indirect branches are all gadget-like, the process is killed. kBouncer defines a sequence of instructions as *gadget-like* if there exists a flow of execution from the first instruction executed to any indirect branch in under 20 instructions.[2] kBouncer is very efficient: it only needs to check the LBR during system calls and only checks 16 different entries in the LBR.

5.2 History Hiding Attack

5.2.1 Attack Overview

We dub our first attack on kBouncer the *history hiding attack* (see Fig. 2). At the core of kBouncer is the assumption that an attack can be detected by inspecting the state of the process at the syscall interface, after the attacker has already gained control of the system for a potentially unbounded period of time. After mounting a traditional ROP attack to prepare the state of memory (and possibly defeat ASLR, if required), we use a history flushing attack to clear evidence of the attack from the LBR. Finally, we use an evasion attack and a few carefully-chosen gadgets to issue the syscall.

We call a process state *valid* if kBouncer's inspection method will not detect an attack when run from that state. A state is valid if all of the entries in the LBR whose source is a `ret` instruction have a call-preceded destination, and if at least one of the last eight entries has more

[2] kBouncer cannot observe the actual path of execution taken during a sequence of instructions between two indirect jumps, so it cannot count the number of instructions actually executed between two indirect jumps. It can only observe the beginning and end of that sequence. For this reason, kBouncer conservatively treats a sequence as gadget-like if it starts with an instruction that can reach an indirect jump in less than 20 instructions.

than 20 instructions between source and the nearest indirect branch. We show that it is easy to return to a valid state while simultaneously maintaining control of the process. The steps of the history hiding attack are as follows:

Initial exploitation. Initially, we mount a traditional ROP attack in whichever way is easiest. We ignore the fact that kBouncer is running and use any gadgets we would like, call-preceded or not. We then prepare memory so we are ready to make the syscall, but we do not invoke it yet.

Hide the history. At this point in our exploit, we are ready to make the syscall, but if we were to actually issue it, kBouncer would detect an attack. To fix this, we must bring the process into a valid state without losing our progress from the prior step. To do this we use the history-flushing primitive discussed previously. As a side effect of using the flushing primitive, the registers may be clobbered, but important memory locations will remain unchanged.

Restore registers and issue the system call. After bringing the process into a valid state, we restore the registers to their desired values while maintaining a valid state. Then, we issue the system call. This is via an evasion attack: because the task is relatively simple, it can be accomplished with fewer than 8 call-preceded gadgets.

```
                    add  [esp+17Ch],ebx
                    mov  ebx,[esp+17Ch]
(1)                 sub  ebx,ebp
   pop  ebp         jmp  A
   ret              ...
                A:  add  [esp+64h],ebx
(2)                 jmp  B
   jmp  A           ...
   ...              mov  esi,[esp+1C0h]
A: mov  eax,3       lea  eax,[esi*8-4]
   ret              sub  eax,[esp+64]
                    and  eax,7h
(3)                 mov  edi,[esp+64]
   cmp  eax,6       lea  eax,[edi+eax+4]
   jbe  B           shr  eax,3
   ...              cmp  eax,esi
B: ret              jbe  C
                    ...
(4)             C:  mov  eax,[esp+1C0h]
   xor  eax,eax     add  esp,19Ch
   ret              pop  ebx
                    pop  esi
(5)                 pop  edi
   mov  [eax],0     pop  ebp
   ret              ret
```

(a) Flushing Gadgets (b) Termination Gadget

Figure 3: Examples of the two types of gadgets used by our history-hiding attack on kBouncer. A flushing gadget flushes the contents of the LBR. A termination gadget brings the system into a valid state.

5.2.2 Initial Exploitation

This step prepares memory to make it as easy as possible to issue the syscall in as few gadgets as possible after the history has been flushed. In particular, we prepare all of the arguments for the system call and save them in some easily recoverable location. We make no restrictions on the methods the attacker may use during this step of our attack. Because we are going to hide our history, kBouncer will not observe anything performed in this step. Since ROP gadgets are Turing-complete, we are able to perform arbitrary computation during this phase, so this step is straightforward to implement.

5.2.3 Hiding the History

Hiding history through LBR flushing. We use a history-flushing primitive, built from two gadgets (Fig. 3), to remove all traces of our attack from the LBR:

1. A short *flushing* gadget: a simple call-preceded gadget that performs a `ret`, and ideally does not modify many registers.

2. A long *termination* gadget: a call-preceded gadget that is long enough for kBouncer to not classify it as a gadget: there must be at least 20 instructions along every possible control path from the start of this gadget to any indirect branch.

We use these two gadgets as follows. First, we repeatedly use the flushing gadget to completely clear the contents of the LBR until it only contains the flushing gadget repeated 16 times. Though the LBR has been flushed and contains no history of the previous ROP attack, the state is still not valid. If kBouncer were to be invoked at this point, every entry in the LBR would be classified as a gadget by kBouncer and an attack would be detected.

We now use the termination gadget. The purpose of this gadget is to bring the LBR into a valid state by making at least one of the last eight entries in the LBR have length greater than 20. That is, the termination gadget is used to *terminate* kBouncer's backwards search for gadget-like sequences. We make no assumptions about the register state after the termination gadget is executed: the only requirement is that after we use it, we still have control of instruction flow.

```
4a833dd4        dec     ecx
4a833dd5        fmul    [4A88BBC8h]
4a833ddb        jne     4A833DD4
```

Figure 4: An example of a context switch gadget found in `icucnv36.dll`.

Note that during the first step where the attacker prepares memory, the attacker may perform arbitrarily complex calculations. This may make it possible to initialize registers and memory so that executing the flushing gadgets and then the termination gadget results in exactly the desired state to issue the syscall. However, this is not always possible. For example, the termination gadget may set `eax` to 0, but issuing the syscall may require `eax` to be 7. Our attack handles this situation by later restoring register state (described below).

Because the termination gadget is over twenty instructions long and might contain conditional branches, it is sometimes necessary to initialize registers and memory to meet the preconditions for successful execution of the termination gadget. First, we need to ensure that any conditional branches in the termination gadget will be followed in a specific manner. Second, memory reads and writes must not fault and crash the process. This is often as easy as initializing registers to specific values before using the termination gadget. We have found that termination gadgets are very common, and that it is often easy to find termination gadgets that perform only a few conditional branches and memory reads and writes (see § 8.3.1).

History hiding by itself does not defeat kBouncer, but it simplifies the attacker's job from expressing the entire attack using call-preceded gadgets to expressing only the final step of the attack using call-preceded gadgets.

Hiding history through context switching. We also found an alternative way to flush history. The LBR is shared across all user-space processes. This lets us flush the LBR using a single gadget, the *context switch* gadget. A context switch gadget is one that will run for many seconds and will not contain any indirect branches. The simplest way to find such a gadget is to look for loops that perform a very limited computation using only registers, see Fig. 4 for one such example.

To flush the LBR, we call the context switch gadget once. Due to the number of cycles this gadget takes to execute, it is almost certain that there will be several context switches to other user threads during its execution. When this happens, the other thread will write its own entries to the LBR, flushing all history of our prior attack. Eventually, when our context switch gadget finishes, the LBR will be in a valid state as long as the other process was not under attack, as the LBR is now full of innocuous entries from the other process.

Future hardware could save and restore the LBR on context switches, which would prevent this method of history flushing. Therefore, we did not use this approach in our case studies (§ 8); instead, we used flushing and termination gadgets, which would suffice to hide history even if the LBR was saved and restored on each context switch.

5.2.4 Restoring Registers with Returns

We must now restore the registers to their desired values in order for the syscall to proceed. This is by far the simplest step and can be usually be accomplished with a few gadgets that pop register values off the stack. kBouncer will be able to observe each gadget we use, so each one must be call-preceded and we must use fewer than eight.

This step is often very easy because of the x86 calling convention: the procedure being called must restore almost all of the registers, so procedures tend to begin by pushing all of the registers onto the stack and end by popping those values off to restore them. This allows us to find a gadget that pops all the registers off the stack and then returns. Usually, we can find all the (call-preceded) gadgets we need in this way.

5.2.5 Restoring Registers without Returns

There are other ways to restore register state. We now discuss four alternative methods. The first two are existing techniques that can be applied here, but in our experience are difficult to apply in practice due to the fact that we must use fewer than eight gadgets. We have found the later two techniques more applicable in practice.

ROP without return instructions. Checkoway et al. found it is possible to mount a ROP attack by looking for a `pop` followed by an indirect jump (e.g., `pop edx; jmp *edx`) [8]. This instruction sequence is functionally identical to a `ret`, and so can simply be used in its place. However, these sequences are less common.

Jump Oriented Programming (JOP). JOP attacks use register-indirect jumps to chain gadgets together. Unfortunately, each useful gadget must be followed by a dispatcher gadget, which is used for chaining. Since we must restore register state with at most eight gadgets, if we want to use JOP, we are limited to four useful JOP gadgets.

Using Non-Call-Preceded Gadgets. Occasionally, it may be easier to use non-call-preceded gadgets. We can invoke a non-call-preceded gadget using a *reflector* gadget. A reflector gadget is a call-preceded gadget that ends in a register-indirect jump; it can be used to jump to any gadget we like, call-preceded or not. This is because kBouncer imposes no constraints on indirect jumps. Our

experience is that this trick is rarely needed in practice, but sometimes it makes constructing the attack easier.

Call Oriented Programming (COP). We have found an alternate method of mounting a ROP-like attacks without using `ret` instructions. We call our approach Call-Oriented Programming (COP). Instead of using gadgets that end in returns, we use gadgets that end with indirect calls. This may at first seem trivially similar to jump-oriented programming, but there is one important distinction: indirect calls are usually memory-indirect (the location to which control is transferred is determined by a value in memory, not directly by the value of a register). As a result, COP attacks do not require a dispatcher gadget. In a COP attack, gadgets are chained together by pointing the memory-indirect locations to the next gadget in sequence. The initialization of these memory locations can be done *in advance*.

This allows our attack to set up these memory locations before the history hiding, then restore register state using COP gadgets. As long as fewer than eight COP gadgets are used, kBouncer will detect no attack. When mounting a COP attack, it is trivial to directly issue the desired system call as well: the final gadget in the sequence will point to the system call to be issued.

We have found that memory-indirect calls, and in particular COP gadgets, are common. They are even more common than call-preceded gadgets that end in a `ret`. There are two reasons why this is the case. First, with dynamically linked libraries, all calls to functions outside of the current module are indirect calls, because the function location is not known in advance. Second, most object-oriented code relies on memory-indirect calls (e.g., the vtable in C++).

COP attacks do not eliminate the need for `ret`-based gadgets. Initializing a COP attack is much more difficult: the attacker must have control of program flow, must overwrite specific indirect-call locations, and must control the stack. This usually is not possible with a single exploit. Therefore, it is natural to combine a ROP attack (for initial setup) with a COP attack (for restoring registers).

5.2.6 Issuing the System Call

The final step of our attack is to issue the desired syscall. We usually accomplish this by calling the appropriate `libc` or `kernel32` wrapper function.

There is one complication. We cannot simply return directly to the beginning of the desired function (e.g., `mprotect`, `VirtualProtect`) as a normal ROP attack would. When kBouncer is in place, this is not possible: the attack would fail because the start of this function is not call-preceded. We have found three different ways to call a function without directly returning to it.

```
    call [7C37A094]
A:  mov eax,[_osplatform]
    jmp B
    ...
B:  dec eax
    neg eax
    sbb eax,eax
    and eax,103
    lea ecx,[ebp-0Ch]
    push ecx
    inc eax
    push eax
    push [EBP-8]
    push [EBP-4]
    call [VirtualProtect]
```

Figure 5: A call-preceded call to `VirtualProtect` in `msvcr71.dll`. The attacker can return directly to `A`.

1. We can use a *reflector gadget*: a call-preceded gadget that ends with a register-indirect jump. This allows us to simply set a register to point to the function we wish to call and then return to the reflector gadget. This is the simplest approach if a reflector gadget can be found.

2. It is still possible to exploit the desired function even if no reflector gadgets are available. This is achieved by finding an call to the desired function somewhere in the program's code and looking backwards in the instruction sequence for a preceding `call`. Fig. 5 shows an example where the `msvcr71.dll` binary directly calls `VirtualProtect`.

3. It is sometimes possible to return into the middle of a desired function, right after a `call` instruction. For example, `execv()` launches a shell with a string and an array of arguments (Fig. 6). If we initially initialize `rax` to contain a valid environment pointer, we can call `execv` by returning directly to `<execv+18>`, which is call-preceded.

Any of these can be used to complete our attack.

5.3 Evasion Attack

Our history hiding attack breaks kBouncer by taking advantage of its limited history. If kBouncer were extended to have a complete view of history, would it become more effective? We show that, even if the LBR were of infinite size, kBouncer could still be broken by an evasion attack.

Our attack is similar to the history hiding attack (§ 5.2), except that the initial preparation phase is mounted using only call-preceded gadgets. This eliminates the need

```
<excve>:
    push   rbp
    mov    rbp,rsp
    push   r14
    push   rbx
    mov    r14,rsi
    mov    rbx,rdi
    call   _NSGetEnviron
    mov    rdx,[rax]
    mov    rdi,rbx
    mov    rsi,r14
    call   execve
    mov    eax,-1
    pop    rbx
    pop    r14
    pop    rbp
    ret
```

Figure 6: Disassembly of the `execv` function in libc on our system. The call to `_NSGetEnviron` allows a call-preceded return directly into this function.

for a flushing gadget, the only piece that an infinite-LBR kBouncer would preclude. Therefore, our attack consists of a (call-preceded) setup, a (call-preceded) termination gadget, followed by (call-preceded) register restoration and syscall.

This yields a successful evasion attack on kBouncer. By using only call-preceded gadgets and by breaking up the chain of short gadgets with a long termination gadget, kBouncer can see the entire attack but still will not recognize it as an attack. Our experiments show that if over 70KB of program text is available, then there are enough call-preceded gadgets that this attack is possible (see § 8.2).

6 Defeating ROPecker

6.1 Overview of ROPecker

ROPecker [11] is a ROP defense that builds on ideas found in kBouncer. ROPecker differs from kBouncer by running its inspection method more frequently and inspecting the program state more thoroughly at the time of inspection. The actual policy it enforces is very similar to the kBouncer policy.

In ROPecker, only a few pages are ever marked executable at one time. We call these pages the *executable set*. Whenever a page not in the executable set is executed, a page fault is generated and ROPecker pauses process execution to check for an attack. If ROPecker does not detect an attack, it marks the new page as executable, marks the least recently executed page as non-executable, and resumes the process. ROPecker also runs its detector whenever the process invokes a syscall as kBouncer does.

ROPecker's detector is more sophisticated than kBouncer's in that it looks at both the recent past and projects forward into the near future. Similar to kBouncer, ROPecker classifies the current state as an attack if there is a long chain of *gadget-like* sequences in the LBR (the recent past). In addition, ROPecker attempts to emulate what will happen in the near future once the process is resumed. It counts the number of gadget-like sequences that are about to execute. If the sum of the number of gadgets found in the LBR and the number of gadgets looking forward exceeds some threshold, ROPecker classifies this as an attack.

ROPecker's emulation works by disassembling the instruction stream from the instruction that is about to execute when the page fault occurs. If there is a short sequence of instructions that leads to an indirect jump, ROPecker classifies this as a potential gadget. ROPecker will then emulate the effects of each of the instructions leading to the indirect jump in order to compute where this jump will go. ROPecker follows this indirect jump and starts disassembling again. When it reaches an instruction where there is not a short sequence of instructions leading to an indirect jump, it stops the search. ROPecker then counts the number of indirect jumps followed, and classifies each of those as gadgets.

ROPecker verifies that from the current execution point there are not 11 gadget-like sequences of instructions.[3] ROPecker classifies an instruction sequence as a gadget if it contains six or fewer instructions ending in an indirect branch, with no direct or conditional branches along the way.

6.2 The Repeated History Hiding Attack

6.2.1 Attack Overview

We show how to break ROPecker using a *repeated history hiding* attack. This attack repeatedly invokes the history-hiding primitive, introduced in § 3.3, just before ROPecker's detector is about to execute. We again define a state to be *valid* if the inspection method will not detect an attack. The state must be valid at two points in time: whenever a new page is loaded in to the executable set and whenever a syscall is executed.

Our attack alternates between three phases, as depicted in Fig. 7. The *loading phase* loads useful pages into the executable set. The *attack phase* invokes gadgets on these pages. The *flushing phase* mounts the history hiding attack from § 5.2 using only gadgets from the pages that are

[3] The ROPecker paper does not pick a specific parameter for the maximum number of gadgets that may execute consecutively. It suggests this number is chosen between 11 and 16, so we conservatively pick 11. Our attacks are made easier if a larger number is chosen.

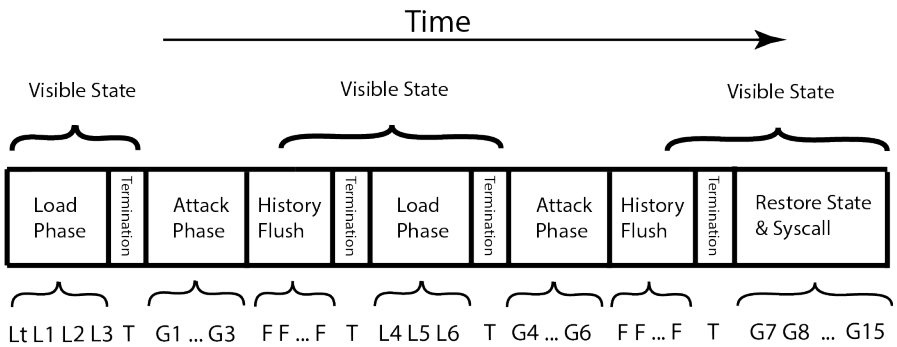

Figure 7: An overview of the repeated history hiding attack on ROPecker. `Ln` gadgets load page `n`. `Lt` loads the termination gadget. `Gn` invokes a gadget on page `n`. `F` is a short flushing gadget, and `T` is a long termination gadget.

in the executable set. We may need to execute each of these three phases multiple times to achieve our goal. We conclude with one final step which actually issues the desired syscall after restoring the required state. Because we use only gadgets in the executable set during each attack phase, ROPecker's detector will execute only when new pages are loaded, which allows us to reason about what will be visible to ROPecker.

6.2.2 Attack Phases

Initialization. Prior to our attack, we insert a termination gadget, which will stop ROPecker from looking further back in the LBR. This long termination gadget is identical to the one used in the kBouncer attacks. This ensures that when ROPecker next runs, it will not count any functions on the call stack prior to initialization as gadgets.

Loading Phase. We load useful pages into the executable set by invoking a page load gadget on each page we want added to the executable set. A *page load gadget* is any call-preceded gadget on that page, which has two properties: first, it must leave the attacker with control of the instruction flow; and second, it must not crash the process. These two requirements are not difficult to meet: any useful gadget is also a page load gadget. The ROPecker detector will run immediately before each page load gadget is invoked. After invoking each set of page load gadgets we call the termination gadget to prevent the detector from looking forward any farther into the future.

ROPecker will not detect an attack because each sequence of page load gadgets is immediately preceded and followed by a termination gadget. When a page fault occurs, ROPecker will count the number of visible gadgets looking backwards in the LBR and forwards as far as it can see. Looking backwards will stop at preceding termination gadget, and looking forward will stop at the subsequent termination gadget. Thus, ROPecker will count the number of page load gadgets. By limiting the number of consecutive page load gadgets, the attacker can evade detection during this phase.

Attack Phase. Now that the useful pages have been loaded, we can use any gadgets on these pages to mount an attack, ignoring any defense which may be running. As long as we use only gadgets on these pages, the defense will never trigger.

Recall that these three phases are repeatedly executed, so no one attack phase needs to perform the entire attack. Instead, the attack can be distributed among multiple attack phases, making each one simpler.

History Hiding. After invoking gadgets on these pages, we now use the history flushing primitive before the detection method next runs. We use the same method we applied against kBouncer to clear the LBR. In particular, we invoke a short flushing gadget enough times to fill the LBR with innocuous entries, then invoke the long termination gadget (which was loaded previously). When the ROPecker detector next runs, it will see no attack prior to this point in time.

6.2.3 Segmenting the Attack Payload

When mounting this attack, we must carefully pick which tasks to perform during each attack step. Because the flushing and termination gadgets clobber some register state between each attack step, it is important to pick small independent operations for each step of the attack.

For any given attack, it may not be possible to modify it to work as an attack which bypasses ROPecker. Instead, attacks must be formed with ROPecker in mind. Each step in the attack must be constructed to use only a limited number of gadgets, so that its work can be saved before loading in a new set of gadgets.

Often, we start by computing the address of the desired `libc` function we wish to call (e.g., `mprotect`) either by adding a constant to the address of some other function

in `libc`, or by loading it directly. We store the result in memory. In the next attack step, we compute the address of the page we wish to mark as executable (typically on the stack). We continue in this way, computing any other needed constants in separate attack steps. We then restore register values and call `mprotect` on the desired page. Finally we can execute a traditional payload with data we have written to this page.

6.2.4 Selecting Pages to Load

Since the executable set can contain only a few pages at one time, we must choose these pages with care. The naive approach is to select each page to load for one useful gadget on that page, and call each gadget exactly once. We have found that this simple method works well in practice in most cases. Because the flushing and termination gadgets may clobber a few registers, we may need reserve one or two of those gadgets to load and save registers to memory, so that a task can be partially completed in one attack step.

A more advanced method is to pick pages that contain multiple gadgets. In our evaluation, we found that in practice there tend to be many "useful" gadgets on the average page. Thus, by selecting the pages carefully, we can find pages with enough useful gadgets. This is enough that we can attack ROPecker even when the size of its executable set is limited to just one or two pages.

6.2.5 Issuing the Syscall

Once we have executed sufficient load/attack phases to set up the state of the process, we append one final step to actually issue the desired syscall. This step is not executed multiple times: it is done only once at the very end.

During this step, we flush history, invoke the termination gadget, and then issue the syscall using one of the three methods from § 5.2.6. We perform this step using at most 10 gadget invocations so that ROPecker will not detect an attack when it examines the LBR at the syscall.

Conveniently, it is possible to use any gadget in the entire binary during this step, even if it is not contained within the executable set. No page loading gadgets are needed. This works because there will be at most 10 gadgets between the termination gadget and the syscall. Thus, even though ROPecker's detector may run during this step (if we use a gadget that's not in the executable set), its count of the number of gadgets will be below 11, the threshold for detecting an attack.

Note that, in particular, an attack which requires fewer than ten gadgets to execute can skip the load/attack phases and directly issue the syscall in this way.

6.3 The Evasion Attack

We now present the ROPecker evasion attack, an alternate attack that would break ROPecker even if the size of the executable set were reduced to just *one* page. As a side benefit, in our experience the evasion attack makes it easier to automate attacks in practice than the repeated history hiding attack of § 6.2.

At a high level, the idea is that we will let ROPecker inspect the execution of our attack at arbitrary points in time. We ensure that no matter when its detector runs, it will never detect an attack. We achieve this through an evasion attack similar to the one presented on kBouncer (§ 5.3).

The ROPecker evasion attack works by inserting a termination gadget in between every ten useful gadgets. When the detector runs, it will check forward and backward to count the number of gadgets in use; there will be fewer than 11 gadgets, the threshold for detection, so ROPecker will not detect the attack.

The authors of ROPecker note that this attack may be possible in § VII(b) of their paper [11]. They propose a mitigation for such an attack. We show that even their mitigation is broken.

The ROPecker mitigation. ROPecker detects an attack if there are more than ten consecutive gadgets. The extended version of ROPecker records how many gadgets existed in previous runs of the detector. It detects an attack if the number of gadgets which executed in the last T runs is larger than some threshold. While it is possible for there to be 10 sequential gadget-like returns in benign program execution, it is unlikely for there to be 10 sequential gadget-like returns *T times in a row*.

Conceptually, this is analogous to running the detection mechanism both forwards and backwards, allowing up to $T-1$ long gadgets before stopping the search. An attack is detected if the number of gadgets found by this extended search is greater than some threshold.

This defense *does not* help against our repeated history hiding attack. In that attack, ROPecker only ever sees as many gadgets as pages that are being loaded. This constant is usually very small (e.g., two or four). The ROPecker authors observed that benign execution does occasionally execute four sequential gadget-like chains (with frequency 0.58%). This frequency is large enough that signaling an attack if there are four gadgets repeated three times would cause too many false positives.

Breaking the mitigation. The extended version of ROPecker can be broken by a simple modification of our evasion attack: instead of invoking the termination gadget once, invoke it T times in a row. We alternate making one step of useful progress (with ten useful gadgets) with invoking the termination gadget T times. This prevents

ROPecker from detecting consecutive long chains of gadgets. Instead, it sees a long chain followed by several short chains, which will not trigger the defense.

Practicality. One might wonder whether evasion attacks are practical. If, between every ten useful operations, we must potentially destroy our progress, can we achieve any useful computation?

We found it is still possible to perform useful tasks even when inserting a termination gadget (or, potentially multiple termination gadgets) in between every ten useful gadget (see § 8.3). We save register state to memory before each termination gadget and restore it afterwards. It is only necessary to save and restore registers that are both clobbered by the termination gadget and used by the rest of our attack. In our experience, it is often possible to find termination gadgets that only clobber one or two registers. This allows for many gadgets that make forward progress, with a few dedicated to saving and restoring state.

6.4 Attack Comparison

These two attacks are useful in different circumstances. The most important difference is when the detection mechanism runs. In repeated history hiding, the detection only ever runs after a history flush, and so the defender can never even see what the attacker is doing. In the evasion attack, the defender is continuously monitoring the attack progress. This leads to the key distinction between the two attacks. In repeated history hiding, we have a very limited set of gadgets, but may use them an unbounded number of times before flushing. In the evasion attack, we have all of the gadgets in the program available to us, but must flush every ten gadgets.

7 Fixable Attacks on ROPecker

We now discuss several ways in which ROPecker is broken that our attack does not rely on. That is, the attacks discussed in the previous sections work *even if we improve ROPecker's detection mechanisms* to prevent each of the following specific attacks. We believe these modifications are possible, and it is only the engineering difficulties of obtaining a low overhead that explains why they are not currently implemented. Because of this, we do not base our previous attack on these fixable implementation issues.

Gadget definition does not allow any branches. ROPecker's definition of a gadget is overly specific and does not allow gadgets to contain either direct or conditional branches. In comparison, we have found that kBouncer's definition of a gadget is strong: it is difficult to find gadgets of length twenty or more that perform useful computation.

ROPecker's choice to not follow any direct or conditional branches is a flaw that, while allowing for a more efficient implementation, makes exploitation nearly trivial. This decision allows an attacker to flush the LBR, and to stop the forward-inspection algorithm, with a no-op-like gadget that jumps directly to a return instruction. This form of gadget is pervasive in program binaries and allows for a much simpler termination gadget that does not clobber any register state.

In fact, when evaluating the practicality of our attacks on kBouncer *before becoming aware of ROPecker*, nearly all of our exploits contained at least one *useful* gadget that would not be classified as a gadget by ROPecker's definition.

Gadget chain threshold is too short. ROPecker's choice to define gadgets as being a sequence of six or fewer instructions makes it nearly trivial to find gadgets that have a predictable behavior while still being classified as a non-gadget by ROPecker. For example, on 64-bit systems, the gadget consisting of popping off registers `r10` through `r15` followed by a `ret` is seven instructions long: not only is this a useful gadget, it is very common. ROPecker's failure to recognize it as a gadget is a serious limitation of ROPecker.

The set of risky system calls is not complete. ROPecker's set of *risky system calls* is too limited and needs to be updated to more closely match those used in kBouncer. Because ROPecker is designed for Linux and kBouncer for Windows, we cannot simply replace one with the other. However, other than performance reasons, there is no reason to not defend all system calls.

8 Evaluation

The attacks discussed in the previous sections are practical. We evaluate these attacks by modify real-world exploits, as well as by demonstrating that only 70KB of code is needed to mount purely call-preceded attacks.

8.1 Our Tool

We built a tool to assist our efforts in finding attacks on real-world exploits. It does not automatically break either of these two defenses, but assists in finding useful gadgets. We wrote our tool as a 1K line Python program. It takes as input a disassembled object file (from `objdump`), and therefore only inspects *intended* instruction sequences: even though there may be unintended instruction sequences which are call-preceded, we ignore these.[4]

[4] Even though ROPecker does not enforce gadgets are call-preceded, we still use this tool to evaluate ROPecker, as we find it is sufficient to identify useful sequences.

Binary	Setup	Flush	Syscall
diff	8	3	2
grops	4	3	4
lsof	12	2	3*
ltrace	4	2	2
grub-mkimage	4	4	3
strace	17	4	2*
pic	11	2	3
apt-get	14	3	2*
info	13	3	3*
apt-ftparchive	4	3	2

Table 1: The number of gadgets for the three steps in our kBouncer attack for binaries from `/usr/bin/`. Entries marked with an asterisk have success probability of $\geq 99.99\%$, the rest with 100%.

Our tool first enumerates all potential call-preceded gadgets. We implemented a simple symbolic execution framework to determine the effects of each of these potential gadgets. This system is not complete, but it models some of the effects of many common instructions.[5] It computes and outputs the path constraints that must hold to follow the conditional branches in a gadget. It also outputs the list of modified memory locations, accessed memory locations, and the new values of updated registers at the end of execution.

The tool returns a list of gadgets sorted by ease of use: gadgets with fewer conditional branches and fewer memory locations which must be valid rise to the top. Each gadget is marked with a hint on how it might be useful (e.g., that the gadget is a memory-load gadget, or that it computes the sum of two registers). It also provides us with a list of termination gadgets, sorted by ease of use and the number of other registers they clobber.

8.2 Fully Call-Preceded Attacks

How practical are fully call-preceded ROP attacks? Our measurements indicate that they are quite practical. The Q ROP compiler [26] is able to mount a ROP attack in 80% of binaries over 20KB in size. Given that only 6% of gadgets Q finds are call-preceded, we would expect that with 333KB of binary, we could achieve similar results. We actually found that it is possible to exploit 10 out of 10 programs we analyzed of size 70KB or larger.

We analyzed 10 binaries from `/usr/bin` on Ubuntu 12.04. In particular, we selected the first 10 binaries that have ASLR disabled and have more than 20k instructions (70KB binary size). In all 10 cases, we were able to find enough gadgets to mount a fully call-preceded history hiding ROP attack on kBouncer. Table 1 shows, for each of these ten binaries, the number of gadgets used for in each of the three phases of our ROP attack. Attacks marked with an asterisk have a success probability of $\geq 99.99\%$ due to the possibility of a module crossing a 32-bit boundary. All other attacks have a 100% success probability.

In each of these binaries, we use only the code present in the actual binary, not any other linked libraries. We are not arguing that these binaries are vulnerable to attack; we are only attempting to determine how much program text is required to mount fully call-preceded attacks.

We believe there to be two main reasons why we were so successful. First, we manually analyzed these binaries in order to construct a ROP attack, whereas Q is an automated tool. However, given Q's sophisticated analysis, we do not believe this accounts for all of the difference. We suspect that even though only 6% of gadgets are call-preceded, they have more diversity and thus are disproportionately likely to cover the space of different kinds of gadgets that are needed.

8.3 Modifying Real-World Exploits

We now evaluate the difficulty of modifying real-world exploits to bypass both kBouncer and ROPecker. To choose our exploits, we pick the ROP attacks that were shown to be prevented by kBouncer and ROPecker.

For kBouncer, we show how all four of these attacks can be modified so kBouncer will not detect them.

We finally modify the one real-world exploit which ROPecker is shown to prevent to bypass ROPecker.

8.3.1 kBouncer Exploits

We modified four real-world exploits to bypass kBouncer. None of the modifications to these exploits took us significant effort. Once we were able to reproduce the exploit on our machine, each exploit took under half of a day's worth of work to make it bypass kBouncer. Given the long and difficult exploitation development process, we do not think this is meaningfully harder, especially for well-trained exploit developers.

MPlayer Lite r33063. This program [19] had a stack-based buffer overflow vulnerability, which was exploited by overwriting the SEH pointer [20]. The `avcodec-52.dll` does not have ASLR enabled. This `dll` is 10MB, and contains plenty of gadgets: there were 748 potential termination gadgets with two or fewer conditional branches. The first of these that we tried worked, and was given previously in Fig. 3(b).

[5] The most important deficiencies in our tool are as follows: we implement only the thirty most-used instructions (covering 99% of instructions used in our binaries), we ignore segment registers, we do not track several of the flags set by instructions, and we do not properly handle referencing variable register widths. Despite this, we have found our tool to be accurate in the vast majority of cases.

Adobe Reader 9.3.4. This Adobe Reader exploit uses a sophisticated JavaScript vulnerability and was built on the Metasploit framework [1]. This exploit relied on `icucnv36.dll` having ASLR disabled. This `dll` is 10MB and has 130 available termination gadgets with two or fewer conditional branches. We created a ROP chain to call `VirtualProtect` on a page and verified that code on this page in memory could be executed.

Adobe Flash 11.3.300. An integer overflow caused this vulnerability in Adobe Flash. This exploit was also built with the Metasploit framework [2]. The exploit relied on `msvcr71.dll` having ASLR disabled. This `dll` is 300KB and has 64 available termination gadgets. In this exploit, we were able to successfully change a page to be executable and spawn another process.

Internet Explorer 8. The final exploit we modified was in IE8 and also used Metasploit [3]. This exploit was the most difficult for us to modify, and required a manual stack-pivot to a controlled location so that we could invoke `VirtualProtect` in a call-preceded manner. We relied again on `msvcr71.dll` to spawn another process.

8.3.2 ROPecker Exploits

ROPecker was built as a Linux kernel module and was shown to stop two exploits. One of these two exploits by the authors is to exploit a 20-line example C program with a trivial stack overflow from ROPEME [17]. The other exploit is a real-world exploit in *hteditor*, which has a published vulnerability [33] they verified they defend against. Because they only evaluate their defense on one binary, we have only this one binary to demonstrate our attack on. We evaluate our two methods of attack (repeated history hiding and evasion attacks) on this binary.

The public vulnerability disclosure included an exploitable version of the *hteditor* source. We downloaded this and compiled it for our system with stack protection disabled, as we want to test how well ROPecker defends against attack, not how well stack canaries work.

Evasion attack. We successfully mounted an evasion attack on hteditor. Our exploit required 12 gadgets. We split the attack into two 10-gadget segments, with the second segment calling `execv` by overwriting the GOT entry for `strlen` and finding a call-preceded intended call to it.

Repeated history hiding attack. We successfully mounted a repeated history hiding attack on hteditor assuming four pages in the executable set. Our attack consisted of three phases. In the first two phases we computed the address of `execv`, and in the third we called it. In the first phase, we were able to use a gadget twice that we loaded once.

9 Related Work

Randomization-based approaches. Address Space Layout Randomization (ASLR) and Address Obfuscation [5] were first introduced to make it more difficult to inject shellcode, and were later applied to the text segment to prevent ROP attacks. Shacham et al. demonstrated a de-randomization attack [28] on PaX ASLR.

Address Space Layout Permutation (ASLP) [16] is similar in many ways to ASLR but provides higher entropy by permuting the locations of functions. Other defenses extends this further by randomizing the addresses of individual instructions [15, 31]. Another technique replaces short sequences of instructions with alternate, functionally-identical, equal-length sequence, hindering an attacker's ability to use unintended gadgets [22]. A recent just-in-time code reuse attack [29] compiles ROP on the fly to bypass ASLR.

Control-Flow Integrity (CFI). Abadi et al. introduced control-flow integrity (CFI) [4] as a method of preventing attacks by restricting jump, call, and return instructions to follow the statically-determined control-flow graph of the program. Due to the difficulty of obtaining a precise control-flow graph of the program, many defenses choose instead to enforce a less precise policy. Often, this policy simply requires that returns be call-preceded, and indirect calls point to the beginning of functions [34, 6, 32].

The attacks presented in this paper show these CFI based defenses are weaker than previously thought. Since call-preceded ROP is possible, most of these defenses can be broken with that technique alone. Concurrent to this work, a detailed examination of attacks on many CFI-based schemes came to this same conclusion [14].

Runtime defenses. There are many other types of defenses that can best be described as runtime defenses. DROP [9] monitors the runtime behavior of the process and, nearly identically to ROPecker, if there is a long consecutive sequence of returns, each of which contain fewer than a fixed length, the program is killed. Our work in this paper constitutes a total break of DROP. ROPGuard [13] contains several heuristics to detect ROP attacks. One of these is the call-preceded defense introduced earlier. ROPdefender [12] implements a shadow-stack and verifies that all returns exist somewhere on the shadow-stack. Our work does not apply to shadow-stack defenses.

Recompilation-based defenses. Other defenses rely on recompilation to remove gadget from the compiled binary. G-Free [21] does this by removing unintended return instructions and encrypting return addresses, so that `ret`-gadgets become nearly impossible to use. The return-less kernel [18] entirely removes the `c3` byte (the opcode of `ret`) from all instructions, and replaces valid returns with a lookup into a table containing the valid return sites.

10 Conclusion

In this paper, we have presented three building blocks for ROP attacks that allow us to break two state-of-the-art ROP defenses. We demonstrate the practicality of our attacks by modifying real-world exploits to bypass these defenses.

More broadly, our work disproves two pieces of conventional wisdom: that ROP attacks only consist of short gadgets, and that ROP attacks cannot be effectively mounted in call-preceded manner.

Future defenses must take care to guard against attacks similar to ours. Specifically, we suggest two particular requirements for future defenses. First, defenses should argue either that they can inspect all relevant past history or, if they have a limited history, that their limited view of history cannot be effectively cleared out by an attacker. Second, defenses that defend against one specific aspect of ROP must argue that is a *necessary* component of one.

We believe an important open research question is to determine what properties are truly *fundamental* about ROP attacks that are different than typical program execution. We hope future work will explore how these fundamental differences can be exploited to create general-purpose defenses.

Abstract

Return-oriented programming (ROP) offers a robust attack technique that has, not surprisingly, been extensively used to exploit bugs in modern software programs (e.g., web browsers and PDF readers). ROP attacks require no code injection, and have already been shown to be powerful enough to bypass fine-grained memory randomization (ASLR) defenses. To counter this ingenious attack strategy, several proposals for enforcement of (coarse-grained) control-flow integrity (CFI) have emerged. The key argument put forth by these works is that coarse-grained CFI policies are sufficient to prevent ROP attacks. As this reasoning has gained traction, ideas put forth in these proposals have even been incorporated into coarse-grained CFI defenses in widely adopted tools (e.g., Microsoft's EMET framework).

In this paper, we provide the first comprehensive security analysis of various CFI solutions (covering kBouncer, ROPecker, CFI for COTS binaries, ROPGuard, and Microsoft EMET 4.1). A key contribution is in demonstrating that these techniques can be effectively undermined, even under weak adversarial assumptions. More specifically, we show that with bare minimum assumptions, turing-complete and real-world ROP attacks can still be launched even when the strictest of enforcement policies is in use. To do so, we introduce several new ROP attack primitives, and demonstrate the practicality of our approach by transforming existing real-world exploits into more stealthy attacks that bypass coarse-grained CFI defenses.

1 Introduction

Today, runtime attacks remain one of the most prevalent attack vectors against software programs. The continued success of these attacks can be attributed to the fact that large portions of software programs are implemented in type-unsafe languages (C, C++, or Objective-C) that do not enforce bounds checking on data inputs. Moreover, even type-safe languages (e.g., Java) rely on interpreters (e.g., the Java virtual machine) that are in turn implemented in type-unsafe languages.

Sadly, as modern compilers and applications become more and more complex, memory errors and vulnerabilities will likely continue to persist, with little end in sight [41]. The most prominent example of a memory error is the stack overflow vulnerability, where the adversary overflows a local buffer on the stack and overwrites a function's return address [4]. While today's defenses protect against this attack strategy (e.g., by using stack canaries [15]), other avenues for exploitation exists, including those that leverage heap [33], format string [21], or integer overflow [6] vulnerabilities.

Regardless of the attacker's method of choice, exploiting a vulnerability and gaining control over an application's control-flow is only the first step of a runtime attack. The second step is to launch malicious program actions. Traditionally, this has been realized by injecting malicious code into the application's address space, and later executing the injected code. However, with the wide-spread enforcement of the non-executable memory principle (called data execution prevention in Windows) such attacks are more difficult to do today [28]. Unfortunately, the long-held assumption that only new injected code bared risks was shattered with the introduction of code reuse attacks, such as return-into-libc [30, 37] and return-oriented programming (ROP) [35]. As the name implies, code reuse attacks do not require any code injection and instead use code already resident in memory.

One of the most promising defense mechanisms against such runtime attacks is the enforcement of *control-flow integrity (CFI)* [1, 3]. The main idea of CFI is to derive an application's control-flow graph (CFG) prior to execution, and then monitor its runtime behavior to ensure that the control-flow follows a legitimate path of the CFG. Any deviation from the CFG leads to a CFI exception and subsequent termination of the application.

Although CFI requires no source code of an application, it suffers from practical limitations that impede

its deployment in practice, including significant performance overhead of 21%, on average [3, Section 5.4], when function returns are validated based on a return address (shadow) stack. To date, several CFI frameworks have been proposed that tackle the practical shortcomings of the original CFI approach. ROPecker [13] and kBouncer [31], for example, leverage the branch history table of modern x86 processors to perform a CFI check on a short history of executed branches. More recently, Zhang and Sekar [46] demonstrate a new CFI binary instrumentation approach that can be applied to commercial off-the-shelf binaries.

However, the benefits of these state-of-the-art solutions comes at the price of relaxing the original CFI policy. Abstractly speaking, coarse-grained CFI allows for CFG relaxations that contains dozens of more legal execution paths than would be allowed under the approach first suggested by Abadi et al. [3]. The most notable difference is that the coarse-grained CFI policy for return instructions only validates if the return address points to an instruction that follows after a call instruction. In contrast, Abadi et al. [3]'s policy for fine-grained CFI ensures that the return address points to the original caller of a function (based on a shadow stack). That is, a function return is only allowed to return to its original caller.

Surprisingly, even given these relaxed assumptions, all recent coarse-grained CFI solutions we are aware of claim that their relaxed policies are sufficient to thwart ROP attacks[1]. In particular, they claim that the property of Turing-completeness is lost due to the fact that the code base which an adversary can exploit is significantly reduced. Yet, to date, no evidence substantiating these assertions has been given, raising questions with regards to the true effectiveness of these solutions.

Contribution. We revisit the assumption that coarse-grained CFI offers an effective defense against ROP. For this, we conduct a security analysis of the recently proposed CFI solutions including kBouncer [31], ROPecker [13], CFI for COTS binaries [46], ROPGuard [20], and Microsofts' EMET tool [29]. In particular, we derived a combined CFI policy that takes for each indirect branch class (i.e., return, indirect jump, indirect call) and behavioral-based heuristics (e.g., the number of instruction executed between two indirect branches), the most restrictive setting among these policies. Afterwards, we use our combined CFI policy and a weak adversary having access to only a *single* — and common used system library — to realize a Turing-complete gadget set. The reduced code base mandated that we develop several new return-oriented programming attack gadgets to facilitate our attacks. To demonstrate the power of our attacks, we show how to harden existing real-world exploits against the Windows version of Adobe Reader [26] and mPlayer [10] so that they bypass coarse-grain CFI protections. We also demonstrate a proof-of-concept attack against a Linux-based system.

2 Background

2.1 Return-Oriented Programming

Return-oriented programming (ROP) belongs to the class of runtime attacks that require no code injection. The basic idea is to combine short code sequences already residing in the address space of an application (e.g., shared libraries and the executable itself) to perform malicious actions. Like any other runtime attack, it first exploits a vulnerability in the software running on the targeted system. Relevant vulnerabilities are memory errors (e.g., stack, heap, or integer overflows [33]) which can be discovered by reverse-engineering the target program. Once a vulnerability has been discovered, the adversary needs to exploit it by providing a malicious input to the program, the so-called ROP payload. The applicability of ROP has been shown on many platforms including x86 [35], SPARC [7], and ARM [27].

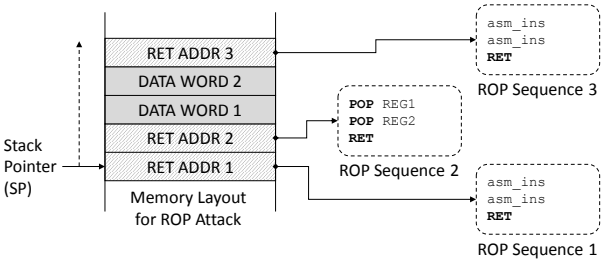

Figure 1: Memory snapshot of a ROP Attack

An example ROP payload and a typical memory layout for a ROP attack is shown in Figure 1. Basically, the ROP payload consists of a number of return addresses each pointing to a short code sequence. These sequences consist of a small number of assembler instructions (denoted in Figure 1 as `asm_ins`), and traditionally terminate in a return [35] instruction[2]. The indirect branches are responsible for chaining and executing one ROP sequence after the other.

In addition to return addresses, the adversary writes several data-words in memory that are used by the invoked code sequences (usually via stack POP instructions as shown in ROP Sequence 2). At the beginning of the attack, the stack pointer (SP) points to the first return address of the payload. Once the first sequence has been executed, its final return instruction (RET) advances the stack pointer by one memory word, loads the next return address from the stack, and transfers the control-flow to the next code sequence.

The combination of the invoked ROP sequences induce the malicious operations. Typically, these sequences are identified within an (offline) static analy-

sis phase on the target program binary and its linked shared libraries. Furthermore, one or multiple ROP sequences can form a *gadget*, where a gadget accomplishes a specific task such as adding two values or storing a data word into memory. These gadgets typically form a Turing-complete language meaning that an adversary can perform arbitrary (malicious) computation.

A well-known defense against ROP is address space layout randomization (ASLR) which randomizes the base address of libraries and executables, thereby randomizing the start addresses of code sequences needed by the adversary in her ROP attack. However, ASLR is vulnerable to memory disclosure attacks, which reveal runtime addresses to the adversary. Memory disclosure can even be exploited to circumvent fine-grained ASLR schemes, where the location of each code block is randomized in memory by identifying ROP gadgets on-the-fly and generating a ROP payload at runtime [36].

2.2 Control-Flow Integrity

Although W⊕X, ASLR and other protection mechanisms have been widely adopted, their security benefits remain open to debate [1]. The main critique is the lack of a clear attack model and formal reasoning. To address this, Abadi et al. [3] proposed a new security property called control-flow integrity (CFI). A program maintains CFI if its path of execution adheres to a certain pre-defined control-flow graph (CFG). This CFG consists of basic blocks (BBLs) as nodes, where a BBL is a sequence of assembler instructions. Edges connect two nodes, whenever the program may legally transfer control-flow from one to the next BBL. A control-flow transfer may be either a direct or indirect branch instruction (e.g., call, jump, or return). To ensure that a program follows a valid path in the CFG, CFI inserts labels at the beginning of basic blocks. Whenever there is a control-flow transfer at runtime, CFI validates whether the indirect branch targets a BBL with a valid label.

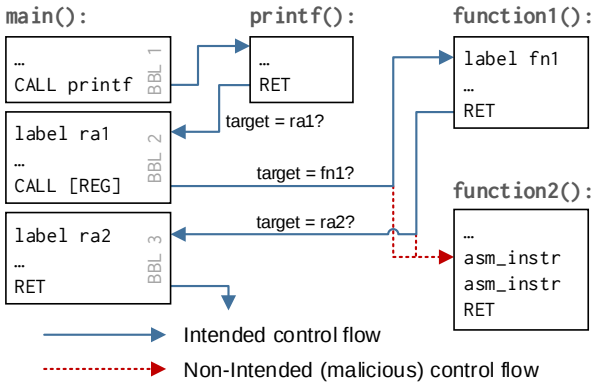

Figure 2: The CFG shepherds control-flow transfers

An example for CFI enforcement is shown in Figure 2. It shows a program consisting of a main function that invokes directly the library function *printf()*, and indirectly the local subroutine *function1()*. The indirect call to *function1()* in BBL 2 is critical, since an adversary may load an arbitrary address into the register by means of a buffer overflow attack. However, the CFG states that this indirect call is only allowed to target *function1()*. Hence, at runtime, CFI validates whether the indirect call in BBL 2 is targeting label **fn1**. If an adversary aims to redirect the call to a code sequence residing in *function2()*, CFI will prevent this malicious control-flow, because label **fn1** is not defined for *function2()*. Similarly, CFI protects the return instructions of *printf()* and *function1()*, which an adversary could both exploit by overwriting a return address on the stack. The specific CFI checks in Figure 2 validate if the returns address label **ra1** or **ra2**, respectively.

It is also prudent to note that CFI has been studied in many domains. For instance, it has been used as an enabling technology for software fault isolation by Abadi et al. [2] and Yee et al. [43]. CFI enforcement has also been shown for hypervisors [42], commodity operating system kernels [16] and mobile devices [18]. In other communities, Zeng et al. [44] and Pewny and Holz [32], for example, have shown how to instrument a compiler to generate CFI-protected applications. Lastly, Budiu et al. [8] have explored architectural support to tackle the performance overheads of software-only based solutions.

2.3 Control-Flow Integrity Challenges

There are several factors that impede the deployment of control-flow integrity (CFI) in practice, including those related to control-flow graph (CFG) coverage, performance, robustness, and ease of deployment.

Before proceeding further, we note that besides presenting the design of CFI, Abadi et al. [3] also included a formal security proof for the soundness of their solution. A key observation noted in that work is that "despite attack steps, the program counter always follows the CFG." [3, p. 4:34]. In other words, in Abadi et al. [3], every control-flow is permitted as long as the CFG allows it. Consequently, the quality of protection from control-flow attacks rests squarely on the level of CFG coverage. And that is exactly where recent CFI solutions have deviated (substantially) from the original work, primarily as a means to address performance issues.

Recall that in the original proposal, the CFG was obtained a priori using binary analysis techniques supported by a proprietary framework called Vulcan. Since the CFG is created ahead of time, it is not capable of capturing the dynamic nature of the call stack. That is, with only the CFG at hand, one can not enforce that functions return to their most recent call site, but only that they re-

turn to any of the possible call sites. This limitation is tackled by adding a shadow stack to the statically created CFG. Intuitively, upon each call, the return address is placed in a safe location in memory, so that an instrumented return is able to compare the return address on the stack with one on a shadow stack, and the program is terminated if a deviation is detected [3, 14, 18]. In this way, many control-flow transfers are prohibited, largely reducing the gadget space available for a return-oriented programming attack.

Given the power of CFI, it is surprising that it has not yet received widespread adoption. The reason lies in the fact that extracting the CFG is not as simple as it may appear. To see why, notice that (1) source code is not readily available (thereby limiting compiler-based approaches), (2) binaries typically lack the necessary debug or relocation information, as was needed for example, in the Vulcan framework, and (3) the approach induces high performance overhead due to dynamic rewriting and runtime checks. Much of the academic research on CFI in the last few years has focused on techniques for tackling these drawbacks.

3 Categorizing Coarse-Grained Control-Flow Integrity Approaches

As noted above, a number of new control-flow integrity (CFI) solutions have been recently proposed to address the challenges of good runtime performance, high robustness and ease of deployment. The most prominent examples include kBouncer [31], ROPecker [13], CFI for COTS binaries [46], and ROPGuard [20]. To aide in better understanding the strenghts and limitations of these proposals, we first provide a taxonomy of the various CFI policies embodied in these works. Later, to strengthen our own analyses, we also derive a combined CFI policy that takes into account the most restrictive CFI policy.

3.1 CFI Policies

Table 1 summarizes the five CFI policies we use throughout this paper to analyze the effectiveness of coarse-grained CFI solutions. Specifically, we distinguish between three types of policies, namely ① policies used for indirect branch instructions, ② general CFI heuristics that do not provide well-founded control-flow checks but instead try to capture general machine state patterns of ROP attacks and ③ a policy class that covers the time CFI checks are enforced.

We believe this categorization covers the most important aspects of CFI-based defenses suggested to date. In particular, they cover polices for each indirect branch the processor supports since all control-flow attacks (including ROP) require exploiting indirect branches. Second, heuristics are used by several coarse-grained CFI approaches (e.g., [20, 31]) to allow more relaxed CFI policies for indirect branches. Finally, the time-of-check policy is an important aspect, because it states at which execution state ROP attacks can be detected. We elaborate further on each of these categories below.

Category	Policy	x86 Example	Description
①	CFI_{RET}	`ret`	returns
	CFI_{JMP}	`jmp reg|mem`	indirect jumps
	CFI_{CALL}	`call reg|mem`	indirect calls
②	CFI_{HEU}		heuristics
③	CFI_{TOC}		time of CFI check

Table 1: Our CFI policies

1 – Indirect Branches. Recall that the goal of CFI is to validate the control-flow path taken at *indirect* branches, i.e., at those control-flow instructions that take the target address from either a processor register or from a data memory area[3]. The indirect branch instructions present on an Intel x86 platform are indirect calls, indirect jumps, and returns. Since CFI solutions apply different policies for each type of indirect branch, it is only natural that there are three CFI policies in this category, denoted as CFI_{CALL} (indirect function calls), CFI_{JMP} (indirect jumps), CFI_{RET} (function returns).

2 – Behavior-Based Heuristics (HEU). Apart from enforcing specific policies on indirect branch instructions, CFI solutions can also validate other program behavior to detect ROP attacks. One prominent example is the number of instructions executed between two consecutive indirect branches. The expectation is that the number of such instructions will be low (compared to ordinary execution) because ROP attacks invoke a chain of short code sequences each terminating in an indirect branch instruction.

3 – Time of CFI Check (TOC). Abadi et al. argued that a CFI validation routine should be invoked whenever the program issues an indirect branch instruction [3]. In practice, however, doing so induces significant performance overhead. For that reason, some of the more recent CFI approaches reduce the number of runtime checks, and only enforce CFI validation at critical program states, e.g., before a system or API call.

3.2 Instantiation in Recent Proposals

Next, we turn our attention to the specifics of how these policies are implemented in recent CFI mechanisms.

3.2.1 kBouncer

The approach of Pappas et al. [31], called kBouncer, deploys techniques that fall in each of the aforementioned categories. Under category ①, Pappas et al. [31] leverage the x86-model register set called last branch record (LBR). The LBR provides a register set that holds the

last 16 branches the processor has executed. Each branch is stored as a pair consisting of its source and target address. kBouncer performs CFI validation on the LBR entries whenever a Windows API call is invoked. Its promise resides in the fact that these checks induce almost no performance overhead, and can be directly applied to existing software programs.

With respect to its policy for returns, kBouncer identifies those LBR entries whose source address belong to a return instruction. For these entries, kBouncer checks whether the target address (i.e., the return address) points to a *call-preceded* instruction. A call-preceded instruction is any instruction in the address space of the application that follows a call instruction. Internally, kBouncer disassembles a few bytes before the target address and terminates the process if it fails to find a call instruction.

While kBouncer does not enforce any CFI check on indirect calls and jumps, Pappas et al. [31] propose behavioral-based heuristics (category ②) to mitigate ROP attacks. In particular, the number of instructions executed between consecutive indirect branches (i.e., "the sequence length") is checked, and a limit is placed on the number of sequences that can be executed in a row.[4]

A key observation by Pappas et al. [31] is that even though pure ROP payloads can perform Turing-complete computation, in actual exploits they will ultimately need to interact with the operating system to perform a meaningful task. Hence, as a time-of-CFI check policy (category ③) kBouncer instruments and places hooks at the entry of a WinAPI function. Additionally, it writes a *checkpoint* after CFI validation to prohibit an adversary from simply jumping over the hook in userspace.

3.2.2 ROPGuard and Microsoft EMET

Similar to Pappas et al. [31], the approach suggested by Fratric [20] (called ROPGuard) performs CFI validation when a critical Windows function is called. However, its policies differ from that of Pappas et al. [31].

First, with respect to policies under category ①, upon entering a critical function, ROPGuard validates whether the return address of that critical function points to a call-preceded instruction. Hence, it prevents an adversary from using a ROP sequence terminating in a return instruction to invoke the critical Windows function. In addition, ROPGuard checks if the memory word before the return address is the start address of the critical function. This would indicate that the function has been entered via a return instruction. ROPGuard also inspects the stack and predicts future execution to identify ROP gadgets. Specifically, it walks the stack to find return addresses. If any of these return addresses points to a non call-preceded instruction, the program is terminated.

Interestingly, there is no CFI policy for indirect calls or indirect jumps. Furthermore, ROPGuard's only heuristic under category ② is for validating that the stack pointer does not point to a memory location beyond the stack boundaries. While doing so prevents ROP payload execution on the heap, it does not prevent traditional stack-based ROP attacks; thus the adversary could easily reset the stack pointer before a critical function is called.

Remarks: ROPGuard and its implementation in Microsoft EMET [5] use similar CFI policies as in kBouncer. One difference is that kBouncer checks the indirect branches executed in the past, while ROPGuard only checks the current return address of the critical function, and for future execution of ROP gadgets. ROPGuard is vulnerable to ROP attacks that are capable of jumping over the CFI policy hooks, and cannot prevent ROP attacks that do not attempt to call any critical Windows function. To tackle the former problem (i.e., bypassing the policy hook), EMET adds some randomness in the length and structure of the policy hook instructions. Hence, the adversary has to guess the right offset to successfully deploy her attack. However, recent memory disclosure attacks show that such randomization approaches can be easily circumvented [36].

3.2.3 ROPecker

ROPecker is a linux-based approach suggested by Cheng et al. [13] that also leverages the last branch record register set to detect past execution of ROP gadgets. Moreover, it speculatively emulates the future program execution to detect ROP gadgets that will be invoked in the near future. To accomplish this, a static offline phase is required to generate a database of all possible ROP code sequences. To limit false positives, Cheng et al. [13] suggest that only code sequences that terminate after at most n instructions in an indirect branch should be recorded.

For its policies in category ①, ROPecker inspects each LBR entry to identify indirect branches that have redirected the control-flow to a ROP gadget. This decision is based on the gadget database that ROPecker derived in the static analysis phase. ROPecker also inspects the program stack to predict future execution of ROP gadgets. There is no direct policy check for indirect branches, but instead, possible gadgets are detected via a heuristic. More specifically, the robustness of its behavioral-based heuristic (category ②) completely hinges on the assumption that ROP code sequences will be short and that there will always be a chain of at least some threshold number of consecutive ROP sequences.

Lastly, its time of CFI check policy (category ③) is triggered whenever the program execution leaves a sliding window of two memory pages.

Remarks: Clearly, ROPecker performs more frequently CFI checks than both kBouncer and ROPGuard. Hence, it can detect ROP attacks that do not necessar-

ily invoke critical functions. However, as we shall show later, the fact that there is no policy for the target of indirect branches is a significant limitation.

3.2.4 CFI for COTS Binaries

Most closely related to the original CFI work by Abadi et al. [3] is the proposal of Zhang and Sekar [46] which suggest an approach for commercial-off-the-shelf (COTS) binaries based on a static binary rewriting approach, but without requiring debug symbols or relocation information of the target application. In contrast to all the other approaches we are aware of, the CFI checks are directly incorporated into the application binary. To do so, the binary is disassembled using the Linux disassembler objdump. However, since that disassembler uses a simple linear sweep disassembly algorithm, Zhang and Sekar [46] suggest several error correction methods to ensure correct disassembly. Moreover, potential candidates of indirect control-flow target addresses are collected and recorded. These addresses comprise possible return addresses (i.e., call-preceded instructions), constant code pointers (including memory locations of pointers to external library calls), and computed code pointers (used for instance in switch-case statements). Afterwards, all indirect branch instructions are instrumented by means of a jump to a CFI validation routine.

Like the aforementioned works, the approach of Zhang and Sekar [46] checks whether a return or an indirect jump targets a call-preceded instruction. Furthermore, it also allows returns and indirect jumps to target any of the constant and computed code pointers, as well as exception handling addresses. Hence, the CFI policy for returns is not as strict as in kBouncer, where only call-preceded instructions are allowed. On the other hand, their approach deploys a CFI policy for indirect jumps, which is largely unmonitored in the other approaches. However, it does not deploy any behavioral-based heuristics (category ②).

Lastly, CFI validation (category ③) is performed whenever an indirect branch instruction is executed. Hence, it has the highest frequency of CFI validation invocation among all discussed CFI approaches.

Similar CFI policies are also enforced by CCFIR (compact CFI and randomization) [45]. In contrast to CFI for COTS binaries, all control-flow targets for indirect branches are collected and randomly allocated on a so-called springboard section. Indirect branches are only allowed to use control-flow targets contained in that springboard section. Specifically, CCFIR enforces that returns target a call-preceded instruction, and indirect calls and jumps target a previously collected function pointer. Although the randomization of control-flow targets in the springboard section adds an additional layer of security, it is not directly relevant for our analysis, since memory disclosure attacks can reveal the content of the entire springboard section [36]. The CFI policies enforced by CCFIR are in principle covered by CFI for COTS binaries. However, there is one noteworthy policy addition: CCFIR denies indirect calls and jumps to target pre-defined sensitive functions (e.g., *VirtualProtect*). We do not consider this policy for two reasons: first, this policy violates the default external library call dispatching mechanism in Linux systems. Any application linking to such a sensitive (external) function will use an indirect jump to invoke it.[5] Second, as shown in detail by Göktas et al. [22] there are sufficient direct calls to sensitive functions in Windows libraries which an adversary can exploit to legitimately transfer control to a sensitive function.

Remarks: The approach of Zhang and Sekar [46] is most similar to Abadi et al. [3]'s original proposal in that it enforces CFI policies each time an indirect branch is invoked. However, to achieve better performance and to support COTS binaries, it deploys less fine-grained CFI policies. Alas, its coarse-grain policies allow one to bypass the restrictions for indirect call instructions (CFI_{CALL}). The main problem is caused by the fact that the integrity of indirect call pointers is not validated. Instead, it is only enforced that an indirect call takes a pointer from a memory location that is expected to hold indirect call targets. A typical example is the Linux global offset table (GOT) which holds the target addresses for library calls. This leaves the solution vulnerable to so-called GOT-overwrite attacks [9] that overwrite pointers (in the GOT) to external library calls. We return to this vulnerability in §5. Moreover, even if one would ensure the integrity of these pointers, we are still allowed to use a valid code pointer defined in the external symbols. Hence, the adversary can invoke dangerous functions such as *VirtualAlloc()* and *memcpy()* that are frequently used in applications and libraries.

3.3 Deriving a Combined CFI Policy

In our analysis that follows, we endeavor to have the best possible protections offered by the aforementioned CFI mechanisms in place at the time of our evaluation. Therefore, our combined CFI policy (see Table 2) selects the most restrictive setting for each policy. Nevertheless, despite this combined CFI policy, we then show that one can still circumvent these coarse-grained CFI solutions, construct Turing-complete ROP attacks (under realistic assumptions) and launch real-world exploits.

At this point, we believe it is prudent to comment on the parameter choices in these prior works — and that adopted in Table 2. In particular, one might argue that the prerequisite thresholds could be adjusted to make ROP attacks more difficult. To that end, we note that Pappas et al. [31] performed an extensive analysis to arrive at the

Control-Flow Integrity (CFI) Policies	CFI for COTS [46]	kBouncer [31]	ROPecker [13]	ROPGuard [20]	EMET 4.1 [29]	*Combined Policy*
CFI_{RET} : destination has to be call-preceded	✓	✓	◯	✓	✓	✓
CFI_{RET} : destination can be taken from a code pointer	✓	✗	◯	✗	✗	✗
CFI_{JMP} : destination has to be call-preceded	✓	◯	◯	◯	◯	✓
CFI_{JMP} : destination can be taken from a code pointer	✓	◯	◯	◯	◯	✓
CFI_{CALL} : destination can be taken from an exported symbol	✓	◯	◯	◯	◯	✓
CFI_{CALL} : destination can be taken from a code pointer	✓	◯	◯	◯	◯	✓
CFI_{HEU} : allow only s consecutive short sequences,	◯	$s <= 7$	$s <= 10$	◯	◯	$s <= 7$
CFI_{HEU} : where *short* is defined as n instructions	◯	$n <= 20$	$n <= 6$	◯	◯	$n <= 20$
CFI_{TOC} : check at every indirect branch	✓	◯	◯	◯	◯	Always observed
CFI_{TOC} : check at critical API functions or system calls	◯	✓	✓	✓	✓	
CFI_{TOC} : check when leaving sliding code window	◯	◯	✓	◯	◯	

Table 2: Policy comparison of coarse-grained CFI solutions: ✓ indicates that the CFI policy is applied and enforced. ✗ means that the CFI policy is prohibited (corresponding execution flows would lead to an attack alarm) . ◯ indicates that the CFI policy is not applied/enforced. The combined policy takes the most restrictive setting for each CFI policy.

best range of thresholds for the recommended number of consecutive short sequences (s) with a given sequence length of $n <= 20$. Their analysis reveals that adjusting the thresholds for s beyond their recommended values is hardly realistic: when every function call was instrumented, 975 false positives were recorded for $s <= 8$.

An alternative is to increase the sequence length n (e.g., setting it to $n <= 40$). Doing so would require an adversary to find a long sequence of 40 instructions after each seventh short sequence (for $s <= 7$). However, increasing the threshold for the sequence length will only exacerbate the false positive issue. For this reason, Pappas et al. [31] did not consider sequences consisting of more than 20 instructions as a gadget in their analyses. We provide our own assessment in §5.3.

The approach of Cheng et al. [13], on the other hand, uses different thresholds for s and n than in kBouncer. Making the thresholds in ROPecker more conservative (e.g., reducing s and increasing n) will lead to the same false positives problems as in kBouncer. Moreover, the problem would be worse, since ROPecker performs CFI validation more frequently than kBouncer. Nevertheless, we show that regardless of the specific choice of parameter chosen in the recommended ranges, our attacks render these defenses ineffective in practice (see Section 5).

4 Turing-Complete ROP Gadget Set

We now explore whether or not it is possible to derive a Turing-complete gadget set even when all state-of-the-art coarse-grained CFI protections are enforced. In particular, we desire a gadget set that still allows an adversary to undermine the combined CFI policy (see Table 2).

Assumptions. To be as pragmatic as possible, we assume that the adversary can only leverage the presence of a single shared library to derive the gadget set. This is a very stringent requirement placed on ourselves since modern programs typically link to dozens of libraries.

Note also that we are not concerned with circumventing other runtime protection mechanisms such as ASLR or stack canaries. The reasons are twofold: first, coarse-grained CFI protection approaches do not rely on the presence of other defenses to mitigate against code reuse attacks. Second, in contrast to CFI, ASLR and protection mechanisms that defend against code pointer overwrites (e.g., stack canaries, bounds checkers, pointer encryption) do not offer a general defense, and moreover, are typically bypassed in practice. In particular, ASLR is vulnerable to memory disclosure attacks [36, 38]. That said, the attacks and return-oriented programming gadgets we present in the following can be also leveraged to mount memory disclosure attacks in the first stage.

Methodology and Outline. Our analysis is performed primarily on Windows as it is the most widely deployed desktop operating system today. Specifically, we inspect `kernel32.dll` (on x86 Windows 7 SP1), a 848kb system library that exposes Windows API functions and is by default linked to nearly every major Windows process (e.g., Adober Reader, IE, Firefox, MS Office). It

is also noteworthy to mention that our results do not only apply to Windows; Although we did not perform a Turing-complete gadget analysis for Linux's default library (`libc.so`), to demonstrate the generality of our approach, we provide a shellcode exploit that uses gadgets from `libc` (see §5.2). To facilitate the gadget finding process, we developed a static analysis python module in `IDA Pro` that outputs all call-preceded sequences ending in an indirect branch. We also developed a sequence filter in the general purpose `D` programming language that allows us to check for sequences containing a specific register, instruction, or memory operand. Note that in the subsequent discussions, we use the Intel assembler syntax, e.g., `mov destination, source`, and use a semicolon to separate two consecutive instructions.

We first review in §4.1 the basic gadgets that form a Turing-complete language [12, 35]. To achieve Turing-completeness, we require gadgets to realize memory load and store operations, as well as a gadget to realize a conditional branch. Afterwards, we present two new gadget types called the Call-Ret-Pair gadget (§4.2.1) and the Long-NOP gadget (§4.2.2). Constructing the latter was a non-trivial engineering task and the outcome played an important role in "stitching" gadgets together, thereby bypassing coarse-grained CFI defenses. It should also be noted that we only present a *subset* of the available sequences. Eliminating the specific few sequences presented here will not prevent our attack, since `kernel32.dll` (and many other libraries) provides a multitude of other sequences we could have leveraged.

4.1 Basic Gadget Arsenal

Loading Registers. Load gadgets are leveraged in nearly every ROP exploit to load a value from the stack into a CPU register. Recall that x86 provides six general registers (`eax`, `ebx`, `ecx`, `edx`, `esi`, `edi`), a base/frame pointer register (`ebp`), the stack pointer (`esp`), and the instruction pointer (`eip`). All registers can be directly accessed (read and write) by assembler instructions except the `eip` which is only indirectly influenced by dedicated branch instructions such as `ret`, `call`, and `jmp`.

Typically, stack loading is achieved on x86 via the `POP` instruction. The call-preceded load gadgets we identified in `kernel32.dll` are summarized in Table 3. Except for the `ebp` register, we are not able to load any other register without inducing a side-effect, i.e., without affecting other registers. That said, notice that the sequence for `esi`, `edi`, and `ecx` only modifies the base pointer (`ebp`). Because traditionally `ebp` holds the base pointer and no data, and ordinary programs can be compiled without using a base pointer, we consider `ebp` as an *intermediate register* in our gadget set. The astute reader would have noticed that the sequences for `edi` and `ecx` modify the stack pointer as well through the `leave` instruction, where `leave` behaves as `mov esp,ebp; pop ebp`. However, we can handle this side-effect, since the stack pointer receives the value from our intermediate register `ebp`. Hence, we first invoke the load gadget for `ebp` and load the desired stack pointer value, and afterwards call the sequence for `edi`/`ecx`.

More challenges arise when loading the general-purpose registers `eax`, `ebx`, and `edx`. While `ebx` can be loaded with side-effects, we were not able to find any useful stack pop sequence for `eax` and `edx`. This is not surprising given the fact that we must use call-preceded sequences. Typically, these sequences are found in function epilogues, where a function epilogue is responsible for resetting the caller-saved registers (`esi`, `edi`, `epb`). We alleviate the side-effects for `ebx` by loading all the caller-saved registers from the stack.

Register	Call-Preceded Sequence (ending in `ret`)
EBP	`pop ebp`
ESI	`pop esi; pop ebp`
EDI	`pop edi; leave`
ECX	`pop ecx; leave`
EBX	`pop edi; pop esi; pop ebx; pop ebp`
EAX	`mov eax,edi; pop edi; leave`
EDX	`mov eax,[ebp-8]; mov edx,[ebp-4]; pop edi; leave`

Table 3: Register Load Gadgets

For `eax` and `edx`, data movement gadgets can be used. As can be seen in Table 3, `eax` can be loaded using the `edi` load gadget in advance. The situation is more complicated for `edx`, especially given our choice to only use `kernel32.dll`. In particular, while there is a sequence that allows one to load `edx` by using the `ebp` load gadget beforehand, it is challenging to do so since the adversary would need to save the state of some registers. That said, other default Windows libraries (such as `shell32.dll`) offer several more convenient gadgets to load `edx` (e.g., a common sequence we observed was `pop edx; pop ecx; jmp eax`), and so this limitation should not be a major obstacle in practice.

Loading and Storing from Memory. In general, software programs can only accomplish their tasks if the underlying processor architecture provides instructions for loading from memory and storing values to memory. Similarly, ROP attacks require memory load and store gadgets. Although we have found several load and store gadgets, we focus on the gadgets listed in Table 4.

In particular, we discovered load gadgets that use `eax` as the destination register. The specific load gadget shown in Table 4 loads a value from memory pointed to by `ebp+8`. Hence, the adversary is required to correctly set the target address of the memory load operation in `ebp` via the register load gadget shown in Table 3.

Type	Call-Preceded Sequence (ending in `ret`)
LOAD (eax)	`mov eax, [ebp+8]; pop ebp`
STORE (eax)	`mov [esi],eax; xor eax,eax;` `pop esi; pop ebp`
STORE (esi)	`mov [ebp-20h],esi`
STORE (edi)	`mov [ebp-20h],edi`

Table 4: Selected Memory Load and Store Gadgets

We also identified a corresponding memory store gadget on `eax`. The shown gadget stores `eax` at the address provided by register `esi`, which needs to be initialized by a load register gadget beforehand. The gadget has no side-effects, since it resets `eax` (which was stored earlier) and loads new values from the stack into `esi` (which held the target address) and `ebp` (our intermediate register).

Given a memory store gadget for `eax` and the fact that we have already identified register load gadgets for each register, it is sufficient to use the same memory load on `eax` to load any other register. This is possible because we use the `eax` load gadget to load the desired value from memory, store it afterwards on the stack, and finally use one of the register load gadgets to load the value into the desired register. Finally, we also identified some convenient memory store gadgets for `esi` and `edi` only requiring `ebp` to hold the target address of the store operation.

Arithmetic and Logical Gadgets. For arithmetic operations we utilize the sequence containing the x86 `sub` instruction shown in Table 5. This instruction takes the operands from `eax` and `esi` and stores the result of the subtraction into `eax`. Both operands can be loaded by using the register load gadgets (see Table 3). The same gadget can be used to perform an addition: one only needs to load the two's complement into `esi`. Based on addition and subtraction, we can realize multiplication and division as well. Unfortunately, logical gadgets are not as commonplace. There is, however, a XOR gadget that takes its operands from `eax` and `edi` (see Table 3).

Type	Call-Preceded Sequence (ending in `ret`)
ADD/SUB	`sub eax,esi; pop esi; pop ebp`
XOR	`xor eax,edi; pop edi; pop esi;` `pop ebp`

Table 5: Arithmetic and Logical Gadgets

Branching Gadgets. We remind the reader that branching in ROP attacks is realized by modifying the stack pointer rather than the instruction pointer [35]. In general, we can distinguish two different types of branches: unconditional and conditional branches. `kernel32.dll`, for example, offers two variants for a unconditional branch gadget (see Table 6). The first uses the `leave` instruction to load the stack pointer (`esp`) with a new address that has been loaded before into our intermediate register `ebp`. The second variant realizes the unconditional branch by adding a constant offset to `esp`. Either one suffices for our purposes.

Type	Call-Preceded Sequence (ending in `ret`)
unconditional branch 1	`leave`
unconditional branch 2	`add esp,0Ch; pop ebp`
conditional LOAD(eax)	`neg eax; sbb eax,eax;` `and eax,[ebp-4];leave`

Table 6: Branching Gadgets

Conditional branch gadgets change the stack pointer iff a particular condition holds. Because load, store, and arithmetic/logic computation can be conveniently done for `eax`, we could place the conditional in this register. Unfortunately, because a direct load of `esp` (that depended on the value of `eax`) was not readily available, we realized the conditional branch in three steps requiring the invocation of only four ROP sequences. That said, our gadget is still within the constraints for the number of allowable consecutive sequences in the Combined CFI-enforcement Policy (see $n = 8$ for CFI_{HEU} in Table 2).

First, we use the conditional branch gadget (see Table 6) to either load `0` or a prepared value into `eax`. In this sequence `neg eax` computes the two's complement and, more importantly, sets the carry flag to zero if and only if `eax` was zero beforehand. This is nicely used by the subsequent `sbb` instruction, which subtracts the register from itself, always yielding zero, but additionally subtracting an extra one if the carry flag is set. Because subtracting one from zero gives `0xFFFFFFFF`, the next `and` masks either none or all the bits. Hence, the result in `eax` will be exactly the contents of `[ebp-4]` if `eax` was zero, or zero otherwise. One might think that it is very unlikely to find sequences that follow the pattern `neg-sbb-and`. However, we found 16 sequences in `kernel32.dll` that follow the same pattern and could have been leveraged for a conditional branch gadget.

We then use the ADD/SUB gadget (see Table 5) to subtract `esi` from `eax` so that the latter holds the branch offset for `esp`. Finally, we move `eax` into `esp` using the stack as temporary storage. The STORE(eax) gadget (see Table 4) will store the branch offset on the stack, where `pop ebp` followed by the unconditional branch 1 gadget loads it into `esp`.

4.2 Extended Gadget Set

For those readers who have either written or analyzed real-world ROP exploits before, it would be clear to them that several other gadgets are useful in practice. For example, modern exploits usually invoke several WinAPI functions to perform malicious actions, e.g., launching

Type	Call-Preceded Sequence
Call 1	`lea eax,[ebp-34h]; push eax;`
	`call esi; ret`
Call 2	`call eax`
Call 3	`push eax; call [ebp+0Ch]`

Table 7: Function Call Gadgets

a malicious executable by invoking *WinExec()*. Calling such functions within a ROP attack requires a function call gadget (§4.2.1). It is also useful to have gadgets that allow one to conveniently write a NULL word to memory (the Null-Byte gadget) or the Stack-pivot gadget [17] which is used by attacks exploiting heap overflows. Our instantiations of the Null-Byte and Stack-pivot gadgets are given in the Appendix as they are not vital to understanding the discussion that follows.

Additionally, to provide a generic method for circumventing the behavioral heuristics of the Combined CFI Policy, we present a new gadget type, coined Long-NOP, containing long sequences of instructions which do not break the semantics of an arbitrary ROP chain (§4.2.2).

4.2.1 Call-Ret-Pair Gadget

CFI policies raise several challenges with respect to calling WinAPI functions within a ROP attack. First, one cannot simply exploit a `ret` instruction because the CFI_{RET} policy states that only a call-preceded sequence is allowed — clearly, the beginning of a function is not call-preceded. Second, the adversary must regain control when the function returns. Hence, the return address of the function to be called must point to a call-preceded sequence that allows the ROP attack to continue.

To overcome these restrictions, we utilize what we coined a *Call-Ret-Pair* gadget. The basic idea is to use a sequence that terminates in an indirect call but provides a short instruction sequence afterwards that terminates in a `ret` instruction. Among our possible choices, the Call 1 sequence shown in Table 7 was selected.

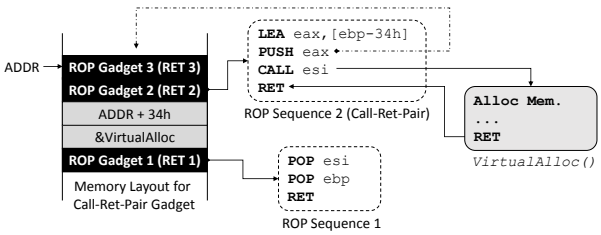

Figure 3: Example for Call-Ret-Pair Gadget

To better understand the intracies of this gadget, we provide an example in Figure 3. This example depicts how we can leverage our gadget to call *VirtualAlloc()*. We start with a load register gadget which first loads the start address of *VirtualAlloc()* into `esi`. Further, it loads into `ebp` an address denoted as `ADDR`. At this address is stored RET 3, the pointer to the ROP sequence we desire to call after *VirtualAlloc()* has returned. The next ROP sequence is our Call-Ret-Pair gadget, where the first instruction effectively loads RET 3 pointed to by `ebp-34h` into `eax`. Next, RET 3 is stored at `ADDR` onto the stack using a `push` instruction before the function call occurs. The `push` instruction also decrements the stack pointer so that it points to RET 2. The subsequent indirect call invokes *VirtualAlloc()* and automatically pushes the return address onto the stack, i.e, it will overwrite RET 2 with the return address. This ensures that the control-flow will be redirected to the `ret` instruction in our Call-Ret-Pair gadget when *VirtualAlloc()* returns. Lastly, the return will use RET 3 to invoke the next ROP sequence.

Note that this Call-Ret-Pair gadget works for subroutines following the *stdcall* calling convention. Such function remove their arguments from the stack upon function return. For functions using cdecl, we use a Call-Ret-Pair gadget that pops after the function call, the arguments of the subroutine from the stack. The details of the gadget we use for cdecl function can be found in the Appendix of our technical report [19].

For ROP attacks that terminate in a function call, we leverage the Call 2 and Call 3 gadgets in Table 7. The difference resides in the fact that Call 2 requires the target address to be loaded into `eax`, whereas Call 3 loads the branch address from memory.

Recall that the CFI policy for indirect calls (CFI_{CALL} in Table 2) only permits the use of branch addresses taken from an exported symbol or a valid code pointer place. However, as we already described in §3.2.4, the integrity of code pointers is not guaranteed. Hence, we can leverage GOT overwrite-like attacks to change the address at a given code pointer location. Alternatively, since modern applications typically make use of many WinAPI functions by default, we can indirectly call one of these functions using the external symbols.

4.2.2 Long-NOP Gadget

Our final gadget is needed to thwart the restriction that after $s = 7$ short sequences in a row is used, another sequence of at least $n = 20$ instructions must follow (see CFI_{HEU} in Table 2). For this task, we developed a new gadget type that we refer to as the long no-operation (long-NOP) gadget. Constructing long-NOP in a way that does not break the semantics of an arbitrary ROP chain was a non-trivial task that required painstaking analyses and a stroke of luck.

To identify possible sequences for this gadget type, we let our sequence finder filter those call-preceded sequences that contain more than $n = 20$ instructions. To ensure that the long sequence does not break the seman-

tics of the ROP chain, we further reduced the set of sequences to those that (i) contain many memory-write instructions, and (ii) make use of only a small set of registers. While the latter requirement is obvious, the former seems counter-intuitive as it can potentially change the memory state of the process. However, if we are able to control the destination address of these memory writes, we can write arbitrary values into the data area of the process outside the memory used by our ROP attack.

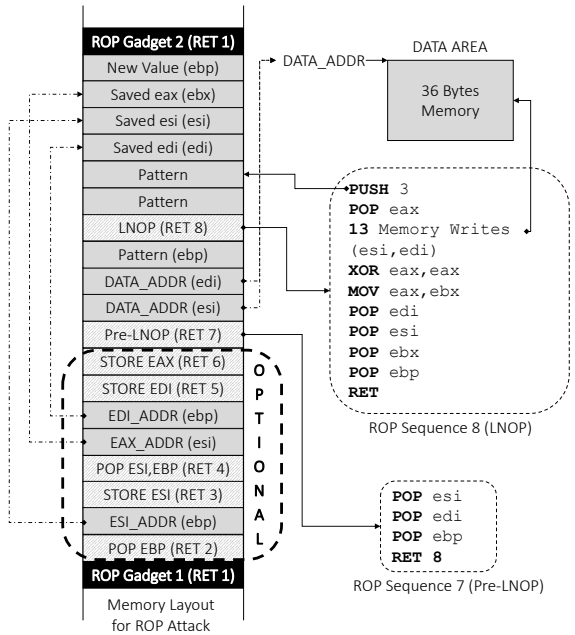

Figure 4: Flow of Long-NOP gadget

Among the sequences that fulfill these requirements, we chose a sequence that is (abstractly)[6] shown in Figure 4. It contains 13 memory write instructions using only the registers `esi` and `edi`. We stress that the entire gadget chain for long-NOP does not induce *any* side-effects, i.e., the content of all registers and memory area used by the ROP attack is preserved.

We distinguish between mandatory and optional sequences used for long-NOP. The latter sequences are only required if the content of all registers needs to be preserved. We classify them as optional, since it is very unlikely that ROP attacks need to operate on all registers during the entire ROP execution phase. If all registers need to be preserved (worst-case scenario), we require 6 ROP sequences before the long-NOP gadget sequence is invoked. Since all registers are preserved, we can issue in each round another ROP sequence until all desired ROP sequences have been executed.

Mandatory Sequences. The mandatory sequences are those labeled Sequence 7 and 8 (in Figure 4). Sequence 7 is used to set three registers: `esi`, `edi`, and `ebp`. We load in `esi` and `edi` the same address, namely `DATA_ADDR`, which points to an arbitrary data memory area in the address space of the application, e.g., stack, heap, or any other data segment of an executable module. Due to the `ret 8` instruction, the stack pointer will be incremented by 8 more bytes leaving space for pattern values. Afterwards, our long-NOP sequence uses `esi` and `edi` to issue 13 memory writes in a small window of 36 bytes. In each round, we use the same address for `DATA_ADDR`, and hence, we always write the same arbitrary values in a 36 byte memory space not affecting memory used by our ROP attack. The long-NOP sequence also destroys the value of `eax` and loads new values via `pop` instructions in other registers. However, these register changes are resolved by our optional sequences discussed next.

Optional Sequences. ROP Sequence 2 to 6 are the optional sequences, and are responsible for preserving the state of all registers. The optional sequences shown in Figure 4 represent those already presented in our basic gadget arsenal in §4.1. Depending on the specific goals and gadgets of a ROP attack, the adversary can choose among the optional sequences as required.

ROP Sequence 2 and 3 store the value of `esi` on the stack in such a way that the `pop esi` instruction in long-NOP resets the value accordingly. ROP Sequence 4 to 6 store the content of `eax` and `edi` on the stack. Similar to the store for `esi`, the content is again re-loaded into these registers via `pop` instructions at the end of the long-NOP sequence. However, the content of register `eax` and `ebx` is exchanged after the long-NOP sequence since `mov eax,ebx` stores `ebx` to `eax`, and the former value of `eax` is loaded via `pop` into `ebx`. However, we can compensate this switch by invoking the Long-NOP gadget twice so that `eax` and `ebx` are exchanged again.

5 Hardening Real-World Exploits

We now elaborate on the hardening of two real-world exploits against 32-bit Windows 7 SP1 and a Linux proof-of-concept exploit. Specifically, we transform publicly available ROP attacks against Adobe PDF reader [26] and the GNU mediaplayer mPlayer [10]. We used the gadget set derived in §4 to perform the transformation. Furthermore, our attacks are executed with the *Caller*, *SimExecFlow*, *StackPivot*, *LoadLib*, and *MemProt* option for ROP detection in Microsoft EMET 4.1 enabled. The source code for both attacks is given in our technical report [19].

5.1 Windows Exploits

The Adobe PDF attack used in this paper exploits the integer vulnerability CVE-2010-0188 in the TIFF image processing library `libtiff`. The vulnerability originally targeted Adobe PDF versions 9.1-9.3 running on Windows XP SP2/SP3. Likewise, the mPlayer attack ex-

ploited a buffer overflow vulnerability that allows the adversary to overwrite an exception handler pointer. Since we perform our analyses on Windows 7, we ported both exploits from Windows XP to Windows 7.

Exploit Requirements: For both exploits, we need to (1) allocate a new read-write-execute (RWX) memory page with *VirtualAlloc()*, (2) copy malicious shellcode into the newly allocated page by using *memcpy()*, and (3) redirect the control-flow to the shellcode. Originally, the exploits made use of non-call-preceded gadgets, and used a long chain of short instruction sequences. For mPlayer 18 consecutive short sequences are executed, while for Adobe PDF 11 sequences are executed until the first system call is issued. Hence, both exploits clearly violate CFI_{RET} and CFI_{HEU} of the combined CFI policy. These exploits are prevented by Microsoft EMET because of CFI_{RET}, and are detected by both kBouncer and ROPecker due to violation of the CFI_{HEU} policy.

Replacing ROP Sequences: A simplified view of the gadget chain we use for our hardened exploits in the PDF exploit is shown in Figure 5. We first replaced all non-call-preceded sequences with one of our call-preceded sequences in our ROP gadget set identified in Section 4. Both exploits mainly use load register and memory gadgets to set the arguments for *VirtualAlloc()* and *memcpy()*, and function call gadgets to invoke both functions. By leveraging only call-preceded sequences, our attacks comply to the CFI policy for returns (CFI_{RET}).

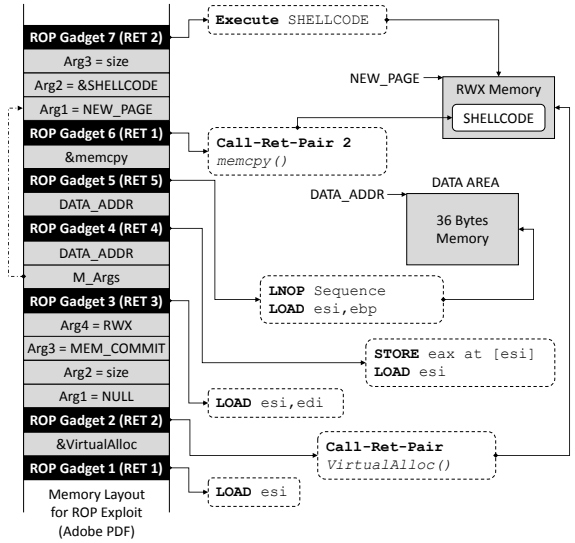

Figure 5: Simplified view of our hardened PDF exploit. See [19] for the full source code.

Since both exploits make use of WinAPI calls, we utilized our Call-Ret-Pair gadget to invoke *VirtualAlloc()* and *memcpy()*. As both functions are default routines used in a benign execution of Adobe PDF and mPlayer, we are allowed to leverage indirect calls to invoke these functions (addressing CFI_{CALL}). Note that even if this were not the case, we could still call these functions by overwriting valid code pointer locations. A demonstration of this weakness — particularly for the approach of Zhang and Sekar [46] — is provided in Section 5.2. Lastly, we need to tackle the CFI policies for behavioral heuristics (addressing CFI_{HEU}) by ensuring that we never execute more than 7 short sequences in a row before calling our long-NOP gadget.

Putting-It-All-Together: Gadget ❶ in Figure 5 loads the target address of *VirtualAlloc()* into `esi`. The arguments to this function (`Arg1-Arg4`) are set on the stack. They are chosen in such a way that *VirtualAlloc()* allocates a new RWX memory page. Gadget ❷ leverages our Call-Ret-Pair gadget to call *VirtualAlloc()*. The start address of the page is placed by *VirtualAlloc()* into `eax`.

ROP Gadgets ❸ and ❹ facilitate two goals: first they store the start address of the new RWX page on the stack. Second, they prepare the execution of the long-NOP gadget. In particular, they set `esi` and `edi` to DATA_ADDR. This address points to an arbitrary data section of one of the linked libraries. Our long-NOP sequence (ROP Gadget ❺) will later perform 13 memory writes on this data region, thereafter setting `esi` to the start address of *memcpy()*. ROP Gadget ❻ invokes *memcpy()* to copy the malicious shellcode onto the newly allocated RWX page. Lastly, our ROP chain transfers the control-flow to the copied shellcode via Gadget ❼, which in both exploits opens the Windows calculator.

For the Adobe PDF attack, we used 7 ROP sequences with 52 instructions executed. In the hardened version of the mPlayer exploit, we used 49 ROP sequences with 380 instructions executed. Note that the 49 sequences include the interspersed long-NOP sequences to adhere to the CFI policy CFI_{HEU}. We used a writable memory area of 36 Bytes for the long-NOP gadget. The requirement of more sequences for the mPlayer attack can be attributed to the fact that this exploit did not allow for the use of any NULL bytes in the payload and so we needed to leverage a NULL-Byte gadget (Appendix A) in this exploit. The mPlayer exploit also required a stack pivot gadget (Appendix B). This attack also required a specific stack pivot gadget adding a large constant to `esp`. Unfortunately, our stack pivot sequences in `kernel32.dll` did not use large enough constants, and the original sequence exploited a non call-preceded one in `avformat-52.dll`. However, we identified another useful call-preceded stack pivot sequence in the same library which allowed us to instantiate the exploit.

The above strategies can be used to easily transform other ROP attacks to bypass current coarse-grained CFI defenses. Furthermore, given our routines for finding and filtering useful call-preceded ROP sequences, the process

of transforming exploits could be fully automated. We leave that as an exercise for future work.

A final remark concerns the control transfer to the injected shellcode. In both exploits, we invoke a call-preceded sequence terminating in an indirect jump. While this approach works for kBouncer, ROPecker, and ROPGuard, it might raise an alarm for CFI for COTS binaries if the shellcode is placed at an address that is not within the set of valid function pointers (i.e., indirect jump targets). However, there are several ways to tackle this issue. A very effective approach has been shown by Göktas et al. [22], where the code section is simply set to be writable, the shellcode copied to an address which resembles a valid function pointer, and after which the code section is reset back to be executable. Alternatively, one can overwrite the location of a valid function pointer with the start address of the shellcode. We provide a detailed example how this can be realized in the next subsection.

5.2 Linux Shellcode Exploit

Since the approach of Zhang and Sekar [46] targets Linux specifically, we also developed a proof-of-concept exploit that shows how our attack bypasses the CFI policies for indirect calls. To do so, we use a sample program that suffers from a buffer overflow vulnerability allowing an adversary to overwrite a return address on the stack. The goal of our attack is to call *execve()*, which is a standard system function defined in `libc.so` to execute a new program. The challenge, however, is that the example program does not include *execve()* in its external symbols, and consequently, we are not allowed to redirect the control-flow to *execve()* using an indirect call.

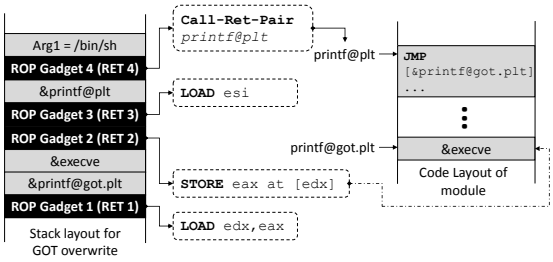

Figure 6: GOT overwrite attack

To overcome this restriction, we make use of an old (but seemingly forgotten) attack technique called global offset table (GOT) overwrite [9]. The basic idea is to write the address of *execve()* at a valid code pointer location. A well-known location for doing so is the GOT table, which contains pointers to library calls such as *printf()*. We reiterate that the weakness here is that CFI for COTS binaries does not validate the integrity of these pointers — a very difficult, if not unsurmountable task, in the current design of Linux since the GOT is initialized at runtime of an application. Hence, we can invoke gadgets to overwrite the pointers placed in the GOT. Specifically, we first find useful sequences from the Linux standard library `libc.so` and use gadgets that perform the GOT overwrite while using only call-preceded sequences.

Putting-It-All-Together: An example on how we bypass the CFI policy for indirect calls is shown in Figure 6. The approach is as follows: first, Gadget ❶ loads the address of the GOT entry we want to modify into `edx`, and loads `eax` with the address of *execve()*. Next, Gadget ❷ overwrites the address of *printf()* with the address of *execve()* in the GOT. Finally, Gadget ❸ loads the address of the *printf()* stub into `esi`, and Gadget ❹ uses a Call-Ret-Pair gadget to invoke *execve()*. At this point, the attack succeeds without violating any of the CFI policies.

5.3 On Parameter Adjustment

As alluded to in §3.3, adjusting the parameters for the CFI_{HEU} policy beyond the recommended settings will negatively impact the false positive rate. To assess that, we extended the analysis beyond what Pappas et al. [31] originally performed in order to analyze the impact of increasing n to 30 or 40 instructions — thereby rendering our Long-NOP gadget (which is only 23 instructions long) stitching ineffective. Specifically, we performed an experiment using three benchmarks of the SPEC CPU 2006 benchmark suite: `bzip2`, `perlbench`, and `xalancbmk`. The first two are programmed in C, while the latter in C++. We developed an Intel Pintool that counts the number of instructions issued between two indirect branches, and the number of consecutive short instruction sequences. Whenever a function call occurs, we check how many short sequences (s) have been executed since the last function call.

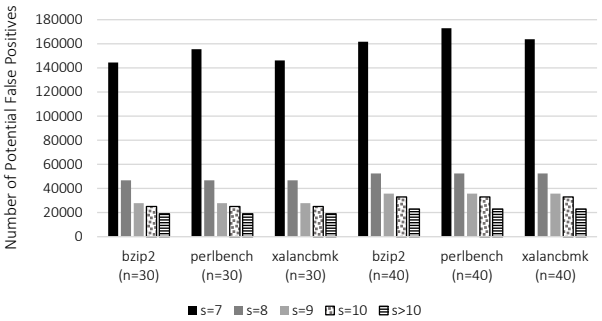

Figure 7: Potential false positives when the parameters for the consecutive sequences (s) and sequence length (n) are adjusted.

As Figure 7 shows, increasing the thresholds for n induces many potential false positives (y-axis). In particular, for each benchmark (x-axis), observe that for $s > 10$ there are about 20,000 potential false positives, i.e., 20,000 times we detected a function call that was preceded by more than 10 short sequences[7].

6 Related Work

Concurrent and independent to our work, several research groups have investigated the security of coarse-grained CFI solutions [11, 22–24, 34]. However, our analysis differs from these works as we examine the security of a combination of coarse-grained CFI policies irrespective of when the CFI check occurs. For instance, the attacks shown in [11, 22, 34] are prevented by our combined CFI policy which monitors the sequence length at any time in program execution. Furthermore, unlike these works, we systematically show the construction of a Turing-complete gadget set based on a weak adversary that has only access to one standard shared Windows library. On the other hand, concurrent work also investigates some other interesting attack aspects: Göktas et al. [22] demonstrate attacks against CCFIR [45] using call-preceded gadgets to invoke sensitive functions via direct calls; Carlini and Wagner [11] and Schuster et al. [34] show flushing attacks that eliminate return-oriented programming traces before a critical function is invoked.

Lastly, new CFI-based solutions have also been proposed. For instance, the approaches of Tice et al. [40] and Jang et al. [25] focus on protecting indirect calls to virtual methods in C++. Both approaches have been implemented as a compiler extension and ensure that an adversary cannot manipulate a virtual table (vtable) pointer so that it points to an adversary-controlled (malicious) vtable. Unfortunately, these schemes do not protect against classical ROP attacks which exploit return instructions, and map malicious code to a memory area reserved for a valid virtual method.

7 Summary

Without question, control-flow integrity offers a strong defense against runtime attacks. Its promise lies in the fact that it provides a general defense mechanism to thwart such attacks. Rather than focusing on patching program vulnerabilities one by one, CFI's power stems from focusing on the integrity of the program's control flow regardless of how many bugs and errors it may suffer from. Unfortunately, several pragmatic issues (most notably, its relatively high performance overhead), have limited its widespread adoption.

To better tackle the performance trade-off between security and performance, several coarse-grained CFI solutions have been proposed to date [13, 20, 31, 45, 46]. Additionally, it has been recently shown that such coarse-grained CFI policies can be applied to operating system kernels [16]. These proposals all use relaxed policies, e.g., allowing returns to target any instruction following a call instruction.

While many advancements have been made along the way, all to often the relaxed enforcement policies significantly diminish the security afforded by Abadi et al. [3]'s seminal work. This realization is a bit troubling, and calls for a broader acceptance that we should not sacrifice security for small performance gains. Doing so simply does not raise the bar high enough to deter skillful adversaries. Indeed, our own work shows that even if coarse-grained CFI solutions are combined, there is still enough leeway to mount reasonable and Turing-complete ROP attacks. Our hope is that our findings will raise better awareness of some of the critical issues when designing robust CFI mechanisms, all-the-while re-energizing the community to explore more efficient solutions for empowering CFI.

A NULL-Byte Write Gadget

In real-world exploits it is useful to have gadgets that allow one to conveniently write a NULL word to memory. This is important as real-world vulnerabilities typically do not allow an adversary to write a NULL byte in the payload, but such functionality is indeed needed to write a 32-bit NULL word on the stack when required as a parameter to function calls.

A prominent example is the traditional *strcpy(dest,src)* vulnerability, which can be exploited to write data beyond the boundaries of the *src* variable. However, *strcpy()* stops copying input data after encountering a NULL byte.

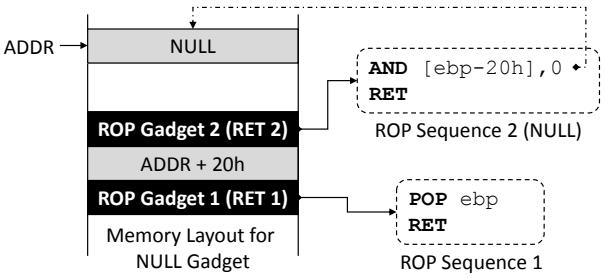

Figure 8: Details of NULL Gadget

Our choice for such a gadget is shown in Figure 8. This gadget first loads the target address into `ebp` with the first ROP sequence. The next sequence exploits the `and` instruction to generate a NULL word at the memory location pointed to by `ebp-20h`.

B Stack Pivot Gadgets

We take advantage of two distinct stack pivot gadgets shown in Table 8. The first one is our unconditional branch gadget, which moves `ebp` via the leave instruction to `esp`. The other sequence takes the value of `esi` and loads it into `esp`. In both sequences, the adversary must control the source register `ebp` and `esi`, respectively. This is achieved by invoking a load register gadget beforehand. Note also that several vulnerabilities allow an adversary to load these registers with the correct values at the time the buffer overflow occurs, which would make the ROP attack easier.

Type	Call-Preceded Sequence (ending in `ret`)
Pivot 1	`leave`
Pivot 2	`mov esp, esi; pop ebx; pop edi; pop esi; pop ebp`

Table 8: Stack Pivot Gadgets

C Details of Long-NOP Gadget

```
pop esi ; ptr to writable mem for NOP
pop edi ; ptr to writable mem for NOP
pop ebp ; unused in NOP
retn 8  ; -> insert 8 bytes junk after
    next gadget
```

Listing 1: Pre-Seuence for LNOP

```
movzx eax, ax
mov [esi+4], eax     ; 5 writes to
mov [esi+8], 1F4Bh   ; a 20 byte
mov [esi+14h], 5     ; memory region
mov [esi+10h], 1Fh
mov [esi+0Ch], 0Ch
push 3Bh
pop eax
mov [esi+1Ch], eax   ; 2 writes to
mov [esi+20h], eax   ; 8 byte region
xor eax, eax
mov [esi+18h], 17h   ; another 8 bytes
mov [esi+24h], 98967Fh
mov [edi+18h], eax   ; if edi == esi
mov [edi+1Ch], eax   ; these writes
mov [edi+20h], eax   ; goto the same
mov [edi+24h], eax   ; region as before
pop edi    ; (optional:) restore edi
pop esi    ; (optional:) restore esi
mov eax, ebx
pop ebx    ; (optional:) load former eax
pop ebp
retn 0Ch
```

Notes

[1]Some of the mechanisms used in kBouncer and ROPGuard (both awarded by Microsoft's BlueHat Prize [39]) have already been integrated in Microsoft's defense tool called EMET [29].

[2]Sequences that end in indirect jumps or calls can also be used [12].

[3]Typically, CFI does not validate direct branches because these addresses are hard-coded in the code of an executable and cannot be changed by an adversary when W⊕X is enforced.

[4]Specifically, kBouncer reports a ROP attack when a chain of 8 short sequences has been executed, where a sequence is referred to as "short" whenever the sequence length is less than 20 instructions.

[5]The target address of an external function is dynamically allocated in the global offset table (GOT) which is loaded by an indirect memory jump in the procedure linkage table (PLT).

[6]For the interested reader, we have placed the specific assembler implementation of the long-NOP sequence in Appendix C.

[7]We also simulated the analysis performed in [31] by setting $n = 20$. However, we arrive at a significantly higher false positive rate than in [31]. This is likely due to the fact that we perform our analysis on industry benchmark programs, while their analysis is based on opening web-browsers or document readers. Furthermore, their focus is on WinAPI calls, whereas in Figure 7 we instrument every call.

Size Does Matter

Why Using Gadget-Chain Length to Prevent Code-Reuse Attacks is Hard

Abstract

Code-reuse attacks based on return oriented programming are among the most popular exploitation techniques used by attackers today. Few practical defenses are able to stop such attacks on arbitrary binaries without access to source code. A notable exception are the techniques that employ new hardware, such as Intel's Last Branch Record (LBR) registers, to track all indirect branches and raise an alert when a sensitive system call is reached by means of *too many* indirect branches to *short* gadgets—under the assumption that such gadget chains would be indicative of a ROP attack. In this paper, we evaluate the implications. What is "too many" and how short is "short"? Getting the thresholds wrong has serious consequences. In this paper, we show by means of an attack on Internet Explorer that while current defenses based on these techniques raise the bar for exploitation, they can be bypassed. Conversely, tuning the thresholds to make the defenses more aggressive, may flag legitimate program behavior as an attack. We analyze the problem in detail and show that determining the right values is difficult.

1 Introduction

Modern protection mechanisms like data execution protection (DEP) [2], address space layout randomization (ASLR) [26] and stack smashing protection (SSP) [9] are now available on most general-purpose operating systems. As a result, exploitation by injecting and executing shellcode directly in the victim process has become rare. Unfortunately, these defenses are not sufficient to stop more sophisticated attacks.

Nowadays, attackers typically use memory disclosures to find exactly the addresses ASLR is trying to hide [30, 34, 36]. Likewise, there is no shortage of tutorials on how to evade state-of-the-art defenses [14, 28]. Attackers are able to hijack control flow and bypass DEP by reusing code that is already available in the binary itself, or in the libraries linked to it. There are several variations of this exploitation method: return-to-libc [37], return-oriented programming (ROP) [31], jump-oriented programming [3, 6], and sigreturn oriented programming (SROP) [4]. Code reuse attacks, and especially ROP, may be the most popular exploitation method used by attackers today, bypassing all popular defense mechanisms. Even additional and explicit protection against ROP attacks over and beyond DEP, ASLR and SSP, such as provided by Microsoft's Enhanced Mitigation Experience Toolkit (EMET), do not stop the attacks in practice [14].

ROP attacks start when an attacker gains control of the stack and diverts the control to a *gadget*: a short sequence of instructions that performs a small subset of the desired functionality and ends with a `ret` instruction. Since the attackers control the return addresses on the stack, they can make the `ret` of one gadget jump to the start of another gadget, daisy chaining the desired functionality out of a large set of small gadgets.

It is no wonder, then, that the security community has scrambled to find alternative methods to defend software assets. For instance, over the past decade or so, there has been a tremendous amount of research interest in control flow integrity (CFI) [1]—a technique to prevent *any* flow of control not intended by the original program. Unfortunately, CFI is fairly expensive. Moreover, research has shown that attempts to make it faster and more practical by employing looser notions of integrity, make it vulnerable to exploitation again [16].

KBouncer and friends Perhaps the main and most practical defense mechanism proposed against ROP attacks nowadays is the one pioneered by kBouncer [25]—grand winner of the Microsoft Blue Hat Prize in 2012. The technique has become quite successful and despite its recent pedigree, it is already used in commercial products like HitmanPro's new Alert 3 service [18].

KBouncer and related approaches like ROPecker [8] use a new set of registers, known as the Last Branch Record (LBR), available in modern Intel CPUs. The registers can be used to log the last n indirect branches taken by the program. Using the LBR, kBouncer checks whether the path that lead to a sensitive system call (like `VirtualProtect`) contains "too many" indirect branches to "short" gadgets—which would be indicative of a ROP chain.

The two obvious questions that we need to ask are: what is "too many," and how short is "short"?

Specifically, suppose the defensive mechanism has thresholds T_C and T_G, such that it raises an alarm when it sees a chain of T_C or more gadgets of at most T_G instructions each. If the attackers can find just a single gadget greater than T_G that they can simply squeeze in between the others to break the sequence, the defensive mechanism would not detect it. Conversely (and more worryingly), if a program itself exhibits T_C gadgets of at most T_G instructions during normal execution, the defense mechanism would erroneously flag it as an attack.

Implemented carefully, the protection offered by this method is quite powerful, but picking the right values for T_G and T_C is a delicate matter. After all, the former scenario suggests that T_G is too small. However, incrementing T_G may lead to more false positives (FPs) because benign execution paths are more likely to contain T_C such gadgets.

Contributions In this paper, we investigate the problem of picking the right values for these two thresholds. We also evaluate whether the solutions proposed today are sufficient to stop exploitation in real software. Specifically, we show that while they raise the bar for exploitation significantly, they can be bypassed. As a demonstration, we discuss a proof of concept exploit against Internet Explorer that bypasses current kBouncer-based defenses. We then analyze the problem by considering the availability of gadgets of different lengths and determining the sequences of gadgets en route to sensitive system calls.

While this work does not fully explore the possibility of FPs with the thresholds used in literature, it shows that defining restrictive thresholds, which do not allow the composition of ROP payloads, is extremely complicated and may not be possible for many applications due to FPs. Finally, we discuss various avenues for ameliorating these techniques and provide evidence that setting the thresholds based on the application at-hand can significantly encumber attackers.

Outline The remainder of this paper is organized as follows. Section 2 provides some background information regarding code-reuse attacks and defenses that use gadget-chain length for detection. Section 3 discusses the weaknesses of such approaches, and in Sec. 4 we present the process of creating an exploit that can circumvent them. We propose countermeasures and discuss possible obstacles for their adoption in Sec. 5. In Sec. 6, we present the results of our experiments that indicate that one of the proposed countermeasure can improve detection. Related work is in Sec. 7 and we conclude in Sec. 8.

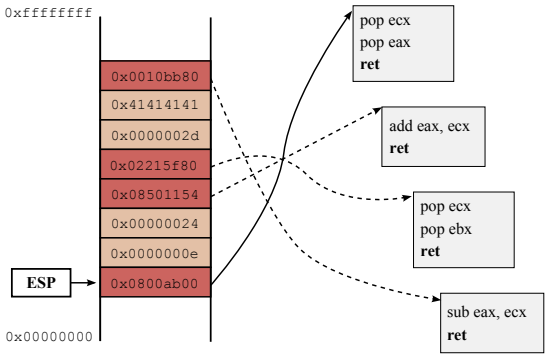

Figure 1: A very simple ROP chain that calculates $0xe + 0x24 - 0x2d$. Result is in the `eax` register.

2 Background

2.1 ROP and Code-reuse Attacks

ROP attacks are the most common vector for launching code-reuse attacks and require that the attacker gains control of the program's stack. By corrupting the return address of the executing function, upon its return, control is diverted to a *gadget* of the attacker's choosing. Gadgets are small sequences of code that end with a `ret`. By carefully positioning data on the stack, the attacker can make the program jump from one gadget to another, chaining together pieces of already existing code that implement the desirable payload, as shown in Fig. 1. While the gadgets that the attacker chains together are usually short in length (i.e., in number of instructions) and limited in functionality, previous work has shown that the attack is Turing complete [31]. That is, applications contain enough gadgets to perform arbitrary computations.

Creating a working ROP exploit is often a complex, multi-step process. It typically starts with a memory disclosure that allows the attacker to obtain code pointers. Next, the attack may require a variety of further preparations, such as advanced heap feng shui [35] to pave the way for a dangling pointer exploit, stack pivoting, and/or buffer overflows. In addition, the attacker needs to identify useful gadgets and construct a ROP program out of them by setting up the appropriate addresses and

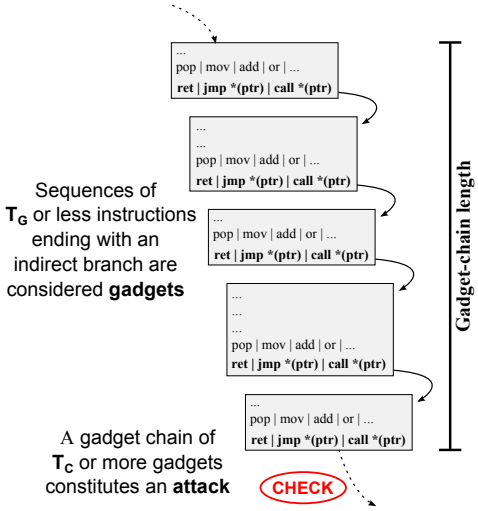

Figure 2: Example of a gadget chaining pattern used to identify code-reuse attacks.

arguments on the (possibly new) stack. Finally, a control flow diversion should start off the ROP chain.

ROP is popular despite its complexity because it provides a way for attackers to bypass defenses like DEP [2]. As a result, many recent works have focused on preventing ROP and other forms of code-reuse attacks [7, 8, 13, 23–25, 31, 33]. Other works have shown that a similar attack can also be performed with gadgets that end with indirect jump or call instructions instead of returns [3, 6, 21].

2.2 Monitoring Gadget Chains to Detect Attacks

kBouncer [25] and ROPecker [8] are two of the most easy to deploy solutions to stop ROP-like attacks. They employ a recent feature of Intel CPUs, known as the Last Branch Record (LBR), that logs the last branches taken by a program in a new set of registers [20, Sec. 17.4]. Intel introduced LBR for both the x86 and x86-64 architectures, so that, with the right configuration, the operating system (OS) is able to log the targets of indirect branches (including calls, jumps, and returns) in 16 machine-specific registers (MSR) registers with little overhead. These registers are accessible only from the OS kernel and are continuously overwritten as new branches occur.

A key observation for detecting ROP attacks, in both kBouncer and ROPecker, is that the attacks need to chain together a significant number of small gadgets to perform any useful functionality, like in the example shown in Fig. 2. From a high-level perspective, they include two parameters: the first controls what is the longest sequence of instructions ending with an indirect branch that will be considered a gadget, and the second specifies the number of successively chained gadgets that indicates an attack. We will refer to these two thresholds as T_G and T_C. These two parameters control the level of difficulty for performing an attack under these solutions. Increasing T_G or reducing T_C makes the construction of ROP payloads harder. However, overdoing it can lead to false positives (FP), due to legitimate execution paths being misclassified as attacks at run time. In the remainder of this section, we will briefly highlight kBouncer and ROPecker.

2.2.1 kBouncer

kBouncer kicks in every time a sensitive API call, like `VirtualProtect()`, `CreateProcess()`, etc., is executed by inserting hooks through the Detours [19] framework for Windows. It then scans the LBR registers to detect if the API call was made by a malicious ROP gadget chain, and terminates the running process if it was.
