Before execution, the *SM* mapping of all global variables that have an address value is set to the address itself, meaning the variable is only linearly correlated with itself initially (rule L-INIT). Function *isAddr(v)* determines if a value *v* could be an address. X-Force monitors all memory allocations and the image loading process. Thus, given a value, X-Force treats it as a pointer if it falls into static, heap, or stack memory regions. Note that we do not need to be sure that the value is indeed an address. Over-approximations only cause some additional linear set tracing. For a memory read operation, the *SR* mapping of the destination register points to the *SM* set of the value in the address register if the *SM* set exists, which implies the value is an address, otherwise it is set to nil (rule L-READ). Note that in the rule we use “r” to denote the symbolic name of r and r_a to denote the value stored in r_a. $SR(\text{“}r\text{”}) \rightarrow SM(r_a)$ means that we set $SR(\text{“}r\text{”})$ to point to the $SM(r_a)$ set. For a memory write, we first eliminate the destination address from its linear set. Then, the address is added to the linear set of the value register as the address essentially denotes a new linearly correlated variable. Finally, the *SM* mapping of the address is updated (rule L-WRITE). Note that operation “=” means set update, which is different from “$\rightarrow$” meaning set reference update. For a simple address assignment, the *SR* set is set to pointing to an empty linear set, which is different from a nil value (rule L-ADDR). The empty set is essentially an *LSet* object that could be pointed to by multiple registers to denote their linear correlation. A nil value cannot serve this purpose. For a linear operator, the *SR* mapping of the destination register is set to pointing to the *SR* mapping of the register holding an address value (rule L-LINEAR). Intuitively, this is because we are only interested in the linear correlation between address values (for the purpose of memory error recovery). For heap de-allocation, we have to remove each de-allocated address from its linear set (rule L-FREE).

Table 2 presents the set of memory error detection and

recovery rules. The relevant definitions are in Fig. 3. An auxiliary mapping *accessible*() is introduced to denote if an address has been allocated and hence accessible. The M-ALLOC and M-FREE rules are standard. Upon reading or writing an un-accessible address, X-Force calls function *recovery ()* with the register holding the invalid address to perform recovery. In the function, we first acquire the values of all the variables in the linear set and identify the minimal and maximum values (lines 1-6). Note that the values may be different (through address offsetting operations). We then allocate a piece of memory on demand according to the range of the values and a pre-defined default memory block size. Then in lines 9-12, the variables in the linear set are updated according to their offsets in the block. We want to point out that on-demand allocation may not allocate enough space. However, such insufficiency will be detected when out-of-bound accesses occur and further on-demand re-allocation will be performed. We also want to point out that a correctly developed program would first write to an address before it reads. As such, the on-demand allocation is often triggered by the first write to an invalid buffer such that the value could be correctly written and later read. In other words, we do not need to recover values in the on-demand allocated buffers.

In our real implementation, we also update all the registers that are linearly correlated, which can be determined by identifying the registers pointing to the same set. Furthermore, the rules only describe how we ensure heap memory safety whereas X-Force protects critical stack addresses such as return addresses and parameters, which we will discuss later.

Example. Fig. 4 presents part of a sample execution with the linear set tracing and memory safety semantics. The program is from the motivation example (Fig. 1). In the execution, the else branch of line 3 is taken but the true branch of line 5 is forced. As such, pointer p has a null value when it is passed to function *genName()*, which would cause an exception at line 22. In Fig. 4, we focus on the executions of lines 6, 22 and 7. The second column shows the binary code (in our simplified language). The third column shows the corresponding linear set computation and memory exception detection and recovery. Initially, $SM(\&p = 0x8004c0)$ is set to pointing to the set $\{0x8004c0\}$ according to rule L-INIT. At binary code line 2, $SR(eax)$ is set to pointing to the set of $SM(\&p)$. At line 3, since the value is further copied to a stack address $0xce0080$, *eax*, $\&p$ and the stack address all point to the same linear set containing $\&p$ and the stack address. Intuitively, these are the three variables that are linearly correlated. At lines 9 and 10, *edi* further points to the same linear set. At line 12, when the program tries to access the address denoted by $edi = 4$, the memory safety component detects the exception and performs on demand allocation. According to the linear set, $\&p$ and the stack address $0xce0080$ are set to the newly allocated address $0xd34780$ while *edi* is updated to $0xd34784$ according to its offset. While it is not presented in the table, the program further initializes the newly allocated data structure. As a result, when pointer p is later passed to *table_put()*, it points to a valid data structure. □

Algorithm 1 Path Exploration Algorithm

Output:	Ex - the set of executions (each denoted by a sequence of switched predicates) achieving a certain given goal (e.g. maximum coverage)
Definition	*switches*: the set of switched predicates in a forced execution, denoted by a sequence of integers. For example, $1 \cdot 3 \cdot 5$ means that the 1st, 3rd, and 5th predicates are switched $WL : \mathcal{P}(\overline{Int})$ - a set of forced executions, each denoted by a sequence of switched predicates $preds : \overline{Predicate \times boolean}$ - the sequence of executed predicates with their branch outcomes

1: $WL \leftarrow \{\text{nil}\}$
2: $Ex \leftarrow$ nil
3: **while** WL **do**
4: $switches \leftarrow WL$.pop()
5: $Ex \leftarrow Ex \cup switches$
6: Execute the program and switch branch outcomes according to *switches*, update fitness function $\mathcal{F}$
7: $preds \leftarrow$ the sequence of executed predicates
8: $t \leftarrow$ the last integer in *switches*
9: $preds \leftarrow$ remove the first t elements in $preds$
10: **for** each $(p,b) \in preds$ **do**
11: **if** $eval(\mathcal{F},p,b)$ **then**
12: update fitness function $\mathcal{F}$
13: $WL \leftarrow WL \cup switches \cdot t$
14: **end if**
15: $t \leftarrow t+1$
16: **end for**
17: **end while**

In the early stage of the project, we tried a much simpler strategy that is to terminate a forced execution when an exception is observed. However, we observed that since we do not provide any real inputs, exceptions are very common. Furthermore, simply skipping instructions that cause exceptions did not work either because that would have cascading effects on program state corruption. Finally, a crash-proof execution model as proposed turned out to be the most effective one.

X-Force also automatically recovers from other exceptions such as division-by-zero, by skipping those instructions that cause exceptions. Details are omitted.

3.2 Path Exploration in X-Force

One important functionality of X-Force is the capability of exploring different execution paths of a given binary to expose its behavior and acquire complete analysis results. In this subsection, we explain the path exploration algorithm and strategies.

To simplify discussion, we first assume a binary only performs control transfer through simple predicates (i.e. predicates with constant control transfer targets). We will introduce how to extend the algorithms in realistic settings, e.g., supporting exploration of indirect jumps in later section.

Algorithm 1 describes a general path exploration algorithm, which generates a pool of forced executions that are supposed to meet our goal specified by a configurable fitness function. It is a work list algorithm. The work list stores a list of (forced) executions that may be further explored by switching more predicates. Each execution is denoted by a sequence of integer numbers that specify the executed predicate instances to switch. Note that X-Force only force-sets the branch outcome of a small set of predicate instances. It lets the other predicate instances run as usual. Initially (line 1), the work list is a singleton set with a nil sequence, representing an execution without switching any predicate. Note that the work list is not empty initially. At the end of a forced execution, we update the fitness function that indicates the remaining space to explore (line 6), e.g., coverage. Then in lines 7-16, we try to determine if it would be of interest to further switch more predicate instances. Lines 7-9 compute the sequence of predicate instances eligible for switching. Note that it cannot be a predicate before the last switched predicate specified in *switches* as switching such a predicate may change the control flow such that the specification in *switches* becomes invalid. In lines 10-16, for each eligible predicate and its current branch outcome, we query the fitness function to determine if we should further switch it to generate a new forced execution. If so, we add it to the work list and update the fitness function. Note that in each new forced execution, we essentially switch one more predicate.

Different Fitness Functions. The search space of all possible paths is usually prohibitively large for real-world binaries. Different applications may define different fitness functions to control the scope they want to explore. In the following, we introduce three fitness functions that we use. Other more complex functions can be similarly developed.

- *Linear Search.* In certain applications, such as constructing control flow graphs and dynamic type reverse engineering (Section 5), the goal may be just to cover each instruction. The fitness function $\mathcal{F}$ could be defined as a mapping $covered : Predicate \times boolean \mapsto boolean$ that determines if a branch of a predicate has been covered. The evaluation in the box in line 11 of Algorithm 1 is hence defined as $!covered(p, \neg b)$, which means we will switch the predicate if the other branch has not been covered. Once we decide to switch an additional predicate, the fitness function is updated to reflect the new coverage (line 12). The number of executions needed is hence $O(n)$ with n the number instructions in the binary.
- *Quadratic Search.* In applications such as identifying indirect call targets, which is a very important challenge in binary analysis, simply covering all instructions may not be sufficient, we may need to cover paths that may lead to indirect calls or generate different indirect call targets. We hence define $\mathcal{F}$ as a set *icalls* to keep the set of the indirect call sites and potential indirect call targets that have been discovered by all the explored paths. The evaluation in line 11 is hence to test if cardinality of *icall* grows with the currently explored path. If so, the execution is considered important and all eligible unique predicates (not instances) in the execution are further explored. The complexity is $O(n^2)$ with n the number of instructions. X-Force can also limit the

quadratic search within a function.

- *Exponential Search.* If we simply set the evaluation in the line 12 to true, the algorithm performs exponential search because it will explore each possible combination. In practice, we cannot afford such search. However, X-Force provides the capability for the user to limit such exponential search within a sub-range of the binary.

Taint Analysis to Reduce Search Space. An observation is that we do not have to force-set predicates in low-level utility methods, because their branch outcomes are usually not affected by any input. Hence in X-Force, we use taint analysis to track if a predicate is related to program input. X-Force will only force branch outcomes of those tainted predicates. Since this is a standard technique, we omit its details.

4 Practical Challenges

In this section, we discuss how we address some prominent challenges in handling real world executables.

Jump Tables. In our previous discussion, we assume control transfer is only through simple predicates. In reality, jump tables allow a jump instruction to have more than two branches. Jump tables are widely used. They are usually generated from `switch` statements in the source code level. In X-Force, we leverage existing jump table reverse engineering techniques [21] to recover the jump table for each indirect jump. Our exploration algorithm then tries to explore all possible targets in the table.

Handling Loops and Recursions. Since X-Force may corrupt variables, if a loop bound or loop index is corrupted, an (incorrect) infinite loop may result. Similarly, if X-Force forces the predicate that guards the termination of some recursive function call, infinite recursion may result. To handle infinite loops, X-Force leverages taint analysis to determine if a loop bound or loop index is computed from input. If so, it resets the loop bound/index value to a pre-defined constant. To handle infinite recursion, X-Force constantly monitors the call stack. If the stack becomes too deep, X-Force further checks if there are cyclic call paths within the call stack. If cyclic paths are detected, X-Force skips calling into that function by simulating a "ret" instruction.

Protecting Stack Memory. Our early discussion on memory safety focused on protecting heap memory. However, it is equally important to protect stack memory. Particularly, the return address of a function invocation and the stack frame base address of the caller are stored on stack upon the invocation. They are restored when the callee returns. Since X-Force may corrupt variable values that affect stack accesses, such critical data could be undesirably over-written. We hence need to protect stack memory as well. However, we cannot simply prevent any stack write beyond the current frame. The strategy of X-Force is to prevent any stack writes that originate in the current stack-frame to go beyond the current frame. Specifically, when a stack write attempts to over-write the return address, the write is skipped. Furthermore, the instruction is flagged. Any later instances of the instruction that access a stack address beyond the current stack-frame are also skipped. The flags are cleared when the callee returns.

Handling Library Function Calls. The default strategy of X-Force is to avoid switching predicates inside library calls as our interest falls in user code. X-Force handles the following library functions in some special ways.

- *I/O functions.* X-Force skips all output calls and most input calls except file inputs. X-Force provides wrappers for file opens and file reads. If the file to open does not exist, X-Force skips calling the real file open and returns a special file handler. Upon file reads, if the file handler has the special value, it returns without reading the file such that the input buffer contains random values. Supporting file reads allows X-Force to avoid unnecessary failure recovery and path exploration if the demanded files are available.
- *Memory manipulation functions.* To support memory safety, X-Force wraps memory allocation and de-allocation. For memory copy functions such as `memcpy()` and `strcpy()`, the X-Force wrappers first determine the validity of the copy operation, e.g., the source and target address ranges must have been allocated, must not overlap with any critical stack addresses. If necessary, on-demand allocation is performed before calling the real function. This eliminates the need of memory safety monitoring, linear set tracing, and memory error recovery inside these functions, which could be quite heavy-weight due to the special structure of these functions. For example, `memcpy()` copies individual addresses one by one and these addresses are linearly correlated as they are computed through pointer manipulation, leading to very large linear sets.

For statically linked executables, X-Force relies on IDA-Pro to recognize library functions in a pre-processing step. IDA leverages a large signature dictionary to recognize library functions with very good accuracy. For functions that are not recognized by IDA, X-Force executes them as user code.

Handling Threads. Some programs spawn additional threads during their execution. It is difficult for X-Force to model multiple threads into a single execution since the order of their execution is nondeterministic. If we

simply skip the thread creation library functions such as *CreateThread()* and *beginthread()*, the functions in the thread could not be covered. To solve this problem, we adopt a simple yet effective approach of serializing the execution of threads. The calls to thread creation library functions are replaced with direct function calls to the starting functions of threads, which avoid creating multiple threads and guarantees code coverage at the same time. Note that as a result, X-Force is incapable of analyzing behavior that is sensitive to schedules. We will leave it to our future work.

5 Evaluation

X-Force is implemented in PIN. It supports WIN32 executables. In this section, we use three application case studies to demonstrate the power of X-Force.

5.1 Control Flow Graph (CFG) and Call Graph (CG) Construction

Construction of CFG and CG is a basic but highly challenging task for binary analysis, especially the identification of indirect call targets. In the first case study, we apply X-Force to construct CFGs and CGs for stripped SPECINT 2000 binaries. We also evaluate the performance of X-Force in this study. To construct CFGs and CGs, we use X-Force to explore execution paths and record all the instructions, control flow edges, and call edges, including indirect jump and indirect call edges. The exploration algorithm is a combination of linear search and quadratic search (Section 3.2). Quadratic search is limited to functions that contain indirect calls or encounter values that look like function pointers.

We compare X-Force results with four other approaches: (1) IDA-Pro; (2) Execute all the test cases provided in SPEC and union the CFGs and CGs observed for each program (i.e., dynamic analysis); (3) Static CG construction using LLVM on SPEC source code (i.e., static analysis) [3]. (4) Dynamic CFG construction using a symbolic execution system S2E [10]. We could not compare with CodeSurfer-X86 [2], which can also generate CFG/CG for executables based on static analysis, because it is not available through commercial or academic license.

Part of the results is presented in Table 3. Columns 2-4 present the instructions that are covered by the different approaches. Particularly, the second column shows the number of instructions recognized by IDA. The third column shows those that are executed by concrete input runs. Columns 5-8 show the indirect call edges recognized by the different approaches[4]. The last five columns show internal data of X-Force.

From the coverage data, we observe that X-Force could cover a lot more instructions than dynamic analysis except `253.perlbmk`. Note that the dynamic analysis results are acquired using all the test, training and reference inputs in SPEC, which are supposed to provide good coverage. Table 4 presents more detailed coverage comparison with dynamic analysis. Observe that X-Force covers all the instructions that are covered by natural runs for all benchmarks except `253.perlbmk`, which we will explain later. X-Force could cover most of the instructions identified by IDA except `252.eon` and `253.perlbmk`. We have manually inspected the differences between the IDA and X-Force coverage. For most programs except `253.perlbmk`, the differences are caused by part of the code in those binaries being unreachable. In other words, they are dead code that cannot be executed by any input. Since IDA simply scans the code body to construct CFG and CG, it reports all instructions it could find including the unreachable ones.

Table 5: Detailed Indirect Call Edges Identification Comparison with Dynamic Analysis

	Input Union	X-Force	Input Union ∩ X-Force	Input Union \ X-Force	X-Force \ Input Union
164.gzip	2	2	2	0	0
176.gcc	169	1720	169	0	1551
252.eon	60	121	60	0	61
253.perlbmk	225	151	103	122	48
254.gap	1103	20485	1103	0	19382
255.vortex	28	30	28	0	2

Indirect call edge identification is very challenging in binary analysis as a call site may have multiple call targets depending on execution states, which are usually difficult to cover or abstract. Some of them are dependent on states related to multiple procedures. Note that there does not exist an oracle that can provide the ground truth for the set of real indirect call edges. From the results, we could observe that LLVM's indirect call identification algorithm generates a large number of edges, much more than X-Force. However, we confirm that most of them are bogus because the LLVM algorithm simply relies on method signatures to identify possible targets and

[3] We cannot compare LLVM CFGs with X-Force CFGs as LLVM CFGs are not represented at the instruction level.

[4] Direct jump and call edges are easy to identify and elided.

Table 3: CFG and CG Construction Results.

	Coverage			Indirect Call Edge				X-Force Internals				
	IDA-Pro	Input Union	X-Force	IDA-Pro	Input Union	LLVM	X-Force	Time (s)	# of Runs	Avg. # of Exp.	Avg./Max. Linear Set Size	Switched/Total # of predicates

hence is too conservative. X-Force could recognize a lot more indirect call edges than dynamic analysis. The detailed comparison in Table 5 shows that the X-Force results cover all the dynamic results and have many more edges, except *253.perlbmk*. We have manually inspected a random set of the selected edges that are reported by X-Force but not the dynamic analysis and confirmed that they are feasible. From the results in Table 3, IDA can hardly resolve any indirect call edges.

Table 6: Result of using S2E to analyze SPEC programs

	Basic Block Coverage	Function Block Coverage	Touched Functions	Fully Covered Functions	Number of Paths
164.gzip	768/2240(34%)	768/1294(59%)	62/186(33%)	21/186(11%)	134
176.gcc	740/46487(1%)	740/1468(50%)	62/1398(4%)	19/1398(1%)	261
252.eon	64/2830(2%)	64/101(63%)	19/649(2%)	13/649(2%)	33
253.perlbmk	1708/37384(4%)	1708/6912(24%)	134/1510(8%)	27/1510(1%)	329
254.gap	1235/28871(4%)	1235/3136(39%)	80/941(8%)	21/941(2%)	29
255.vortex	10933/35979(30%)	10933/20822(52%)	437/1031(42%)	21/1031(2%)	9

We also use S2E to analyze the six SPECINT 2000 programs that contain indirect calls. The four programs other than `252.eon` and `255.vortex` read input from *stdin*, so we use the *s2ecmd* utility tool provided by S2E to write 64 bytes to *stdout* and pipe the symbolic bytes into these programs. We run each program in S2E and use the `ExecutionTracer` plugin to record the execution trace. We use the IDA scripts provided by S2E to extract information of basic blocks and functions from the binaries, and then use the `coverage` tool provided by S2E to calculate the result.

The result is shown in Table 6. The columns show the following metrics from left to right: (1) coverage of basic blocks; (2) coverage of basic blocks when excluding the basic blocks in those functions that are not executed; (3) coverage of functions; (4) percentage of fully-covered functions; (5) the number of different paths that S2E explored. Observe that the coverage is much lower than X-Force in general. `176.gcc`, `253.perlbmk` and `254.gap` are parsers/compilers. They have poor coverage on S2E because they get stuck in the parsing loops/automatas, whose termination conditions are dependent on the symbolic input. Regarding `255.vortex`, S2E fails to solve the constraints when an indirect jump uses the symbolic variable as the index of jump table. As a result, S2E fails to identify most of the indirect call edges due to the failure of creating different objects. In `252.eon`, S2E fails to solve the constraints of the input file format, which must contain a specific string as header. The program throws exception and terminates quickly, which leads to poor coverage.

`253.perlbmk` is a difficult case for X-Force. It parses perl source code to generate syntax trees. The indirect call targets are stored in the nodes of syntax trees. However, since the syntax tree construction is driven by finite automata, path coverage does not seem to be able to cover enough states in the automata to generate enough syntax trees of various forms. A few other benchmarks such as `176.gcc` and `254.gap` also leverage automata based parsers, however their indirect call targets are not so closely-coupled with the state of the automata and hence X-Force can still get good coverage. We will leave it to our future work to address this problem.

The last five columns show some statistics of X-Force. The run time and the number of explorations are largely linear regarding the number of instructions except for a small number of functions on which quadratic search is performed. Some take a long time (e.g., close to 50 hours for `176.gcc`) due to their complexity. The average number of exceptions is the number of exceptions encountered and recovered from in each execution (e.g. memory exceptions, division by zero). The numbers are smaller than we expected given that we execute these programs without any inputs and switch branch outcomes. It shows that our exception recovery could effectively prevent cascading exceptions. The linear set sizes are manageable. The last column shows the average number of switched predicates versus the average number of predicate instances in total in an execution. It shows that X-Force may violate path feasibility only in a very small part of execution. The performance overhead of X-Force compared to the vanilla PIN is 473 times on average. It is measured by comparing the number of instructions that could be executed by X-Force and the vanilla PIN within the same amount of time.

5.2 Malware Analysis

One common approach to understanding the behavior of an unknown malware sample is by looking at the library calls it makes. This could be done by static, dynamic or symbolic analysis; however, they all have limitations.

Table 7: Result of using X-Force for malware analysis compared with IDA Pro and native run.

Name	MD5	File Size(KB)	Number of Library Functions			Number of Library Call Sites			No. of Runs
			IDA Pro	Native Run	X-Force	IDA Pro	Native Run	X-Force	in X-Force

Static analysis could not obtain the parameters of library calls that are dynamically computed and is infeasible when the sample is packed or obfuscated. Traditional dynamic analysis can obtain parameters and is immune to packing and obfuscation, however, it could only explore some of the execution paths depending on the input and the environment. Unfortunately, the input is usually unknown for malware. Symbolic analysis, while being able to construct input according to path conditions, has difficulty in handling complex or packed binaries.

X-Force overcomes these problems as traditional dynamic analysis could be built upon X-Force to explore various execution paths without providing any inputs or the environment. In this case study, we demonstrate the use of a library call analysis system we built on top of X-Force to analyze real-world malware samples.

When we implement library call analysis on top of X-Force, we slightly adjust X-Force to make it suitable for handling malware: (1) We enable the concrete execution of most library functions including output functions because many packers use output functions (e.g. `RtlDecompressBuffer()`) to unpack code. We continue to skip some library calls such as `Sleep()` and `DeleteFile()`; (2) We intercept a few functions that allocate memory and change page attributes, such as `VirtualAlloc()` and `VirtualProtect()`. This is for tracking the memory areas of code and data which keep changing at runtime due to self-modifying and dynamically generated code.

Given a malware sample, we use X-Force to explore its paths. We use the linear search algorithm (Section 3.2) as it provides a good balance between efficiency and coverage. During each execution, we record a trace of function calls. For library calls, we also record the parameter values. The trace is then transformed into an interprocedural flow graph that has control transfer instructions, including jumps and calls, as its nodes, and control-flow/call edges as its edges. The parameters of library calls are also annotated on the graph. The graphs generated in multiple executions are unioned to produce the final graph. We then manually inspect the final graphs to understand malware behavior.

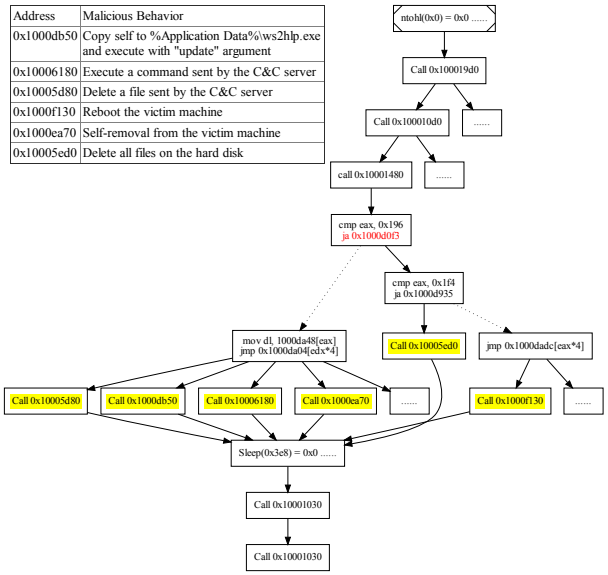

Figure 5: The flow graph of the function at *0x1000c630* generated by X-Force when analyzing dg003.exe.

We evaluate our system on 10 real-world malware samples which are either wild-captured virus/trojan or APT samples described in [9]. Since our analysis focuses on library calls, we choose the number of identified library functions and the total number of their call sites as the evaluation metric[5]. We also compare our results with IDA-Pro and the native run. In IDA, library functions are identified from the import table; the call sites are identified by scanning the disassemblies. In the native run, we execute the malware without any arguments and record the library calls using a PIN tool.

The results are shown in Table 7. We can see that for packed or obfuscated samples such as *dg003.exe*, *Win32/PWSteal.F*, *APT1.DAIRY*, and *APT1.BOUNCER*, IDA gets fewer library functions and call sites compared to X-Force. For other samples that are not packed or obfuscated, since the executables could be properly disassembled, the metrics obtained in IDA and X-Force are

[5]We exclude the C/C++ runtime initialization functions which are only called before the main function.

very close. However, even in such cases, static analysis is insufficient to understand the malicious behavior because it does not show the values of the library function parameters. Compared to the native run method, X-Force can identify more library functions and call sites.

Next, we present detailed analysis for two representative samples.

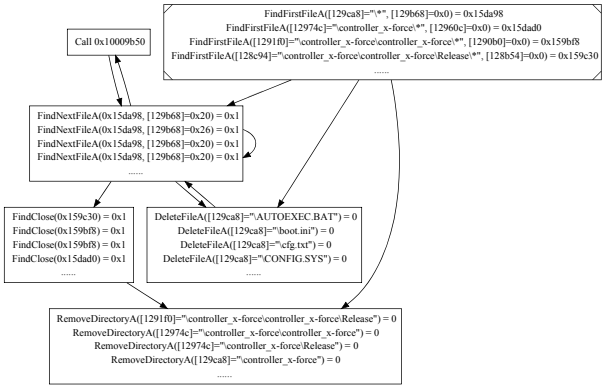

Figure 6: The flow graph of the function at *0x10009b50* in dg003.exe that delete all files on the hard disk.

Dg003.exe. This is a typical APT malware sample that features multi-staged, condition-guarded and environment-specific payload. In the first stage, the malware extracts a DLL which it carries as its resource, packs the DLL in memory using a proprietary algorithm and writes the packed DLL to the disk. In the second stage, the packed DLL is loaded, unpacks itself in memory and executes the main payload.

There is a previous report [26] in which the analysts used both static and dynamic analyses to analyze this sample. To perform static analysis using IDA Pro, they manually extract and unpack the DLL. This requires reverse engineering the unpacking algorithm, which could be both time consuming and difficult. Our system avoids such trouble by concretely executing the unpacking routine which performs the unpacking for us. Compared with their dynamic analysis, it takes X-Force about 5 hours to finish 800 executions to explore all paths in both the first and second stages of the malware. After that, the traces are transformed into a flow graph containing 378 functions. Our system is able to discover a set of malicious behaviors that are *NOT* mentioned in the previous report. As shown in Fig. 5, each highlighted function call in the graph corresponds to a previously unrevealed malicious behavior. Each behavior is identified using the library calls made in the corresponding function. For example, as shown in Fig. 6, the library calls and the parameters in the function at *0x10009b50* show that it recursively enumerates and deletes files and directories starting from the root directory, which indicates its behavior is to delete all files on the disk.

In Fig. 5 we can see that the common dominator of all these function calls (highlighted in red color) determines if the value of *eax* register is larger than 0x196. With taint analysis in X-Force, we find that the value of the *eax* register is related to an input which is a buffer in a previous *recv* library function call. This indicates it represents the command ID sent by the C&C server, which leads to the execution of different malicious behaviors. Hence, we suspect that the previous analysts missed some behaviors because the C&C server only sent part of the possible commands at the time they ran the malware. We also find that the buffer in the *recv* function call is translated to the command ID using a private decryption algorithm, so it would be infeasible for symbolic analysis to solve the constraints and construct a valid input. We also want to point out that at the time we perform the analysis, the C&C server of this malware is already inactive; we would not be able to discover these malicious behaviors, had we not used X-Force.

Win32/PWSteal.F. Before trying X-Force on this sample, we first try static analysis using IDA-Pro. Surprisingly, this sample does not import any suspicious library function; not even a function that could perform I/O (e.g. read/write file, registry or network socket). The `LoadLibrary()` and `GetProcAddress()` functions are not imported either, which means the common approach of dynamically loading libraries is not used. The strings in the executable do not contain any DLL name or library function name either. This indicates the sample is equipped with advanced API obfuscation technique to thwart static analysis.

Since static analysis is infeasible, we submit the sample to the Anubis malware analysis platform for dynamic analysis. The result shows the malware does read some registry entries and files, however, none of them seems malicious. Hence, we feed the sample to our system in hopes of revealing its real intent. X-Force achieves full coverage after exploring 30 paths and generates a graph with 15 functions. By traversing the graph, we find that this malware aims at stealing the password that is stored by IE and Firefox in the victim's machine. It enumerates the registry entry that stores the encrypted auto-complete password for IE and calls library functions such as `CryptUnprotectData()` to decrypt the stored password. This is very similar to the attack mentioned in [1]. Regarding Firefox, it first gets the user name from `profiles.ini` under the Firefox application data directory, and then steals the password that is stored in the `signons*.txt` under the directory of the user name. The password is then uploaded to a remote FTP server using the file name `[Computer Name].[IP Address].txt`. Clearly, this sample finds the entry addresses of these library functions at runtime using some obfuscation techniques. X-Force allows us to identify the

malicious behavior without spending unnecessary time on reverse-engineering the API obfuscation.

Moreover, the flow graph also reveals the reason why Anubis missed the malicious behavior: the malware performs environment checks to make sure the targets exist before trying to attack. For example, in the function where the malware steals password from IE, it will try to open the registry entry that contains the auto-complete password; if such entry does not exist or is empty, the malware will cease its operation and return from that function. Also, before it tries to steal password stored by Firefox, it will first try querying the installation directory of Firefox from registry to make sure the target program exists in the system. Such "prerequisites" are unlikely to be fulfilled in automated analysis systems as they are unpredictable. However, by force-executing through different paths, X-Force is able to get through these checks to reveal the real intent of the malware.

```
TYPE_1 func1(TYPE_2 arg1, TYPE_3 arg2) {
        TYPE_4 var1;
1       var1 = strlen (arg1);
2       if (arg2 >= var1)
3               return 0;
4       return arg1[arg2];
}
```

Figure 7: REWARDS example.

5.3 Type Reverse Engineering

Researchers have proposed techniques to reverse engineer variable and data structure types for stripped binaries [30, 39, 25]. The reverse engineered types can be used in forensic analysis and vulnerability detection. There are two common approaches. REWARDS [30] and HOWARD [39] leverage dynamic analysis. They can produce highly precise results but incompleteness is a prominent limitation – they cannot reverse engineer types of variables if such variables are not covered by executions. TIE [25] leverages static analysis and abstract interpretation such that it provides good coverage. However, it is challenging to apply the technique to large and complex binaries due to the cost of analysis.

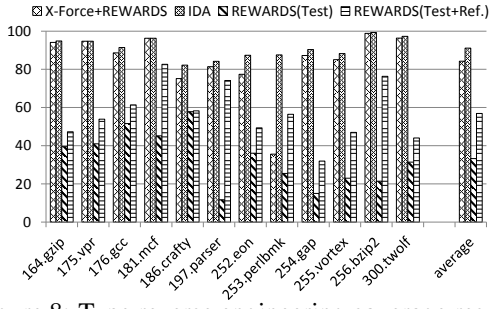

Figure 8: Type reverse engineering coverage results.

One advantage of X-Force is that the forced executions are essentially concrete executions such that existing dynamic analyses could be easily ported to X-Force to benefit from the good coverage. Therefore in the third case study, we port the implementation of REWARDS to X-Force. Given a binary executable and a few test inputs, REWARDS executes it while monitoring dataflow during execution. When execution reaches system or library calls, the types of the parameters of these calls are known. Such execution points are called *type sinks*. Through the dynamic dataflow during execution, such types could be propagated to variables that (transitively) contributed to the parameters in the past and to variables that are (transitively) dependent on these parameters.

Consider the example in Fig. 7. Assume `func1` is executed. After line 1, the type of `arg1` and `var1` get resolved using the interface of `strlen()`. So `TYPE_2` is `char *`, and `TYPE_4` is `unsigned int`. In line 2, `arg2` is compared with `var1`, implying they have the same type. Thus `TYPE_3` gets resolved as `unsigned int`. Later when line 4 gets executed, it returns `TYPE_1` which is resolved as `char` since `arg1` is of `char *`.

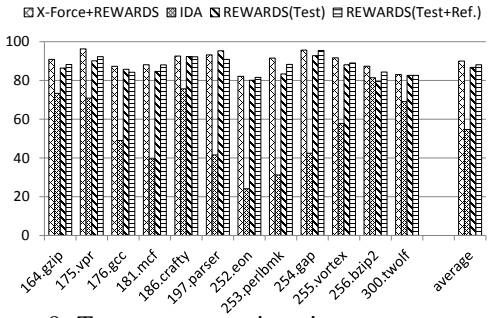

Figure 9: Type reverse engineering accuracy results.

Porting REWARDS to X-Force requires very little modification of either the REWARDS or the X-Force systems as they only interface through the (forced) concrete executions. Facilitated by X-Force, REWARDS is able to run legacy binaries and COTS binaries without any inputs. In our experiment, we run the new system on the 12 SPEC2000 INT binaries. They are a lot more complex than the Linux core-util programs used in the original paper [30]. To acquire the ground truth, we compile the programs with the option of generating debugging symbols as PDB files, and use DIA SDK to read the type information from the PDB files.

We evaluate the system in terms of both coverage and accuracy. Coverage means the percentage of variables in the program that have been executed by our system. Accuracy is the percentage of the covered variables whose types are correctly reverse engineered. From Fig. 8, the average coverage is around 84%. The coverage heavily relies on the code coverage of X-Force. Recall that these programs have non-trivial portion of unreachable code. The variables in those code regions cannot be reverse engineered by our system. From Fig.9, the average accuracy is about 90%. The majority of type inference

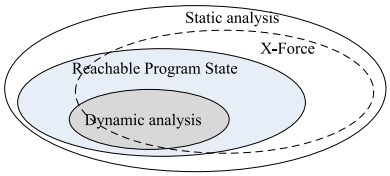

Figure 10: Essence of X-Force.

failures is caused by the fact that the variables are not related to any *type sink*.

We also compare with IDA and the original REWARDS. IDA has a static type inference algorithm that works in a similar fashion. When we run the original REWARDS, we have two configurations: (1) use the test input only (1 input per program) and (2) use both the test and the reference inputs (around 4 inputs per program). From Fig. 8 and Fig. 9, our system has much better accuracy than IDA (90% vs. 55% on average) and better coverage than the original REWARDS, i.e., 84% vs. 57% (test+reference) or 34% (test input only). The better accuracy than IDA is achieved by the more precise modeling of behavior difficult for static analysis, such as heap accesses and indirect calls and jumps.

6 Discussion and Future Work

X-Force is intended to be a *practical* solution for analyzing unknown (malicious) binaries without requiring any source code or inputs. Hence, X-Force trades soundness and completeness for practicality. It is unsound as it could explore infeasible paths. It is incomplete as it cannot afford exploring all paths. Figure 10 shows how X-Force compares with static and dynamic analysis: The "Reachable Program State" oval denotes all states that can be reached through possible program inputs – the ideal coverage for program analysis. Static analyses often make conservative approximations such that they yield *over-approximate* coverage. Dynamic analyses analyze a number of real executions and hence yield *under-approximate* results. X-Force explores a larger set of executions than dynamic analyses. Since X-Force makes unsound approximations, its results may be invalid (i.e., outside the ideal oval). Furthermore, it is incomplete as its results may not cover the ideal ones.

However, we argue that X-Force is still of importance in practice: (1) There are many security applications whose analysis results are not so sensitive to paths, such as the three studies in this paper. As such, path infeasibility may not affect the results much. However, having concrete states in path exploration is still critical in these applications such that an execution based approach like X-Force is suitable; (2) Only a very small percentage of predicates are switched (Section 5.1) in X-Force. Execution is allowed to proceed naturally in most predicates, respecting path feasibility. According to our observations, most of the predicates that got switched in linear search are those checking if the program has been provided the needed parameters, if files are properly opened, and if certain environmental configurations are correctly set-up; (3) In X-Force, taint analysis is used to identify predicates that are affected by inputs and only such predicates are eligible for switching.

Moreover, X-Force allows users to (1) *rapidly* explore the behaviors of any (unknown) binary as it simply executes the binary (without solving constraints); (2) handle binaries in a much *broader* spectrum (e.g., large, packed, or obfuscated binaries); (3) easily port or develop dynamic analysis on X-Force as the executions in X-Force are no different from regular concrete executions.

Future Work. We believe this paper is just an initial step in developing a unique type of program analysis different from the traditional static, dynamic, and symbolic analysis. We have a number of tasks in our future research agenda.

- While X-Force simply forces the branch outcomes of a few predicates without considering their feasibility, we suspect that there is a chance in practice the forced paths are indeed feasible in many cases. Note that the likelihood of infeasibility is not high if the forced predicates are not closely correlated. We plan to use a symbolic analysis engine that models the path conditions along the forced paths to observe how often they are infeasible.

- We develop 3 exploration algorithms in this paper. From the evaluation data on the SPECINT2000 programs, there are cases (e.g., perlbmk) that the current exploration algorithms cannot handle well. More effective algorithms, for example, based on modeling functions behaviors and caching previous exploration choices, will be developed.

- We currently handle multi-threaded programs by serializing their executions. In the future, we will explore forcing real concurrent executions. We envision this has to be integrated with flipping schedule decisions, which is a standard technique in exploring concurrent execution state. How to handle the enlarged state space and the potentially introduced infeasible thread schedules will be the new challenges.

- The current system is implemented as a tool on top of PIN. To build a tool that makes use of X-Force, for example REWARDS, the implementation of the additional tool is currently mixed with X-Force. They are compiled together to a single PIN-tool. We aim to make X-Force transparent to dynamic analysis developers by providing an PIN-like interface. Ideally, existing PIN-tools can be easily

ported to X-Force to benefit from the large number of executions provided by the X-Force engine.

- We also plan to port the core X-Force engine to other platforms such as mobile and HTML5 platforms.

7 Related Work

Researchers proposed to force branch outcomes for patching software failures in [51]. Hardware support was proposed to facilitate path forcing in [31]. Both require source code and concrete program inputs. Branch outcomes are forced to explore paths of binary programs in [48] to construct control flow graphs. The technique does not model any heap behavior. Moreover, it skips all library calls. Similar techniques are proposed to expose hidden behavior in Android apps [22, 45]. These techniques randomly determine each branch's outcome, posing the challenge of excessive infeasible paths. Forced execution was also proposed to identify kernel-level rootkits [46]. It completely disregards branch outcomes during execution and performs simple depth-first search. None of these techniques performs exception recovery and instead simply terminates executions when exceptions arise. Constraint solving was used in exploring execution paths to expose malware behavior in [33, 6]. They require concrete inputs to begin with and then mutate such inputs to explore different paths.

X-Force is related to static binary analysis [21, 3, 25, 42, 41], dynamic binary analysis [30, 39, 24] and symbolic binary analysis [10, 40]. We have discussed their differences from X-Force in Section 6, which are also supported by our empirical results in Section 5. X-Force is also related to failure oblivious computing [36] and on-the-fly exception recovery [34], which are used for failure tolerance and debugging and require source code.

8 Conclusion

We develop a novel binary analysis engine X-Force, which forces a binary to execute without any inputs or the needed environment. It systematically forces the branch outcomes at a small number of predicates to explore different paths. It can recover from exceptions by allocating memory on-demand and fixing correlated pointers accordingly. Our experiments on three security applications show that X-Force has similar precision as dynamic analysis but much better coverage due to the capability of exploring many paths with any inputs.

Abstract

Function identification is a fundamental challenge in reverse engineering and binary program analysis. For instance, binary rewriting and control flow integrity rely on accurate function detection and identification in binaries. Although many binary program analyses assume functions can be identified a priori, identifying functions in stripped binaries remains a challenge.

In this paper, we propose BYTEWEIGHT, a new automatic function identification algorithm. Our approach automatically learns key features for recognizing functions and can therefore easily be adapted to different platforms, new compilers, and new optimizations. We evaluated our tool against three well-known tools that feature function identification: IDA, BAP, and Dyninst. Our data set consists of 2,200 binaries created with three different compilers, with four different optimization levels, and across two different operating systems. In our experiments with 2,200 binaries, we found that BYTEWEIGHT missed 44,621 functions in comparison with the 266,672 functions missed by the industry-leading tool IDA. Furthermore, while IDA misidentified 459,247 functions, BYTEWEIGHT misidentified only 43,992 functions.

1 Introduction

Binary analysis is an essential security capability with extensive applications, including protecting binaries with control flow integrity (CFI) [1], extracting binary code sequences from malware [9], and hot patching vulnerabilities [25]. Research interest in binary analysis shows no sign of waning. In 2013 alone, several papers such as CFI for COTS [34] (referred to as COTS-CFI in this paper), the Rendezvous search engine for binaries [21], and the Phoenix decompiler [28] focus on developing new binary analysis techniques.

Function identification is a preliminary and necessary step in many binary analysis techniques and applications. For example, one property of CFI is to constrain inter-function control flow to valid paths. In order to reason about such paths, however, binary-only CFI infrastructures need to be able to identify functions accurately. In particular, COTS-CFI [34], CCFIR [33], MoCFI [12], Abadi et al. [1], and extensions like XFI [15] all depend on accurate function identification to be effective.

CFI is not the only consumer of binary-level function identification techniques. For example, Rendezvous [21] is a search engine that operates at the granularity of function binaries; incorrect function identification can therefore result in incomplete or even incorrect search results. Decompilers such as Phoenix [28], Boomerang [32], and Hex-Rays [18] recover high-level source code from binary code. Naturally, decompilation occurs on only those functions that have been identified in the input binary.

Given the foundational impact of accurate function identification in so many security applications, is this problem easy and can thus be regarded as "solved"? Interestingly, recent security research papers seem to have conflicting opinions on this issue. On one side, Kruegel et al. argued in 2004 that function start identification can be solved "very well" [23, §4.1] in regular binaries and even some obfuscated ones. On the other side, Perkins et al. described static function start identification as "a complex task in a stripped x86 executable" [25, §2.2.3] and therefore applied a dynamic approach in their ClearView system. A similar opinion is also shared by Zhang et al., who stated that "it is difficult to identify all function boundaries" [34, §3.2] and used a set of heuristics for this task.

So how good are the current tools at identifying functions from stripped, non-malicious binaries? To find out, we collected a dataset of 2,200 Linux and Windows binaries generated by GNU `gcc`, Intel `icc`, and Microsoft Visual Studio (`VS`) with multiple optimization levels. We then use our dataset to evaluate the most recent release of three popular off-the-shelf solutions for function identification: (i) IDA (v6.5 at submission), used in CodeSurfer/x86 [2], Choi et al.'s work on statically determining binary similarity [11], BinDiff [4], and BinNavi [5]; (ii) the CMU Binary Analysis Platform

(BAP, v0.7), used in the Phoenix decompiler [28] and the vulnerability analysis tool Mayhem [10]; and (iii) the `unstrip` utility in Dyninst (dated 2012-11-30), used in BinSlayer [7], Sharif et al.'s work on dynamic malware analysis [29], and Sidiroglou et al.'s work on software recovery navigation [30].

Our finding is that while IDA performs better than BAP and Dyninst on our dataset, its result can still be quite alarming—in our experiment, IDA returned 521,648 true positives (41.81%), 266,672 false negatives (21.38%), and 459,247 false positives (36.81%). While there is no doubt that such failures can have a negative impact on downstream security analyses, a real issue is in setting the right expectation on the subject within the security research community. If there is a publicly-available function identification solution where both its mechanism and limitations are well-understood by researchers, then researchers may be come up with creative strategies to cope with the limitations in their own projects. The goal of this paper is to explain our process of developing such a solution and to establish its quality through evaluating it against the aforementioned solutions.

We draw inspirations from how BAP and Dyninst perform function identification since their source code is available. Both solutions rely on fixed, manually-curated signatures. Dyninst, at the version we tested, uses the byte signature `0x55` (`push %ebp` in assembly) to recognize function starts in ELF x86 binaries [14]. BAP v0.7 uses a more complex signature, but it is also manually generated. Unfortunately, the process of manually generating such signatures do not scale well. For example, each new compiler release may introduce new idioms that require new signatures to capture. The myriad of different optimization settings, such as omit frame pointers, may also demand even more signatures. Clearly, we cannot expect to manually catch up.

One approach to recognizing functions is to automatically learn key features and patterns. For example, seminal work by Rosenblum et al. proposed binary function start identification as a supervised machine learning classification problem [27]. They model function start identification as a Conditional Random Field (CRF) in which binary offsets and a number of selected idioms (patterns) appear in the CRF. Since standard inference methods for CRF on large, highly-connected graphs are expensive, Rosenblum et al. adopted feature selection and approximate inference to speed up their model. However, using hardware available in 2008, they needed 150 compute-days just for the feature selection phase on 1,171 binaries.

In this paper, we propose a new automated analysis for inferring functions and implemented it in our BYTEWEIGHT system. A key aspect of BYTEWEIGHT is the ability to learn signatures for new compilers and optimizations at least one order of magnitude faster than as reported by Rosenblum et al. [27], even after generously accounting for CPU speed increase since 2008. In particular, we avoid using CRFs and feature selection, and instead opt for a simpler model based on learning prefix trees. Our simpler model is scalable using current computing hardware: we finish training 2,064 binaries in under 587 compute-hours. BYTEWEIGHT also does not require compiler information of testing binaries, which makes the tool more powerful in practice. In the interest of open science, we also make our tools and datasets available to seed future improvements.

At a high level, we learn signatures for function starts using a weighted prefix tree, and recognize function starts by matching binary fragments with the signatures. Each node in the tree corresponds to either a byte or an instruction, with the path from the root node to any given node representing a possible sequence of bytes or instructions. The weights, which can be learned with a single linear pass over the data set, express the confidence that a sequence of bytes or instructions corresponds to a function start. After function start identification, we then use value set analysis (VSA) [2] with an incremental control flow recovery algorithm to find function bodies with instructions, and extract function boundaries.

To evaluate our techniques, we perform a large-scale experiment and provide empirical numbers on how well these tools work in practice. Based on 2,200 binaries across operating systems, compilers and optimization options, our results show that BYTEWEIGHT has a precision and recall of 97.30% and 97.44% respectively for function *start* identification. BYTEWEIGHT also has a precision and recall of 92.84% and 92.96% for function *boundary* identification. Our tool is adaptive for varying compilers and therefore more general than current pattern matching methods.

Contributions. This paper makes the following contributions:

- We enumerate the challenges we faced and implement a new function start identification algorithm based on prefix trees. Our approach is automatic and does not require a priori compiler information (see §4). Our approach models the function start identification problem in a novel way that makes it amenable to much faster learning algorithms.
- We evaluate our method on a large test suite across operating systems, compilers, and compiling optimizations. Our model achieves better accuracy than previously available tools.
- We make our test infrastructure, data set, implementation, and results public in an effort to promote open science (see §5).

(b) Assembly compiled by `gcc -O3`

Figure 1: Example C Code. IDA fails to identify functions `sum`, `sub`, and `assign` in the compiled binary.

2 Running Example

We start with a simple example written in C, shown in Figure 1. In this program, three functions are stored as function pointers in the array `funcs`. When the program is run, input from the user dictates which function gets called, as well as the function arguments. We compiled this example code on Linux Debian 7.2 x86-64 using `gcc` with `-O3`, and stripped the binary using the command `strip`. We then used IDA to disassemble the binary and perform function identification. Many security tools use IDA in this way as a first step before performing additional analysis [9, 20, 24]. Unfortunately, for our example program IDA failed to identify the functions `sum`, `sub`, and `assign`.

IDA's failure to identify these three critical functions has significant implications for security analyses that rely on accurate function boundary identification. Recall that the CFI security policy dictates that runtime execution must follow a path of the static control flow graph (CFG). In this case, when the CFG is recovered by first identifying functions using IDA, any call to `sum`, `sub`, or `assign` would be incorrectly disallowed, breaking legitimate program behavior. Indeed, any indirect jump to an unidentified or mis-identified function will be blocked by CFI. The greater the number of functions missed, the more legitimate software functionality incorrectly lost. Secondly, suppose we are checking code for potential security-critical bugs. In our sample program, the function `assign` is vulnerable to a buffer overflow attack, but is not identified by IDA as a function. For tools like ClearView [25] that operate on binaries at the function level, missing functions can mean missing vulnerabilities.

In our analysis of 1,171 binaries, we observed that that IDA failed to identify 266,672 functions. BYTEWEIGHT improves on this number, missing only 44,621. BYTEWEIGHT also makes fewer mistakes, incorrectly identifying functions 43,992 times compared to 459,247 with IDA. While these results are not perfect, they demonstrate that our automated machine learning approach can outperform years of manual hand-tuning that has gone into IDA.

3 Problem Definition and Challenges

The goal of function identification is to faithfully determine the set of functions that exist in binary code. Determining what functions exist and which bytes belong to which functions is trivial if debug information is present.

For example, "unstripped" Linux binaries contain a symbol table that maps function names to locations in a binary, and Microsoft program database (PDB) information contains similar information for Windows binaries. We start with notation to make our problem definition precise and then formally define three function identification problems. We then describe several challenges to any approach or algorithm that addresses the function identification problems. In subsequent sections we provide our approach.

3.1 Notation and Definitions

A binary program is divided into a number of sections. Each section is given a type, such as code, data, read-only data, and so on. In this paper we only consider executable code, which we treat as a binary string.

Let B denote a binary string. For concreteness, think of this as a binary string from the `.text` section in a Linux executable. Let $B[i]$ denote the i^{th} byte of a binary string, and $B[i:i+j]$ refer to the list of contiguous bytes $B[i], B[i+1], \ldots, B[i+j-1]$. Thus, $B[i:i+j]$ is j-bytes long (with $j \geq 0$).

Each byte in an executable is associated with an *address*. The address of byte i is calculated with respect to a fixed section offset, i.e., if the section offset is ω, the address of byte i is $i+\omega$. For convenience, we omit the offset, and refer to i as the i^{th} address. Since the real address can always be calculated by adding the fixed offset, this can be done without loss of generality.

A function F_i in a binary B is a list of addresses corresponding to statements in either a function from the original compiled language or a function introduced directly by the compiler, denoted as

$$F = \{B[i], B[j], \ldots, B[k]\}$$

Note that function bytes need not be a set of contiguous addresses. We elaborate in §3.3 on real optimizations that result in high-level functions being compiled to a set of non-contiguous intervals of instructions.

Towards our goal of determining which bytes of a binary belong to which functions, we define the *set of functions* in a binary

$$\mathbf{FUNCS}(B) = \{F_1, F_2, \ldots, F_k\}.$$

Note that functions may share bytes, i.e., it may be that $F_1 \cap F_2 \neq \emptyset$. We give examples in §3.3 where this is the case.

We call the lowest address of a function F_i the *function start* address s_i, i.e., $s_i = \min(F_i)$. The *function end* address e_i is the maximum byte in a function body, i.e., $e_i = \max(F_i)$. We define the *function boundary* (s_i, e_i) as the function start and end addresses for F_i.

In order to evaluate function identification algorithms, we define ground truth in terms of oracles, which may have a number of implementations:

Function Oracle. $\mathbf{O}_{\text{func}}$ is an oracle that, given a binary B, returns a list of functions $\mathbf{FUNCS}(B)$ where each F_i is a set of bytes representing higher-level function i, as defined above.

Boundary Oracle. $\mathbf{O}_{\text{bound}}$ is an oracle that, given B, returns the set of function boundaries $\{(s_1, e_1), (s_2, e_2), \ldots, (s_k, e_k)\}$.

Start Oracle. $\mathbf{O}_{\text{start}}$ is an oracle that, given B, returns the set of function start addresses $\{s_1, s_2, \ldots, s_k\}$.

These oracles are successively less powerful. For example, implementing a boundary oracle $\mathbf{O}_{\text{bound}}$ from a function oracle $\mathbf{O}_{\text{func}}$ requires simply taking the minimum and maximum element of each F_i. Similarly, a start oracle $\mathbf{O}_{\text{start}}$ can be implemented from either $\mathbf{O}_{\text{func}}$ or $\mathbf{O}_{\text{bound}}$ by finding the minimum element of each F_i.

We do not restrict ourselves to a specific oracle implementation, as realizable oracles may vary across operating system and compiler. For example, the boundary oracle can be implemented by retaining debug information for Windows or Linux binaries. The function oracle can be implemented by instrumenting a compiler to output a list of instruction addresses included in each compiled function.

3.2 Problem Definition

With the above definitions, we are now ready to state our problem definitions. We start with the least powerful identification (function start) and build up to the most difficult one (entire function).

Definition 3.1. The *Function Start Identification* (FSI) problem is to output the complete list of function starts $\{s_1, s_2, \ldots, s_k\}$ given a binary B compiled from a source with k functions.

Suppose there is an algorithm $\mathscr{A}_{\mathsf{FSI}}(B)$ for the FSI problem which outputs $S = \{s_1, s_2, \ldots, s_k\}$. Then:

- The set of true positives, TP, is $S \cap \mathbf{O}_{\text{start}}(B)$.
- The set of false positives, FP, is $S - \mathbf{O}_{\text{start}}(B)$.
- The set of false negatives, FN, is $\mathbf{O}_{\text{start}}(B) - S$.

We also define precision and recall. Roughly speaking, precision reflects the number of times an identified function start is really a function start. A high precision means that most identified functions are indeed functions, whereas a low precision means that some sequences are incorrectly identified as functions. Recall is the measurement describing how many functions were identified within a binary. A high recall means an algorithm detected most functions, whereas a low recall means most functions were missed. Mathematically, they can be expressed as

$$\text{Precision} = \frac{|\text{TP}|}{|\text{TP}| + |\text{FP}|}$$

and

$$\text{Recall} = \frac{|\text{TP}|}{|\text{TP}| + |\text{FN}|}.$$

A more difficult problem is to identify both the start *and* end addresses for a function:

Definition 3.2. The *Function Boundary Identification* (FBI) problem is to identify the start and end bytes (s_i, e_i) for each function i in a binary, i.e., $S = \{(s_1, e_1), (s_2, e_2), \ldots, (s_k, e_k)\}$, given a binary B compiled from a source with k identified functions.

Suppose there is an algorithm $\mathscr{A}_{\text{FBI}}(B)$ for the FBI problem which outputs $S = \{(s_1, e_1), (s_2, e_2), \ldots, (s_k, e_k)\}$. We then define true positives, false positives, and false negatives similarly to above with the additional requirement that *both* the start and end addresses must match the output of the boundary oracle, i.e., for oracle output (s_{gt}, e_{gt}) and algorithm output $(s_{\mathscr{A}}, e_{\mathscr{A}})$, a positive match requires $s_{gt} = s_{\mathscr{A}}$ *and* $e_{gt} = e_{\mathscr{A}}$. A false negative occurs if either the start or end address is wrong. Precision and recall are defined analogously to the FSI problem.

Finally, we define the general function identification problem:

Definition 3.3. The *Function Identification* (FI) problem is to output a set $\{F_1, F_2, \ldots, F_k\}$ where each F_i is a list of bytes corresponding to high-level function i given a binary B with k identified functions.

We define true positives, false positives, false negatives, precision, and recall for the FI problem in the same ways as FSI and FBI but add the requirement that all bytes of a function must be matched between agorithm and oracle.

The above problem definitions form a natural hierarchy, where function start identification is the easiest and full function identification is the most difficult. For example, an algorithm $\mathscr{A}_{\text{FBI}}$ for function boundaries can solve the function start problem by returning the start element of each tuple. Similarly, an algorithm for the function identification problem needs only return the maximum and minimum element to solve the function boundary identification problem.

3.3 Challenges

Identifying functions in binary code is made difficult by optimizing compilers, which can manipulate functions in unexpected ways. In this section we highlight several challenges posed by the behavior of optimizing compilers.

Not every byte belongs to a function. Compilers may introduce extra instructions for alignment and padding between or within a function. This means that not every instruction or byte must belong to a function. For example, suppose we have symbol table information for a binary B. One naive algorithm is to first sort symbol-table entries by address, and then ascribe each byte between entry f_i and f_{i+1} as belonging to function f_i. This algorithm has appeared in several binary analysis platforms used in security research, such as versions of BAP [3] and BitBlaze [6]. This heuristic is flawed, however. For example, in Figure 2 lines 7–8 are not owned by any function.

```
1    <_func1>:
2    100000e20:   push   %rbp
3    100000e21:   mov    %rsp,%rbp
4    100000e24:   lea    0x69(%rip),%rdi
5    100000e2b:   pop    %rbp
6    100000e2c:   jmpq   100000e5e <_puts$stub>
7    100000e31:   nopl   0x0(%rax)
8    100000e38:   nopl   0x0(%rax,%rax,1)
9    <func2>:
```

Figure 2: Unreachable function example: source code and assembly.

Functions may be non-contiguous. Functions may have gaps. The gaps can be jump tables, data, or even instructions for completely different functions [26]. As noted by Harris and Miller [19], function sharing code can also lead to non-contiguous functions. Figure 3 shows code that starts out with the function `ConvertDefaultLocale`. Midway through the function at lines 17–21, however, the compiler decided to include a few lines of code for `FindNextFileW` as an optimization. Many binary analysis platforms, such as BAP [3] and BitBlaze [6], are not able to handle non-contiguous functions.

Functions may not be reachable. A function may be dead code and never called, but nonetheless appear in the binary. Recognizing such functions is still important in many security scenarios. For example, suppose two malware samples both contain a unique, identifying, yet uncalled function. Then the two malware samples are likely related even though the function is never called. One consequence of this is that techniques based solely on recursive disassembling from program start are not well-suited to solve the function identification problem. A recursive disassembler only disassembles bytes that occur along some control flow path, and thus by definition will miss functions that are not called.

Unreachability may occur for several reasons, including compiler optimizations. For example, Figure 4 shows a function for computing factorials called `fac`. When compiled by `gcc -O3`, the result of the call to `fac` is precomputed and inlined. Although the code of `fac` appears, it is never called in the binary code.

Security policies such as CFI and XFI must be aware of all low-level functions, not just those in the original code.

```
1   <ConvertDefaultLocale>
2     7c8383ff:   mov    %edi,%edi
3     7c838401:   push   %ebp
4     ...
5     7c83840c:   jz     7c848556
6     7c838412:   test   %eax, %eax
7     7c838414:   jz     7c83965c
8     7c83841a:   mov    $1024,%ecx
9     7c83841f:   cmp    %ecx,%eax
10    7c838421:   jz     7c83965c
11    7c838427:   test   $252,%ah
12    7c83842a:   jnz    7c838442
13    7c83842c:   mov    %eax,%edx
14    ...
15    7c838442:   pop    %ebp
16    7c838443:   ret    4
17    ; chunk of different function FindNextFileW
18    7c838446:   push   6
19    7c838448:   call   sub_7c80935e
20    7c83844d:
21    ; end of chunk
22    ...
23    7c83965c:   call   GetUserDefaultLCID
24    7c890661:   jmp    7c838442
25    ...
26    7c848556:   mov    $8,%eax
27    7c84855b:   jmp    7c838442
```

Figure 3: Lines 17–21 show code from `FindNextFileW` included in the middle of `ConvertDefaultLocale`.

Functions may have multiple entries. High-level languages use functions as an abstraction with a single entry. When compiled, however, functions may have multiple entries as a result of specialization. For example, the `icc` compiler with `-O1` specialized the `chown_failure_ok` function in GNU LIBC. As shown in Figure 5, a new function entry `chown_failure_ok.` (note the period) is added for use when invoking `chown_failure_ok` with `NULL`. The compiled binary has both symbol table entries. Unlike shared code for two functions that were originally separate, the compiler here has introduced shared code via multiple entries as an optimization.

Identifying both functions is necessary in many security scenarios, e.g., CFI needs to identify each function entry point for safety, and realize that both are possible targets. More generally, any binary rewriting for protection (e.g., memory safety, control safety, etc.) would need to reason about both entry points.

Functions may be removed. Functions can be removed by function inlining, especially small functions. Compilers perform function-inlining to reduce function call overhead and expose more optimization opportunities. For example, the function `utimens_symlink` is inlined into the function `copy_internal` when compiled by `gcc` with `-O2`. The source code and assembly code are shown in Figure 6. Note that function inlining does not have to be explicitly declared with `inline` annotation in source code. Many compilers inline functions by default unless explicitly disabled with options such as `-fno-deault-inline` [17]. This indicates that for those binary analysis techniques which need function information, even though source code is accessible, a robust function identification technique should still operate on the program binary. If using source code, function identification may be less precise due to functions that are inlined during compilation.

Each compilation is different. Binary code is not only heavily influenced by the compiler but also the compiler version and specific optimizations employed. For example, `icc` does not pre-compute the result of `fac` in Figure 4, but `gcc` does. Even different versions of a compiler may change code. For example, traditionally `gcc` (e.g., version 3) would only omit the use of the frame pointer register `%ebp` when given the `-fomit-frame-pointer` option. Recent versions of `gcc` (such as version 4.2), however, opportunistically omit the frame pointer when compiled with `-O1` and `-O2`. As a result several tools that identified functions by scanning for `push %ebp` break. For example, Dyninst, used for instrumentation in several security projects, relies on this heuristic to identify functions and breaks on recent versions of `gcc`.

4 BYTEWEIGHT

In this section, we detail the design and algorithms used by BYTEWEIGHT to solve the function identification problems. We first start with the FSI problem, and then move to the more general function identification problem.

We cast FSI as a machine learning classification problem where the goal is to label each byte of a binary as either a function start or not. We use machine learning to automatically generate literal patterns so that BYTEWEIGHT can handle new compilers and new optimizations without relying on manually generated patterns or heuristics. Our algorithm works with both byte sequences and disassembled instruction sequences.

Our overall system is shown in Figure 7. Like any classification problem, we have a training phase followed by a classification phase. During training, we first compile a reference corpus of source code to produce binaries where the start addresses are known. At a high level, our algorithm creates a weighted prefix tree of known function start byte or instruction sequences. We *weight* vertices in the prefix tree by computing the ratio of true positives to the sum of true and false positives for each sequence in the reference data set. We have designed and implemented two variations of BYTEWEIGHT: one working with raw bytes and one with normalized disassembled instructions. Both use the same overall algorithm and data structures. We show in our evaluation that the normalization approach provides higher precision and recall, and costs less time (experiment 5.2).

In the classification phase, we use the weighted prefix tree to determine whether a given sequence of bytes or

```
1       int fac(int x)
2       {
3         if (x == 1) return 1;
4         else return x * fac(x - 1);
5       }
6
7       void main(int argc, char **argv)
8       {
9         printf("%d", fac(10));
10      }
```

(a) Source code

```
1       080483f0 <fac>:
2       ...
3       08048410 <main>:
4       ...
5       movl   $0x375f00,0x4(%esp)
6       movl   $0x8048510,(%esp)
7       call   8048300  ;call printf without fac
8       xor    %eax,%eax
9       add    $0x8,%esp
10      pop    %ebp
11      ret
```

Figure 5: `chown_failure_ok` is specialized: source code and assembly.

instructions corresponds to a function start. We say that a sequence corresponds to a function start if the corresponding *terminal node* in the prefix tree has a weight value larger than the threshold t. In the case where the sequence exactly matches a path in the prefix tree, the terminal node is the final node in this path. If the sequence does not exactly match a path in the tree, the terminal node is the last matched node in the sequence.

Once we identify function starts, we infer the remaining bytes (and instructions) that belong to a function using a CFG recovery algorithm. The algorithm incrementally determines the CFG using a variant of VSA [2]. If an indirect jump depends on the value of a register, then we over-approximate a solution to the function identification problem by adding edges that correspond to locations approximated using VSA.

4.1 Learning Phase

The input to the learning phase is a corpus of training binaries $\mathbb{T}$, and a maximum sequence length $\ell > 0$. ℓ serves as a bound on the maximum tree height.

In BYTEWEIGHT, we first generate the oracle $\mathbf{O}_{\text{bound}}$ by compiling known source using a variety of optimization levels while retaining debug information. The debug information gives us the required (s_i, e_i) pair for each function i in the binary.

In this paper, we consider two possibilities: learning over raw bytes and learning over normalized instructions. We refer to both raw bytes and instructions as a sequence of elements. The sequence length ℓ determines how many raw sequential bytes or instructions we consider for training.

Step 1: Extract first ℓ elements for each function (Extraction). In the first step, we iterate over all (s_i, e_i) pairs and extract the first ℓ elements. If there are fewer than ℓ elements in the function, we extract the maximum number of elements. For raw bytes, this is $B[s : s+\ell]$ bytes, and for instructions, it is the first ℓ instructions disassembled linearly starting from $B[s]$.

Step 2: Generate a prefix tree (Tree Generation). In step 2, we generate a *prefix tree* from the extracted sequences to represent all possible function start sequences up to ℓ elements.

A prefix tree, also called a trie, is a data structure enabling efficient information retrieval. In the tree, each non-root node has an associated byte or instruction. The sequence for a node n is represented by the elements that appear on the path from the root to n. Note that the tree represents all strings up to ℓ elements, not just exactly ℓ elements.

Figure 8a shows an example tree on instructions, where node `callq 0x43a28` represents the instruction sequence:

```
push   %ebp            ;saved stack pointer
mov    %esp,%ebp       ;establish new frame
callq  0x43a28         ;call another function
```

If the sequence is over bytes, the prefix tree is calculated directly, although our experiments indicate that a prefix tree calculated over normalized instructions fairs

```
1   static inline int
2   utimens_symlink (char const *file,
3                    struct timespec const *timespec)
4   {
5     int err = lutimens (file, timespec);
6     if (err && errno == ENOSYS)
7       err = 0;
8     return err;
9   }
10
11  static bool
12  copy_internal (char const *src_name,
13                 char const *dst_name,
14                 ...)
15  {
16    ...
17    if ((dest_is_symlink
18         ?utimens_symlink (dst_name,
19                           timespec)
20         :utimens (dst_name, timespec))
21         != 0)
22    ...
23  }
```

(a) Source Code

```
1   <_copy_internal>:
2   100003170:      push   %rbp
3   100003171:      mov    %rsp,%rbp
4   100003174:      push   %r15
5   100003176:      push   %r14
6   ...
7   10000468c:      test   %r14b,%r14b
8   10000468f:      je     100005bfd
9   100004695:      lea    -0x738(%rbp),%rsi
10  10000469c:      mov    -0x750(%rbp),%rdi
11  1000046a3:      callq  10000d020 <_lutimens>
12  1000046a8:      test   %eax,%eax
13  1000046aa:      mov    %eax,%ebx
14  ...
```

(b) Assembly compiled by `gcc -O2`

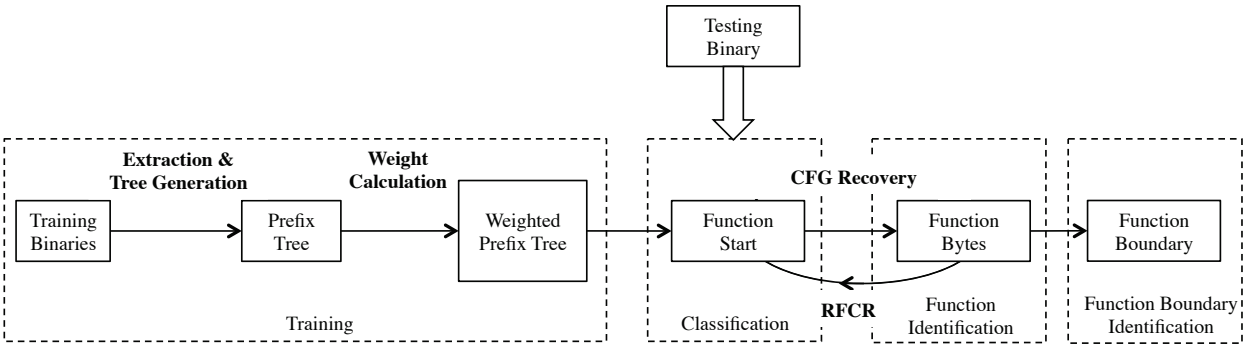

Figure 7: The BYTEWEIGHT function boundary inference approach.

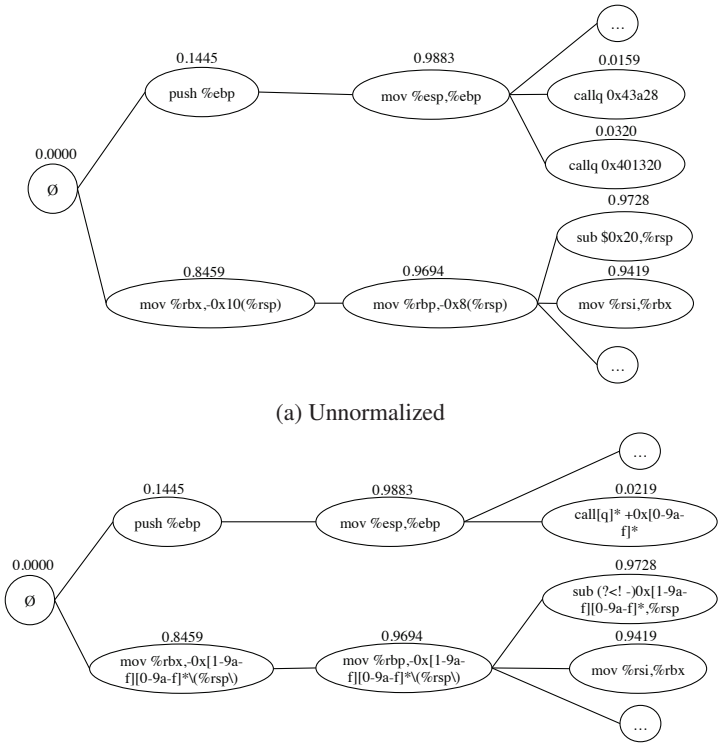
better. We perform two types of normalization: immediate number normalization and call & jump instruction normalization. As shown in Table 1, normalization takes an instruction as input and generalizes it so that it can match against very similar, but not identical instructions. These two types of normalization help us improve recall at the cost of a little precision (Table 2). In our running example, only the function `assign` is recognized as a function start when matched against the unnormalized prefix tree (Figure 8a), while functions `assign`, `sub`, and `sum` can all be recognized when matched against the normalized prefix tree (Figure 8b).

Step 3: Calculate tree weights (Weight Calculation). The prefix tree represents possible function start sequences up to ℓ elements. For each node, we assign a weight that represents the likelihood that the sequence corresponding to the path from the root node to this node is a function start in the training set. For example, according to Figure 8, the weight of node `push %ebp` is 0.1445, which means that during training, 14.45% of all sequences with prefix of `push %ebp` were truly function starts, while 85.55% were not.

To calculate the weight, we first count the number of occurrences $\mathbb{T}_+$ in which each prefix in the tree matches a true function start with respect to the ground truth $\mathbf{O}_{\text{start}}$ for the entire training set $\mathbb{T}$.

Second, we lower the weight of a prefix if it occurs in a binary, but is not a function start. We do this by performing an exhaustive disassembly starting from every address that is *not* a function start [23]. We match each exhaustive disassembly sequence of ℓ elements against the tree. We call these *false matches*. The number of false matches $\mathbb{T}_-$ is the number of times a prefix represented



(a) Unnormalized

(b) Normalized

Figure 8: Example of unnormalized (a) and normalized (b) prefix tree. Weight is shown above its corresponding node.

in the tree is not a function start in the training set $\mathbb{T}$. The weight for each node n is then the ratio of true positives to overall matches

$$W_n = \frac{\mathbb{T}_+}{\mathbb{T}_+ + \mathbb{T}_-}. \quad (1)$$

Since the prefix tree can end up being quite large, it is beneficial to prune the tree of unnecessary nodes. For each node in the tree, we remove all its child nodes if the value of $\mathbb{T}_-$ for this node is 0. For any child node, the value of $\mathbb{T}_-$ is never negative and never larger than the value of $\mathbb{T}_-$ for the parent node. Hence, if $\mathbb{T}_-$ is 0 for a parent node, then the value must be 0 for all of the child nodes as well. The intuition here is that if a child node matches a sequence that is not a function start, then so must the parent node. Thus, if the parent node does not have any false matches, then neither can a child node. Based on Equation 1, if $\mathbb{T}_- = 0$ and $\mathbb{T}_+ > 0$, then the weight of the node is 1. Since the child nodes of such a node also have a $\mathbb{T}_-$ value of 0 and are not included in the tree if $\mathbb{T}_+ = 0$, they must also have a weight of 1. As discussed more in Section 4.2, child nodes with identical weights are redundant and can safely be removed without affecting classification.

This pruning optimization helps us greatly reduce the space needed by the tree. For example, pruning reduced the number of nodes in the prefix tree from 2,483 to 1,447 for our Windows x86 dataset. Moreover, pruning increases the speed of matching, since we can determine the weight of test sequences after traversing fewer nodes in the tree.

4.2 Classification Phase Using a Weighted Prefix Tree

The output of the learning phase is a weighted prefix tree (e.g., Figure 8). The input to the classification step is a binary B, the weighted prefix tree, and a weight threshold t.

To classify instructions, we perform exhaustive disassembly of the input binary B and match against the tree. Matching is done by tokenizing the disassembled stream, performing normalization as done during learning, and walking the tree. To classify bytes rather than instructions, we again start at every offset but instead match the raw bytes instead of normalized instructions.

The weight of a sequence is determined by last matching node (the *terminal* node) during the walk. For example, given the tree in Figure 8a, and our running example with sequences

```
mov    %rbx,-0x10(%rsp)
mov    %rbp,-0x8(%rsp)
sub    %0x28,%rsp
```

Type		Unnormalized Signature	Normalized Signature
Immediate	all	`mov $0xaa,%eax`	`mov \$-*0x[0-9a-f]+,%eax`
		`mov %gs:0x0,%eax`	`mov %gs:-*0x[0-9a-f]+,%eax`
		`mov 0x80502c0,%eax`	`mov -*0x[0-9a-f]+,%eax`
	zero	`mov $0xaa,%eax`	`mov \$-*0x[1-9a-f][0-9a-f]*,%eax`
		`mov %gs:0x0,%eax`	`mov %gs:0x0+,%eax`
		`mov 0x80502c0,%eax`	`mov -*0x[1-9a-f][0-9a-f]*,%eax`
	positive	`mov $0xaa,%eax`	`mov \$(?<! -)0x[1-9a-f][0-9a-f]*,%eax`
		`mov %gs:0x0,%eax`	`mov %gs:-0x[0-9a-f]+|0x0+,%eax`
		`mov 0x80502c0,%eax`	`mov (?<! -)0x[1-9a-f][0-9a-f]*,%eax`
	negative	`mov $0xaa,%eax`	`mov \$(?<! -)0x[0-9a-f]+,%eax`
		`mov %gs:0x0,%eax`	`mov %gs:(?<! -)0x[0-9a-f]+,%eax`
		`mov 0x80502c0,%eax`	`mov (?<! -)0x[0-9a-f]+,%eax`
		`movzwl -0x6c(%ebp),%eax`	`movzl -0x[1-9a-f][0-9a-f]*\(%ebp\),%eax`
	npz	`mov $0xaa,%eax`	`mov \$(?<! -)0x[1-9a-f][0-9a-f]*,%eax`
		`mov %gs:0x0,%eax`	`mov %gs:0x0+,%eax`
		`mov 0x80502c0,%eax`	`mov (?<! -)0x[1-9a-f][0-9a-f]*,%eax`
		`movzwl -0x6c(%ebp),%eax`	`movzl -0x[1-9a-f][0-9a-f]*\(%ebp\),%eax`
Call & Jump		`call 0x804cf32`	`call[q]* +0x[0-9a-f]*`

For immediate normalization, we generalize immediate operands. There are five kinds of generalization: all, zero, positive, negative, and npz. For jump and call instruction normalization, we generalize callee and jump addresses.

Table 1: Normalizations in signature.

the matching node will be `mov%rbp,-0x8(%rsp)`, giving a weight of 0.9694. However, for another sequence

```
push   %ebp
and    $0x2,%esp
```

we would have weight 0.1445. We say the sequence is the beginning of a function if the output weight w is not less than the threshold t.

4.3 The Function Identification Problem

At a high level, we address the function identification problem by first determining the start addresses for functions, and then performing static analysis to recover the CFG of instructions that are reachable from the start. Direct control transfers (e.g., direct jumps and calls) are followed using recursive disassembly. Indirect control transfers, e.g., from indirect calls or jump tables, are enumerated using VSA [2]. The final CFG then represents all instructions (and corresponding bytes) that are owned by the function starting at the given address.

CFG recovery starts at a given address and recursively finds new nodes that are connected to found nodes. The process ends when no more vertices are added into graph. Starting at the addresses classified for FSI, CFG recovery recursively adds instructions that are reachable from these starts. A first-in-first-out vertex array is maintained during CFG recovery.

At the beginning, there is only one element – the start address in the array. In each round, we process the first element by exploring new reachable instructions. If the new instruction is not in the array, it will be appended to the end. Elements in the array are handled accordingly until all elements have been processed and no more instructions are added.

If the instruction being processed is a branch mnemonic, the reachable instruction is the branch reference. If it is a call mnemonic, the reachable instructions include both the call reference and the instruction directly following the call instruction. If it is an exit instruction, there will be no new instruction. For the rest of mnemonics, the new instruction is the next one by address. We handle indirect control transfer instruction by VSA: we infer a set that over-approximates the destination of the indirect jump and thus over-approximate the function identification problem.

Note that functions can exit by calling a no-return function such as `exit`. This means that some call instructions in fact never return. To detect these instances, we check the call reference to see if it represents a known no-return function such as `abort` or `exit`.

4.4 Recursive Function Call Resolution

Pattern matching can miss functions; for example, a function that is written directly in assembly may not obey calling conventions. To catch these kinds of missed functions, we continue to supplement the function start list during CFG recovery. If a call instruction has its callee in

the `.text` section, we consider the callee to be a function start. We then do CFG recovery again, starting at the new function start until there are no more functions added into the function start list. We will refer to this strategy as recursive function call resolution (RFCR). In §5.3, we discuss the effectiveness of this technique in function start identification.

4.5 Addressing Challenges

In this section, we describe how BYTEWEIGHT addresses the challenges raised in §3.3.

First, BYTEWEIGHT recovers functions that are unreachable via calls because it does not depend on calls to identify functions. In particular, BYTEWEIGHT recovers any function start that matches the learned weighted prefix tree as described above. Similarly, our approach will also learn functions that have multiple entries, provided a similar specialization occurs in the training set. This seems realistic in many scenarios since the number of compiler optimizations that create multiple entry functions are relatively few and can be enumerated during training.

BYTEWEIGHT also deals with overlapping byte or instruction sequences provided that there is a unique start address. Consider two functions that start at different addresses, but contain the same bytes. During CFG recovery, BYTEWEIGHT will discover that both functions use the same bytes, and attribute the bytes to both functions. BYTEWEIGHT can successfully avoid false identification for inlined functions when inlined function does not behave like an empirical function start (does not weighted over threshold in training).

Finally, note that BYTEWEIGHT does not need to attribute every byte or instruction to a function. In particular, only bytes (or instructions) that are reachable from the recovered function entries will be owned by a function in the final output.

5 Evaluation

In this section, we discuss our experiments and performance. BYTEWEIGHT is a cross-platform tool which can be run on both Linux and Windows. We used BAP [3] to construct CFGs. The rest of the implementation consists of 1988 lines of OCaml code and 222 lines of shell code. We set up BYTEWEIGHT on one desktop machine with a quad-core 3.5GHz i7-3770K CPU and 16GB RAM. Our experiments aimed to address three questions:

1. Does BYTEWEIGHT's pattern matching model perform better than known models for function start identification? (§5.2)
2. Does BYTEWEIGHT perform function start identification better than existing binary analysis tools? (§5.3)
3. Does BYTEWEIGHT perform function boundary identification better than existing binary analysis tools? (§5.4)

In this section, we first describe our data set and ground truth (the oracle), then describe the results of our experiments. We performed three experiments answering the above three questions. In each experiment, we compared BYTEWEIGHT against existing tools in terms of both accuracy and speed.

Because BYTEWEIGHT needs training, we divided the data into training and testing sets. We used standard 10-fold validation, dividing the element set into 10 sub-sets, applying 1 of the 10 on testing, and using the remaining 9 for training. The overall precision and recall represent the average of each test.

5.1 Data Set and Ground Truth

Our data set consisted of 2,200 different binaries compiled with four variables:

Operating System. Our evaluation used both Linux and Windows binaries.

Instruction Set Architecture (ISA). Our binaries consisted of both x86 and x86-64 binaries. One reason for varying the ISA is that the calling convention is different, e.g., parameters are passed by default on the stack in Linux on x86, but in registers on x86-64.

Compiler. We used GNU `gcc`, Intel `icc`, and Microsoft `VS`.

Optimization Level. We experimented with the four optimization levels from no optimization to full optimization.

On Linux, our data set consisted of 2,064 binaries in total. The data set contained programs from `coreutils`, `binutils`, and `findutils` compiled with both `gcc` 4.7.2 and `icc` 14.0.1. On Windows, we used `VS` 2010, `VS` 2012, and `VS` 2013 (depending on the requirements of the program) to compile 68 binaries for x86 and x86-64 each. These binaries came from popular open-source projects: putty, 7zip, vim, libsodium, libetpan, HID API, and pbc (a library for protocol buffers). Note that because Microsoft Symbol Server releases only public symbols which do not contain information of private functions, we were unable to use Microsoft Symbol Server for ground truth and include Windows system applications in our experiment.

We obtained ground truth for function boundaries from the symbol table and PDB file for Linux and Windows binaries, respectively. We used `objdump` to parse symbol tables, and `Dia2dump` [13] to parse PDB files. Additionally, we extracted "thunk" addresses from PDB files. While most tools do not take thunks into account, IDA considers thunks in Windows binaries to be special functions. To get a fair result, we filtered out thunks from IDA's output using the list of thunks extracted from PDB files.

5.2 Signature Matching Model

Our first experiment evaluated the signature matching model for function start identification. We compared BYTEWEIGHT and Rosenblum et al.'s implementation in terms of both accuracy and speed. In order to equally evaluate the signature matching models, recursive function call resolution was not used in this experiment.

The implementation of Rosenblum et al. is available as a matching tool with 12 hard-coded signatures for `gcc` and 41 hard-coded signatures for `icc`. Their learning code was not available, nor was their dataset. Although they evaluated `VS` in their paper, the version of the implementation that we had did not support `VS` and was limited to x86. Each signature has a weight, which is also hard-coded. After calculating the probability for each sequence match, it uses a threshold of 0.5 to filter out function starts. Taking a binary and a compiler name (`gcc` or `icc`), it generates a list of function start addresses. To adapt to their requirements, we divide Linux x86 binaries into two groups by compiler, where each group consists of 516 binaries. We did 10-fold cross validation for BYTEWEIGHT, and use the same threshold as Rosenblum et al.'s implementation.

We also evaluated another two varieties of our model: one without normalization, and one with a maximum tree height of 3, which is same as the model used by Rosenblum et al. and BYTEWEIGHT (3), respectively.

Table 2 shows precision, recall, and runtime for each compiler and each function start identification model. From the table we can see that Rosenblum et al.'s implementation had an accuracy below 70%, while both BYTEWEIGHT-series models achieved an accuracy of more than 85%. Note that BYTEWEIGHT with 10-length and normalized signatures (the last row in table) performed particularly well, with an accuracy of approximately 97%, a more than 35% improvement over Rosenblum et al.'s implementation.

Table 2 also details the accuracy and performance differences among BYTEWEIGHT with different configurations. Comparing against the full configuration model (BYTEWEIGHT), the model with a smaller maximum signature length (BYTEWEIGHT (3)) performs slightly faster (3% improvement), but sacrifices 7% in accuracy. The model without signature normalization (BYTEWEIGHT (no-norm)) has only 1% higher precision but 6.68% lower recall, and the testing time is ten times longer than that of the normalized model.

5.3 Function Start Identification

The second experiment evaluated our full function start identification against existing static analysis tools. We compared BYTEWEIGHT (no-RFCR)—a version without recursive function call resolution, BYTEWEIGHT, and the following tools:

IDA. We used IDA 6.5, build 140116 along with the default FLIRT signatures. All function identification options were enabled.

BAP. We used BAP 0.7, which provides a `get_function` utility that can be invoked directly.

Dyninst. Dyninst offers the tool *unstrip* [31] to identify functions in binaries without debug information.

Naive Method. This matched simple `0x55` (`push %ebp` or `push %rbp`) and `0xc3` (`ret` or `retq`) signatures only.

We divided our data set into four categories: ELF x86, ELF x86-64, PE x86, and PE x86-64. Unlike the previous experiment, binaries from various compilers but the same target were grouped together. Overall, we had 1032 ELF x86 and ELF x86-64 binaries, and 68 PE x86 and PE x86-64 binaries. We evaluated these categories separately, and again applied 10-fold validation. During testing, we used the same score threshold $t = 0.5$ as in the first experiment.

Note that not every tool in our experiment supports all binary targets. For example, Dyninst does not support ELF x86-64, PE x86, or PE x86-64 binaries. We use "-" to indicate when the target is not supported by the tool. Also, we omitted 3 failures in BYTEWEIGHT, and 10 failures in Dyninst during this experiment. Due to a bug in BAP, BYTEWEIGHT failed in 3 `icc` compiled ELF x86-64 binaries: *ranlib* with `-O3`, *ld_new* with `-O2`, and *ld_new* with `-O3`. Dyninst failed in 8 `icc` compiled ELF x86-64 binaries and 2 `gcc` compiled ELF x86-64 binaries. The results of our experiment are shown in Table 3.

As evident in Table 3, BYTEWEIGHT achieved a higher precision and recall than BYTEWEIGHT without recursive function call resolution. BYTEWEIGHT performed above 96% in Linux, while all other tools all performed below 90%. In Windows, we have comparable performance to IDA in terms of precision, but improved results in terms of recall.

Interestingly, we found that the naive method was not able to identify any functions in PE x86-64. This is mainly because `VS` does not use `push %rbp` to begin a function; instead, it uses move instructions.

5.4 Function Boundary Identification

The third experiment evaluated our function boundary identification against existing static analysis tools. As in the last experiment, we compared BYTEWEIGHT, BYTEWEIGHT (no-RFCR), IDA, BAP, and Dyninst, classified binaries by their target, and applied 10-fold validation on each of the classes. The results of our experiment are shown in Table 4.

Our tool performed the best in Linux, and was comparable to IDA in Windows. In particular, for Linux binaries, BYTEWEIGHT and BYTEWEIGHT (no-RFCR) have both precision and recall above 90%, while IDA is below 73%.

	GCC			ICC		
	Precision	Recall	Time(sec)	Precision	Recall	Time(sec)
Rosenblum et al.	0.4909	0.4312	1172.41	0.6080	0.6749	2178.14
BYTEWEIGHT (3)	0.9103	0.8711	1417.51	0.8948	0.8592	1905.34

For Windows binaries, IDA achieves better results than BYTEWEIGHT with x86-64 binaries, but is slightly worse for x86 binaries.

5.5 Performance

Training. We compare BYTEWEIGHT against Rosenblum et al.'s work in terms of time required for training. Since we do not have access to either their training code or their training data, we instead compare the results based on the performance reported in paper. There are two main steps in Rosenblum et al.'s work. First, they conduct feature selection to determine the most informative idioms – patterns that either immediately precede a function start, or immediately follow a function start. Second, they train parameters of these idioms using a logistic regression model. While they did not provide the time for parameter learning, they did describe that feature selection required 150 compute *days* for 1,171 binaries. Our tool, however, spent only 586.44 compute *hours* to train on 2,064 binaries, including overhead required to setup cross-validation.

Testing. We list the performance of BYTEWEIGHT, IDA, BAP, and Dyninst for testing. As described in section 4, BYTEWEIGHT has three steps in testing: function start identification by pattern matching, function boundary identification by CFG and VSA, and recursive function call resolution (RFCR). We report our time performance separately, as shown in Table 5.

IDA is clearly the fastest tool for PE files. For ELF binaries, it takes a similar amount of time to use IDA and BYTEWEIGHT to identify function starts, however our measured times for IDA also include the time required to run other automatic analyses. BAP and Dyninst have better performance on ELF x86 binaries, mainly because they match fewer patterns than BYTEWEIGHT and do not normalize instructions. This table also shows that function boundary identification and recursive function call resolution are expensive to compute. This is mainly because we use VSA to resolve indirect calls during CFG recovery, which costs more than typical CFG recovery by recursive disassembly. Thus while BYTEWEIGHT with RFCR enabled has improved recall, it is also considerably slower.

6 Discussion

Recall that our tool considers a sequence of bytes or instructions to be a function start if the weight of the corresponding terminal node in the learned prefix tree is greater than 0.5. The choice to use 0.5 as the threshold was largely dictated by Rosenblum et al., who also used 0.5 as a threshold in their implementation. While this appears to be a good choice for achieving high precision and recall in our system, it is not necessarily the optimal value. In the future, we plan to experiment with different thresholds to better understand how this affects the accuracy of BYTEWEIGHT.

While there are similarities betwen Rosenblum et al.'s approach and ours, there are also several key differences that are worth highlighting:

- Rosenblum et al. considered sequences of bytes or instructions immediately preceding functions, called prefix idioms, as well the entry idioms that start a function. Our present model does not include prefix idioms. Rosenblumet al.'s experiments show prefix

Table 5: Performance for different function identification tools (in seconds).

idioms increase accuracy in their model. In the future, we plan to investigate whether adding prefix matching to our model can increase its accuracy as well.

- Rosenblum et al.'s idioms are limited to at most 4 instructions [27, p. 800] due to scalability issues with forward feature selection. With our prefix tree model, we can comfortably handle longer instruction sequences. At present, we settle on a length of 10. In the future, we plan to optimize the length to strike a balance between training speed and recognition accuracy.
- Rosenblum et al.'s CRF model considers both positive and negative features. For example, their algorithm is designed to avoid identifying two function starts where the second function begins within the first instruction of the first function (the so-called "overlapping disassembly"). Although we consider both positive and negative features as well, in constrast the above outcome is feasible with our algorithm.

While our technique is not compiler-specific, it is based on supervised learning. As such, obtaining representative training data is key to achieving good results with BYTEWEIGHT. Since compilers and optimizations do change over time, BYTEWEIGHT may need to be retrained in order to accurately identify functions in this new environment. Of course, the need for retraining is a common requirement for every system based on supervised learning. This is applicable to both BYTEWEIGHT and Rosenblum et al.'s work, and underscores the importance of having a computationally efficient training phase.

Despite our tool's success, there is still room for improvement. As shown in Section 5, over 80% of BYTEWEIGHT failures are due to the misclassification of the end instruction for a function, among which more than half are functions that do not return and functions that call such no-return functions. To mitigate this, we could backward propagate information about functions that do not return to the functions that call them. For example, if function `f` always calls function `g`, and `g` is identified as a no-return function, then `f` should also be considered a no-return function. We could also use other abstract domains along with the strided intervals of VSA to increase the precision of our indirect jump analysis [2], which can in turn help us identify more functions more accurately.

One other scenario where BYTEWEIGHT currently struggles is with Windows binaries compiled with hot patching enabled. With such binaries, functions will start with an extra `mov %edi,%edi` instruction, which is effectively a 2-byte `nop`. A training set that includes binaries with hot patching can reduce the accuracy of BYTEWEIGHT. Because the extra instruction `mov %edi,%edi` is treated as the function start in binaries with hot patching, any subsequent instructions are treated as false matches. Thus, any sequence of instructions that would normally constitute a function start but now follows a `mov %edi,%edi` is considered to be a false match. Consider a hypothetical dataset where all functions start with `push %ebp; mov %esp,%ebp`, but half of the binaries

are compiled with hot patching and thus start functions with an extra `mov %edi,%edi`. Half of the time, the sequence `push %ebp; mov %esp,%ebp` will be treated as a function start, but in the other half it will not be treated as such, thus leaving the sequence with a weight of 0.5 in our prefix tree. In order to deal with this compiler peculiarity, we would need give special consideration to `mov %edi,%edi`, treating both this instruction and the instruction following it as a function start for the sake of training.

Although training BYTEWEIGHT for function start identification is relatively fast, training for function *boundary* identification is still quite slow. Profiling reveals that most of the time is spent building CFGs, and in particular resolving indirect jumps using VSA. In future work, we plan to explore alternative approaches that avoid VSA altogether.

Finally, obfuscated or malicious binaries which intentionally obscure function start information are out of scope of this paper.

7 Related Work

In addition to the already discussed Rosenblum et al. [27], there are a variety of existing binary analysis platforms tackle the binary identification problem. BitBlaze [6] assumes debug information. If no debug information is present, it treats the entire section as one function. BitBlaze also provides an interface for incorporating Hex Rays function identification information.

Dyninst [19] also offers tools, such as *unstrip* [31], to identify functions in binaries without debug information. Within the Dyninst framework, potential functions in the `.text` section are identified using the hex pattern `0x55` representing `push %ebp`. First, Dyninst will start at the entry address and traverse inter- and intra-procedural control flow. The algorithm will scan the gaps between functions and check if `push %ebp` is present. This does not preform well across different optimizations and operating systems.

IDA using proprietary heuristics and FLIRT [16] technique attempts to help security researchers recover procedural abstractions. However, updating the signature database requires an amount of manual effort that does not scale. In addition, because FLIRT uses a pattern matching algorithm to search for signatures, small variations in libraries such as different compiler optimizations or the use of different compiler versions, prevent FLIRT from recognizing important functions in a disassembled program. The Binary Analysis Platform (BAP) also attempts to provide a reliable identification of functions using custom-written signatures [8].

Kruegel et al. perform exhaustive disassembly, then use unigram and bigram instruction models, along with patterns, to identify functions [23]. Jakstab uses two predefined patterns to identify functions for x86 code [22, §6.2].

8 Conclusion

In this paper, we introduce BYTEWEIGHT, a system for automatically learning to identify functions in stripped binaries. In our evaluation, we show on a test suite of 2,200 binaries that BYTEWEIGHT outperforms previous work across two operating systems, two compilers, and four different optimizations. In particular, BYTEWEIGHT misses only 44,621 functions in comparison with the 266,672 functions missed by the industry-leading tool IDA. Furthermore, while IDA misidentifies 459,247 functions, BYTEWEIGHT misidentifies only 43,992 functions. To seed future improvements to the function identification problem, we are making our tools and dataset available in support of open science.

Abstract

Randomly mutating well-formed program inputs or simply *fuzzing*, is a highly effective and widely used strategy to find bugs in software. Other than showing fuzzers find bugs, there has been little systematic effort in understanding the science of how to fuzz properly. In this paper, we focus on how to mathematically formulate and reason about one critical aspect in fuzzing: how best to pick seed files to maximize the total number of bugs found during a fuzz campaign. We design and evaluate six different algorithms using over 650 CPU days on Amazon Elastic Compute Cloud (EC2) to provide ground truth data. Overall, we find 240 bugs in 8 applications and show that the choice of algorithm can greatly increase the number of bugs found. We also show that current seed selection strategies as found in Peach may fare no better than picking seeds at random. We make our data set and code publicly available.

1 Introduction

Software bugs are expensive. A single software flaw is enough to take down spacecrafts [2], make nuclear centrifuges spin out of control [17], or recall 100,000s of faulty cars resulting in billions of dollars in damages [5]. In 2012, the software security market was estimated at $19.2 billion [12], and recent forecasts predict a steady increase in the future despite a sequestering economy [19]. The need for finding and fixing bugs in software before they are exploited by attackers has led to the development of sophisticated automatic software testing tools.

Fuzzing is a popular and effective choice for finding bugs in applications. For example, fuzzing is used as part of the overall quality checking process employed by Adobe [28], Microsoft [14], and Google [27], as well as by security companies and consultants to find bugs and vulnerabilities in COTS systems.

One reason fuzzing is attractive is because it is relatively straightforward and fast to get working. Given a target application P, and a set of seed input files S, the programmer needs to:

Step 1. Discover the command line arguments to P so that it reads from a file. Popular examples include `-f`, `-file`, and using `stdin`. This step can be manual, or automated in many cases using simple heuristics such as trying likely argument combinations.

Step 2. Determine the relevant file types for an application automatically. For example, we are unlikely to find many bugs fuzzing a PDF viewer with a GIF image. Currently this step is performed manually, and like the above step the manual process does not scale to large program bases.

Step 3. Determine a subset of seeds $S' \subseteq S$ to fuzz the program. For example, an analyst may consider the possible set of seeds S as every PDF available from a search engine. Clearly fuzzing on each seed is computationally prohibitive, thus a *seed selection strategy* is necessary. Two typical choices are choosing the set of seed files ad-hoc, e.g., those immediately handy, and by finding the minimal set of seeds necessary to achieve code coverage.

Step 4. Fuzz the program and reap risk-reducing, or profitable, bugs.

Throughout this paper we assume maximizing the number of unique bugs found is the main goal. We make no specific assumptions about the type of fuzzer, e.g., we do not assume nor care whether black-box, white-box, mutational, or any other type of fuzzing is used. For our

experiments, we use BFF, a typical fuzzer used in practice, though the general approach should apply to any fuzzer using seeds. Our techniques also make no specific assumptions about the fuzz scheduling algorithm, thus are agnostic to the overall fuzzing infrastructure. To evaluate seed selection strategies, we use popular scheduling algorithms such as round-robin, as well as the best possible (optimal) scheduling.

We motivate our research with the problem setting of creating a hypothetical fuzzing testbed for our system, called COVERSET. COVERSET periodically monitors the internet, downloads programs, and fuzzes them. The goal of COVERSET is to maximize the number of bugs found within a limited time period or budget. Since budgets are forever constrained, we wish to make intelligent design decisions that employ the optimal algorithms wherever possible. How shall we go about building such a system?

Realizing such an intelligent fuzzing system highlights several deep questions:

Q1. Given millions, billions, or even trillions of PDF files, which should you use when fuzzing a PDF viewer? More generally, what algorithms produce the best result for seed selection of $S' \subseteq S$ in step 3?

Q2. How do you measure the quality of a seed selection technique *independently* of the fuzzing scheduling algorithm? For example, if we ran algorithm A on seed set S_1 and S_2, and S_1 maximized bugs, we would still be left with the possibility that with a more intelligent scheduling algorithm A' would do better with S_2 rather than S_1. Can we develop a theory to justify when one seed set is better than another with the best possible fuzzing strategy, instead of specific examples?

Q3. Can we converge on a "good" seed set for fuzzing campaigns on programs for a particular file type? Specifically, if S' performs well on program P_1, how does it work on other similar applications $P_2, P_3, \ldots$? If there is one seed set that works well across all programs, then we would only need to precompute it once and forever use it to fuzz any application. Such a strategy would save immense time and effort in practice. If not, we will need to recompute the best seed set for each new program.

Our main contribution are techniques for answering the above questions. To the best of our knowledge, many of the above problems have not been formalized or studied systematically. In particular:

- We formalize, implement, and test a number of existing and novel algorithms for seed selection.
- We formalize the notion of ex post facto optimality seed selection and give the first strategy that provides an optimal algorithm even if the bugs found by different seeds are correlated.
- We develop evidence-driven techniques for identifying the quality of a seed selection strategy with respect to an optimal solution.
- We perform extensive fuzzing experiments using over 650 CPU days on Amazon EC2 to get ground truth on representative applications. Overall, we find **240** unique bugs in 8 widely-used applications, all of which are on the attack surface (they are often used to process untrusted input, e.g., images, network files, etc.), most of which are security-critical.

While our techniques are general and can be used on any data set (and are the main contribution of this work), our particular result numbers (as any in this line of research) are data dependent. In particular, our initial set of seed files, programs under test, and time spent testing are all important factors. We have addressed these issues in several ways. First, we have picked several applications in each file type category that are typical of fuzzing campaigns. This mitigates incorrect conclusions from a non-representative data set or a particularly bad program. Second, we have performed experiments with reasonably long running times (12 hour campaigns per file), accumulating over 650 CPU days of Amazon EC2 time. Third, we are making our data set and code available, so that: 1) others need not spend time and money on fuzzing to replicate our data set, 2) others can further analyze the statistics to dig out additional meaning (e.g., perform their own hypothesis testing), and 3) we help lower the barrier for further improvements to the science of vulnerability testing and fuzzing. For details, please visit: http://security.ece.cmu.edu/coverset/.

2 Q1: Seed Selection

How shall we select seed files to use for the fuzzer? For concreteness, we downloaded a set of seed files S consisting of $4,912,142$ distinct files and 274 file types from Bing. The overall database of seed files is approximately 6TB. Fuzzing each program for a sufficient amount of time to be effective across all seed files is computationally expensive. Further, sets of seed files are often duplicative in the behavior elicited during fuzzing, e.g., s_1 may produce the same bugs as s_2, thus fuzzing both s_1 and s_2 is wasteful. Which subset of seed files $S' \subseteq S$ shall we use for fuzzing?

Several papers [1, 11], presentations from well-respected computer security professionals [8, 22, 26], as well as tools such as Peach [9], suggest using executable code coverage as a seed selection strategy. The intuition is that many seed files likely execute the same code blocks,

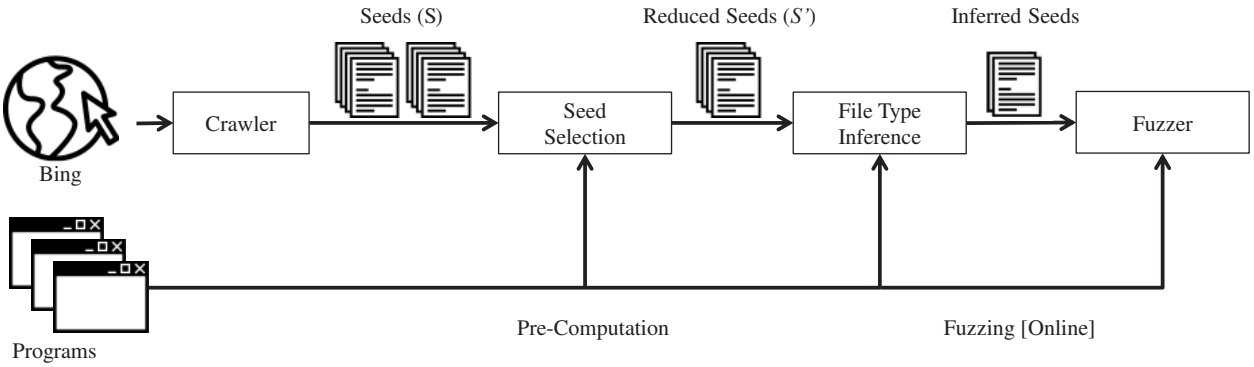

Figure 1: The COVERSET pipeline.

and such seeds are likely to produce the same bugs. For example, Miller reports a 1% increase in code coverage increases the percentage of bugs found by .92% [22]. This intuition can be formalized as an instance of the set cover problem [1, 11]. Does set cover work? Is the minimal set cover better than other set covers? Should we weight the set cover, e.g., by how long it takes to fuzz a particular seed? Previous work has shown a correlation between coverage and bugs found, but has not performed *comparative* studies among a number of approaches, nor studied how to measure optimality (§ 3).

Recall that in the *set cover problem* (SCP) [6] we are given a set X and a finite list of subsets $\mathbb{F} = \{S_1, S_2, \ldots, S_n\}$ such that every element of X belongs to at least one subset of $\mathbb{F}$:

$$X = \bigcup_{S \in \mathbb{F}} S$$

We say that a set $\mathbb{C} \subseteq \mathbb{F}$ is a set cover of X when:

$$X = \bigcup_{S \in \mathbb{C}} S$$

The seed selection strategy is formalized as:

Step 1. The user computes the coverage for each of the n individual seed files. The output is the set of code blocks [1] executed per seed. For example, suppose a user is given $n = 6$ seeds such that each seed executes the following code blocks:

$$S_1 = \{1,2,3,4,5,6\} \quad S_2 = \{5,6,8,9\}$$
$$S_3 = \{1,4,7,10\} \quad S_4 = \{2,5,7,8,11\}$$
$$S_5 = \{3,6,9,12\} \quad S_6 = \{10,11\}$$

Step 2. The user computes the cummulative coverage $X = \bigcup S_i$, e.g., $X = \{1,2,\ldots,12\}$ for the above.

[1] We assume code blocks, though any granularity of unit such as instruction, function, etc. also work.

Step 3. The user computes a set cover to output a subset $\mathbb{C}$ of seeds to use in a subsequent fuzzing campaign. For example, $\mathbb{C}_1 = \{S_1, S_4, S_3, S_5\}$ is one set cover, as is $\mathbb{C}_2 = \{S_3, S_4, S_5\}$, with $\mathbb{C}_2$ being optimal in the unweighted case.

The goal of the *minimal set cover problem* (MSCP) is to minimize the number of subsets in the set cover $\mathbb{C} \subseteq \mathbb{F}$. We call such a set $\mathbb{C}$ a *minset*. Note that a minset need not be unique, i.e., there may be many possible subsets of equal minimal cardinality. Each minset represents the fewest seed files needed to elicit the maximal set of instructions with respect to S, thus represents the maximum data seed reduction size.

In addition to coverage, we may also consider other attributes, such as speed of execution, file size, etc. A generalization of the set cover is to include a weight $w(S)$ for each $S \in \mathbb{F}$. The total cost of a set cover $\mathbb{C}$ is:

$$Cost\,(\mathbb{C}) = \sum_{S \in \mathbb{C}} w(S)$$

The goal of the *weighted* minimal set cover problem (WMSCP) is to find the minimal cost cover set, i.e., $\underset{\mathbb{C}}{argmin}\ Cost\,(\mathbb{C})$.

Both the MSCP and WMSCP can be augmented to take an optional argument k (forming k-SCP and k-WSCP respectively) specifying the maximum size of the returned solution. For example, if $k = 2$ then the number of subsets is restricted to at most 2 ($|\mathbb{C}| \leq 2$), and the goal is to *maximize* the number of covered elements. Note the returned set may not be a complete set cover.

Both MSCP and WMSCP are well-known NP-hard problems. Recall that a common approach to dealing with NP-hard problems in practice is to use an approximation algorithm. An approximation algorithm is a polynomial-time algorithm for approximating an optimal solution. Such an algorithm has an *approximation ratio* $\rho(n)$ if, for any input of size n, the cost C of the solution produced by the algorithm is within a factor of $\rho(n)$ of the cost C^* of

an optimal solution. The minimal set cover and weighted set cover problems both have a *greedy* polynomial-time $\ln|X|+1$-approximation algorithm [4, 16], which is a threshold below which set cover cannot be approximated efficiently assuming NP does not have slightly super-polynomial time algorithms, i.e., the greedy algorithm is essentially the best algorithm possible in terms of the approximation ratio it guarantees [10]. Since $\ln|X|$ grows relatively slowly, we expect the greedy strategy to be relatively close to optimal.

The optimal greedy polynomial-time approximation algorithm[2] for WSCP is:

GREEDY-WEIGHTED-SET-COVER$(X,\mathbb{F})$

```
1  U = X
2  ℂ = ∅
3  while U ≠ ∅
4      S = argmax_{S∈𝔽} |S∩U| / w(S)
5      ℂ = ℂ ∪ S
6      U = U \ S
7  return ℂ
```

Note that the unweighted minset can be solved using the same algorithm by setting $\forall S : w(S) = 1$.

2.1 Seed Selection Algorithms

In this section we consider: the set cover algorithm from Peach [9], a minimal set cover [1], a minimal set cover weighted by execution time, a minimal set cover weighted by size, and a hotset algorithm. The first two algorithms have previously been proposed in literature; the remaining are additional design points we propose and evaluate here. We put these algorithms to the test in our evaluation section to determine the one that yields the best results (see § 6).

All algorithms take the same set of parameters: given $|\mathbb{F}|$ seed files, the goal is to calculate a data reduction to k files where $k \ll |\mathbb{F}|$. We assume we are given t seconds to perform the data reduction, after which the selected k files will be used in a fuzzing campaign (typically of much greater length than t). We break ties between two seed files by randomly choosing one.

PEACH SET. Peach 3.1.53 [9] has a class called MinSet that calculates a cover set $\mathbb{C}$ as follows: [3]

PEACH-MINSET$(P,\mathbb{F})$

```
1  ℂ = ∅
2  i = 1
3  for S in 𝔽
4      cov[i] = MeasureCoverage( S )
5      i = i + 1
6  sort( cov ) // sort seeds by coverage
7  for i = 1 to |𝔽|
8      if cov[i] \ ℂ ≠ ∅
9          ℂ = ℂ ∪ cov[i]
10 return ℂ
```

Despite having the name MinSet, the above routine does not calculate the minimal set cover nor a proven competitive approximation thereof.

RANDOM SET. Pick k seeds at random. This approach serves as a baseline for other algorithms to beat. Since the algorithm is randomized, RANDOM SET can have high variance in terms of seed quality and performance. To measure the effectiveness of RANDOM SET, unless specified otherwise, we take the median out of a large number of runs (100 in our experiments).

HOT SET. Fuzz each seed for t seconds and return the top k seeds by number of unique bugs found. The rationale behind HOT SET is similar to multi-armed bandit algorithms—a buggy program is more likely to have more bugs. In our experiments, we fuzz each seeds for 5 minutes ($t = 300$) to compute the HOT SET.

UNWEIGHTED MINSET. Use an unweighted k-minset. This corresponds to standard coverage-based approaches [1, 23], and serves as a baseline for measuring their effectiveness. To compute UNWEIGHTED MINSET when k is greater than the minimum required to get full coverage, the minset is padded with files sorted based on the quality metric (coverage). We follow the same approach for TIME MINSET and SIZE MINSET.

TIME MINSET. Return a k-execution time weighted minset. This algorithm corresponds to Woo et al.'s observation that weighting by time in a multi-armed bandit fuzzing algorithm tends to perform better than the unweighted version [29]. The intuition is that seeds that are fast to execute ultimately lead to far more fuzz runs during a campaign, and thus potentially more bugs.

SIZE MINSET. Return a k-size weighted minset. Weighting by file size may change the ultimate minset, e.g., many smaller files that cover a few code blocks may be preferable to one very large file that covers many code blocks—both in terms of time to execute and bits to flip.

[2] Other algorithms exist to compute the weighted minset (see [6, 35-3.3]).

[3] This is a high-level abstraction of the `Delta` and `RunCoverage` methods. We checked the Peach implementation after the paper submission, and noticed that the sorting was removed (At Line 4 of the algorithm) in their MinSet implementation since Peach 3.1.95.

For example, SIZE MINSET will always select a 1KB seed over a 100MB seed, all other things being equal.

2.2 Specific Research Questions

Previous wisdom has suggested using UNWEIGHTED MINSET as the algorithm of choice for computing minsets [1, 23]. Is this justified? Further, computing the minset requires measuring code coverage. This computation requires time, time that could be spent fuzzing as in the HOT SET algorithm. Are coverage-based minsets beneficial and when?

More precisely, we formulate the following hypothesis:

Hypothesis 1 (MINSET > RANDOM.) *Given the same size parameter k,* MINSET *algorithms find more bugs than* RANDOM SET.

Hypothesis 1 is testing whether the heuristics applied by the algorithms presented above (§ 2.1) are useful. If they are as useful as choosing a random set, then the entire idea of using any of these MINSET algorithms is fundamentally flawed.

Hypothesis 2 (MINSET Benefits > Cost.) *Computing the* MINSET *for a given application and set of seed files and then starting fuzzing finds more bugs than just fuzzing.*

Hypothesis 2 tests whether the benefits of the minset outweigh the cost. Instead of spending time computing code coverage of seed files, should we instead spend it fuzzing? If yes, then the idea of reducing the files for *every* fuzzed application is flawed. It would also imply that precomputing minsets is necessary for the minsets to be useful. This observation leads to our next hypothesis.

Hypothesis 3 (MINSET Transferability.) *Given applications A and B that accept the same filetype F,* MINSET_F^A *finds the same or more bugs in application B as* MINSET_F^B.

Hypothesis 3 tests the transferability of seeds across applications that accept the same file type. For example, is the MINSET for PDF viewer A effective on PDF viewer B? If yes, we only need to compute a minset once per file type, thus saving resources (even if Hypothesis 2 is false).

Hypothesis 4 (MINSET Data Reduction.) *Given a target application A, a set of seed files F, and a* MINSET_F^A*, fuzzing with* MINSET_F^A *finds more bugs than fuzzing with the entire set F.*

Hypothesis 4 tests the main premise of using a reduced data set. Our MINSET contains fewer bugs than the full set in total. Under what conditions is the reduction beneficial?

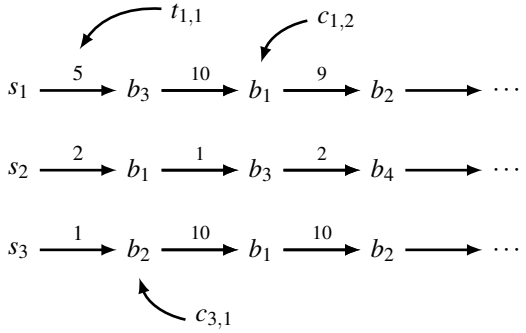

Figure 2: An example of output from fuzzing 3 seeds. Bugs may be found across seeds (e.g., b_1 is found by all seeds. A single seed may produce the same bug multiple times, e.g., with s_3. We also show the corresponding ILP variables t (interarrival times) and c (crash ids).

3 Q2: Measuring Selection Quality

There are a variety of seed selection strategies, e.g., to use minset or pick k seeds at random. How can we argue a particular seed selection strategy performs well?

One strawman answer is to run seed selection algorithm A to pick subset S_A, algorithm B to pick subset S_B. We then fuzz S_A and S_B for an equal amount of time and declare the fuzz campaign with the most bugs the winner. The fuzz campaign will incrementally fuzz each seed in each set according to its own scheduling algorithm. While such an approach may find the best seed selection for a *particular* fuzzing strategy, it provides no evidence that a particular subset is inherently better than another in the limit.

The main intuition in our approach is to measure the *optimal case* for bugs found with a particular subset of seeds. The best case provides an upper bound on any scheduling algorithm instead of on a particular scheduling algorithm. Note the lower bound on the number of bugs found for a subset is trivially zero, thus all we need is an upper bound.

To calculate the optimal case, we fuzz each seed in s_i for t seconds, recording as we fuzz the arrival rate of bugs. Given n seeds, the total amount of time fuzzing is $n * t$. For example, given 3 seeds we may have a bug b_i arrival time given by Figure 2.

Post-fuzzing, we then calculate the ex post facto optimal search strategy to maximize the number of bugs found. It may seem strange at first to calculate the optimal seed selection strategy after all seeds have been fuzzed at first blush. However, by doing so we can measure the quality of the seed selection strategy with respect to the optimal, thus give the desired upper bound. For example, if the seed selection strategy picks s_1 and s_2, we can calculate the maximum number of bugs that could be

found by any scheduler, and similarly for the set s_2, s_3 or any other set. Note we are calculating the upper bound to scientifically justify a particular strategy. For example, our experiments suggest to use UNWEIGHTED MINSET for seed selection. During a practical fuzzing campaign, one would not recompute the upper bound for the new dataset; instead, she would use the seed selection strategy that was shown to empirically perform best in previous tests.

3.1 Formalization

Let $Fuzz$ be a single-threaded fuzzer that takes in a set of seeds $\mathbb{C} \subseteq \mathbb{F}$ and a time threshold t_{thres} and outputs a sequence of unique bugs b_i along with the seed files that triggered them S_i and timestamps t_i:

$$Fuzz(\mathbb{C}, t_{\text{thres}}) = \{(b_1, S_1, t_1), \ldots, (b_n, S_n, t_n)\}$$

Given that we know the ground truth, i.e., we know the value of $Fuzz$ when applied on every singleton in $\mathbb{F}$: $Fuzz(\{S_i\}, t_{\text{thres}}) = \{(b_1, S_i, t_1), \ldots, (b_k, S_i, t_k)\}$, we can model the computation of the optimal scheduling/seed selection across all seed files in $\mathbb{F}$. Note that the ground truth is necessary, since any optimal solution can be only computed in retrospect (if we know how each seed would perform). We measure optimality of a scheduling/seed selection by computing the maximum number of unique bugs found.

The *optimal budgeted ex post facto scheduling problem* is given the ground truth for a set of seeds $Fuzz(\{S_i\}, t_{\text{thres}}) = \{(b_1, S_i, t_1), \ldots, (b_k, S_i, t_k)\}$ and a time threshold t_{thres}, automatically compute the interleaving of fuzzed seeds (time slice spent analyzing each one) to maximize the number of bugs found. The number of bugs found for a given minset gives an upper bound on the performance of the set and can be used as a quality indicator. Note that the same bug may be found by different seeds and may take different amounts of time to find.

Finding an optimal schedule for a given ground truth is currently an open problem. Woo et al. come the closest, but their algorithm assumes each seed produces independent bugs [29]. We observe finding an optimal scheduling algorithm is inherently an integer programming problem. We formulate finding the exact optimal seed scheduling as an Integer Linear Programming (ILP) problem. While computing the optimal schedule is NP-hard, ILP formulations tend to work well in practice.

First, we create an indicator variable for unique bugs found during fuzzing.

$$b_x = \begin{cases} 1 & \text{The schedule includes finding unique bug } x \\ 0 & \text{Otherwise} \end{cases}$$

The goal of the optimal schedule is to maximize the number of bugs. However, we do not see bugs, we see individual crashes arriving during fuzzing. We create an indicator variable $c_{i,j}$ that determines whether the optimal schedule includes the j^{th} crash of seed i:

$$c_{i,j} = \begin{cases} 1 & \text{The schedule includes crash } j \text{ for seed } i \\ 0 & \text{otherwise} \end{cases}$$

Note that multiple crashes $c_{i,j}$ may correspond to the same bug. Crashes are triaged to unique bugs via a uniqueness function denoted by μ. In our experiments, we use stack hash [24], a non-perfect but industry standard method. Thus, if the total number of unique stack hashes is U, we say we found U unique bugs in total. The invariant is:

$$b_x = 1 \text{ iff } \exists\, i, j : \mu(c_{i,j}) = x \tag{1}$$

Thus, if two crashes $c_{i,j}$ and $c_{i',j'}$ have the same hash, a schedule can get at most one unique bug by including either or both crashes.

Finally, we include a cost for finding each bug. We associate with each crash the incremental fuzzing cost for seed S_i to find the bug:

$$\forall i : t_{i,j} = \begin{cases} a_{i,1} & , j = 1 \\ a_{i,j} - a_{i,j-1} & , j > 1 \end{cases}$$

where $a_{i,j}$ is the arrival time for the $c_{i,j}$ crash, and $t_{i,j}$ represents interarrival time—the time interval between the occurrences of $c_{i,j-1}$ and $c_{i,j}$. Figure 2 visually illustrates the connection between $c_{i,j}$, b_x and $t_{i,j}$.

We are now ready to phrase optimal scheduling with a fixed time-budget as an ILP maximization problem:

$$\begin{aligned}
&\text{maximize} && \sum_x b_x \\
&\text{subject to} && \bigwedge_{i,j} . \, c_{i,j+1} \leq c_{i,j} && (2) \\
& && \sum_{i,j} c_{i,j} \cdot t_{i,j} \leq t_{\text{thres}} && (3) \\
& && \bigwedge_{i,j} . \, c_{i,j} \leq b_x \text{ where } \mu(c_{i,j}) = x && (4) \\
& && \bigwedge_{x} . \, b_x \leq \sum_{i,j} c_{i,j} \text{ where } \mu(c_{i,j}) = x && (5)
\end{aligned}$$

Constraint (2) ensures that the schedule considers the order of crashes found. In particular, if the j-th crash of a seed is found, all the previous crashes must be found as well. Constraint (3) ensures that the time to find all the crashes does not exceed our time budget t_{thres}. Constraints (4) and (5) link crashes and unique bugs. Constraints (4) says that if a crash is found, its corresponding bug (based on stack-hash) is found, and the next equation guarantees that if a bug is found, at least one crash triggering this bug was found.

Additionally, by imposing one extra inequality:

$$\sum_i c_{i,1} \leq k \tag{6}$$

we can bound the number of used seeds by k (if the first crash of a seed is not found, there is no value in fuzzing the seed at all), thus getting k-bounded optimal budgeted scheduling, which gives us the number of bugs found with the optimal minset of size up to k.

Optimal Seed Selection for Round-Robin. The formulation for optimal budgeted scheduling gives us a best solution any scheduling algorithm could hope to achieve both in terms of seeds to select (minset) and interleaving between explored seeds (scheduling). We can also model the optimal seed selection for specific scheduling algorithms with the ILP formulation. We show below how this can be achieved for Round-Robin, as this may be of independent interest.

Round-Robin scheduling splits the time budget between the seeds equally. Given a time threshold t_{thres} and N seeds, each seed will be fuzzed for $\frac{t_{\text{thres}}}{N}$ units of time. Round-Robin is a simple but effective scheduling algorithm in many adversarial scenarios [29]. Simulating Round-Robin for a given set of seeds is straightforward, but computing the optimal subset of seeds of size k with Round-Robin cannot be solved with a polynomial algorithm. To obtain the optimal minset for Round-Robin, we add the following inequality to Inequalities 2-6:

$$\forall_i . \sum_j c_{i,j} \cdot t_{i,j} \leq \frac{t_{\text{thres}}}{k} \tag{7}$$

The above inequality ensures that none of the seeds will be explored for more than $\frac{t_{\text{thres}}}{k}$ time units, thus guaranteeing that our solution will satisfy the Round-Robin constraints. Similar extensions can be used to obtain optimal minsets for other scheduling algorithms.

4 Q3: Transferability of Seed Files

Precomputing a good seed set for a single application P_1 may be time intensive. For example, the first step in a minset-based approach is to run each seed dynamically to collect coverage information. Collecting this information may not be cheap. Collecting coverage data often requires running the program in a dynamic analysis environment like PIN [18] or Valgrind [25], which can slow down execution by several orders of magnitude. In our own experiments, collecting coverage information on our data set took 7 hours. One way COVERSET could minimize overall cost is to find a "good" set of seeds and reuse them from one application to another.

There are several reasons to believe this may work. One reason is most programs rely on only a few libraries for PDF, image, and text processing. For example, if application P_1 and P_2 both link against the `poppler` PDF library, both applications will likely crash on the same inputs. However, shared libraries are typically easy to detect, and such cases may be uninteresting. Suppose instead P_1 and P_2 both have independent implementations, e.g., P_1 uses `poppler` and P_2 uses the GhostScript graphics library. One reason P_1 and P_2 may crash on similar PDFs is that there are intrinsically hard portions of the PDF standard to implement right, thus both are likely to get it wrong. However, one could speculate any number of reasons the bugs in applications would be independent. To the best of our knowledge, there has been no previous systematic investigation to resolve this question when the bugs are found via fuzzing.

5 System Design

A precondition to fuzzing is configuring the fuzzer to take the seed file as input. In this step, we are given the entire database of seeds and a particular program under test P. To fuzz, we must:

1. Recover P's command line options.
2. Determine which argument(s) causes P to read in from the fuzzing source. For simplicity, we focus on reading from a file, but the general approach may work with other fuzzing sources.
3. Determine the proper file type, e.g., giving a PDF reader a PDF as a seed is likely to work better than giving a GIF. We say a file type is valid for a program if it does non-trivial processing on the file.

Current fuzz campaigns typically require a human to specify the above values. For our work, we propose a set of heuristics to help automate the above procedure.

In our approach, we first use simple heuristics to infer likely command lines. The heuristics try the obvious and common command line arguments for accepting files, e.g., `-f file`. We also brute force common help options (e.g., `-help`) and parse the output for additional possible command line arguments.

As we recover command lines, we check if they cause P to read from a file as follows. We create a unique file name x, run P `x`, and monitor for system calls that open `x`.

In our data set we have 274 different file types, such as JPEG, GIF, PNG, and video files. Once we know the proper way to run P with seeds, the question becomes which seed types should we give P? We infer appropriate file types based on the following hypothesis: if s is a seed

handled by P and s' is not, then we expect the coverage of $P(s) > P(s')$. This hypothesis suggests an efficient way to infer file types accepted by an application. First, create a set of sample file type seeds F, where each element consists of a seed for a unique file type. Second, for each $s_i \in F$, count the number of basic blocks executed by $P(s_i)$. Third, select the top candidate (or candidates if desired) by total execution blocks. Though simple, we show in our evaluation this strategy works well in practice.

6 Experiments

We now present our experiments for checking the validity of the hypotheses introduced in § 2.2 and evaluate the overall performance in terms of bug discovered of COVERSET. We start by describing our experimental setup.

Experimental Setup. All of our experiments were run on medium and small VM instance types on Amazon EC2 (the type of the instance used is mentioned in every experiment). All VMs were running the same operating system, Debian Linux 7.4. The fuzzer used throughout our experiments is the CERT Basic Fuzzing Framework (BFF) [15]. All seed files gathered for our fuzzing experiments (4,912,142 files making up more than 6TB of data) were automatically crawled from the internet using the Bing API. Specifically, file type information was extracted from the open source Gnome Desktop application launcher data files and passed to the Bing API such that files of each type could be downloaded, filtered, and stored on Amazon S3. Coverage data was gathered by instrumenting applications using the Intel PIN framework and a standard block-based coverage collection PIN tool.

6.1 Establishing Ground Truth

To test the MINSET hypotheses, we need to obtain the ground truth (recall from § 3.1) for a fuzzing campaign that accounts for every possible seed selection and scheduling. We now present our methodology for selecting the target applications, files to fuzz, and parameters for computing the ground truth.

Target Applications. We selected 10 applications and 5 popular file formats: PDF, MP3, GIF, JPG and PNG for our experiments. Our program selection contains GUI and command line applications, media viewers, players, and converters. We manually mapped each program to a file format it accepts and formed 13 distinct (application, file formats) to be fuzzed—shown in Table 2. We selected at least two distinct command lines for each file type to test transferability (Hypothesis 3).

Seed Files. For each file type used by the target applications, we sampled uniformly at random 100 seed files (hence selecting $|\mathbb{F}| = 100$ for the seed file pool size) of the corresponding type from our seed file database. Note that determining ground truth for a single seed requires 12 hours, thus finding ground truth on all 4,912,142 is—for our resources—infeasible.

Fuzzing Parameters. Each of the target applications was fuzzed for 12 hours with each of the 100 randomly selected seed files of the right file type. Thus, each target application was fuzzed for 1,200 hours for a total of 650 CPU-days on an EC2 (m1.small) instance. All detected crashes were logged with timestamps and triaged based on BFF's stack hash algorithm.

The end result of our ground truth experiment is a log of crashes for each (seed file, application) tuple:

$$BFF(\{S_i\}, t_{\text{thres}} = 12h) = \{(b_1, S_i, t_1), \ldots, (b_k, S_i, t_k)\}$$

Fuzzing results. BFF found 2,941 unique crashes, identified by their stack hash. BFF crashed 8 programs out of the 10 target applications. 2,702 of the unique crashes were found on one application, `mp3gain`. Manual inspection showed that the crashes were due to a single exploitable buffer overflow vulnerability that mangled the stack and confused BFF's stack-based uniqueness algorithm. When reporting our results, we therefore count the 2,702 unique crashes in `mp3gain` as one. With that adjustment, BFF found 240 bugs. Developing and experimenting with more robust, effective, and accurate triaging algorithms is an open research problem and a possible direction for future work.

Simulation. The parameters of the experiment allow us to run simulations and reason about all possible seed selections (among the 100 seeds of the application) and scheduling algorithms for a horizon of 12 hours on a single CPU. Our simulator uses our ILP formulation from § 3 to compute optimal seed selections and scheduling for a given time budget. Using the ground truth, we can run simulations to evaluate the performance of hour-long fuzzing campaigns within minutes, following a replay-based fuzzing simulation strategy similar to FUZZSIM [29].

We used the simulator and ran a set of experiments to answer the following three questions: 1) how good are seed selection algorithms when compared against RANDOM SET (§ 6.2) and when compared against each other (§ 6.2.1)?, 2) can we reuse reduced sets across programs (§ 6.3)?, and 3) can our algorithm correctly identify file types for applications (§ 6.4)?

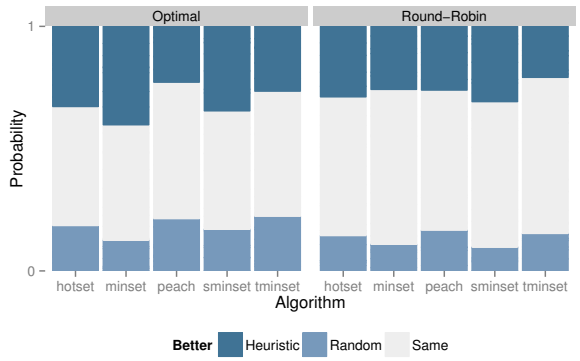

Figure 3: Comparing bug-finding performance of seed selection algorithms against RANDOM SET.

	Optimal	Round-Robin
HOT SET	63.58%	67.12%
PEACH SET	50.64%	60.30%
UNWEIGHTED MINSET	75.24%	70.24%
SIZE MINSET	66.33%	75.78%
TIME MINSET	52.60%	57.62%

Table 1: Conditional probability of an algorithm outperforming RANDOM SET with k=10, given that they do not have the same performance (P_{win}).

6.2 Are Seed Selection Algorithms Better than Random Sampling?

Spending resources on a seed selection algorithm is only useful if the selected seeds outperform random seed sampling (RANDOM SET). In this experiment, we compare the performance of selection algorithms as presented in §2.1 against the random sampling baseline.

All selection algorithms are deterministic, while RANDOM SET is randomized. Thus, we cannot show that RANDOM SET is always better (or worse), but we can instead compute the probability that RANDOM SET is better (or worse). To estimate the probability, we setup the following random experiment: we randomly sample a set of seeds—the size of the set is the same ($k = 10$ in our experiment for an order of magnitude reduction) as the competing reduced set—from the seed pool and measure the number of bugs found. The experiment has three possible outcomes: 1) the random set finds more bugs, 2) the random set finds fewer bugs, or 3) the random and the competitive set find the same number of bugs.

We performed 13,000 repetitions of the above experiment—1,000 for each (application, file format) tuple—and measured the frequency of each event when the optimal scheduling algorithm is employed for both. We then repeated the same experiment while using Round-Robin as the scheduling algorithm. We calculated the probability by dividing the frequency by the number of samples. Figure 3 summarizes the results. For instance, the left-most bar is the result for HOT SET with the optimal scheduling. You can see that HOT SET finds more bugs than a RANDOM SET of the same size with a probability of 32.76%, and it is worse with a probability of 18.57%. They find the same amount of bugs with a probability of 48.66%.

The first pattern that seems to persist through scheduling and selection algorithms (based on Figure 3) is that there is a substantial number of ties—RANDOM SET seems to behave as well as selection algorithms for the majority of the experiments. This is not surprising, since 3/13 (23%) of our (application, file format) combinations—(mplayer, MP3), (eog, JPG), (jpegtran, JPG)—do not crash at all. With no crash to find, any algorithm will be as good as random. Thus, to compare an algorithm to RANDOM SET we focus on the cases where the two algorithms differ, i.e., we compute the conditional probability of winning when the two algorithms are not finding the same number of bugs.

We use P_{win} to denote the conditional probability of an algorithm outperforming RANDOM SET, given that they do not have the same performance. For example, for SIZE MINSET, P_{win} is defined as: $P[\text{SIZE MINSET} > \text{RANDOM SET} \mid \text{SIZE MINSET} \neq \text{RANDOM SET}]$. Table 1 shows the values of P_{win} for all algorithms for sets of size $k = 10$. We see that UNWEIGHTED MINSET and SIZE MINSET are the algorithms that more consistently outperform RANDOM SET with a P_{win} ranging from 66.33% to 75.78%. HOT SET immediately follows in the 63-67% range, and TIME MINSET, PEACH SET have the worst performance. Note that PEACH SET has a P_{win} of 50.64% in the optimal schedule effectively meaning that it performs very close to a random sample on our dataset.

Conclusion: seed selection algorithms help. With the exception of the PEACH SET and TIME MINSET algorithms which perform very close to RANDOM SET, our data shows that heuristics employed by seed selection algorithms perform better than fully random sampling. Thus, hypothesis 1 seems to hold. However, the bug difference is not sufficient to show that *any* of the selection algorithms is *strictly* better with statistical significance. Fuzzing for longer and/or obtaining the ground truth for a larger seed pool are possible future directions for showing that seed selection algorithms are *strictly* better than choosing at random.

Table 2: Programs fuzzed to evaluate seed selection strategies and obtain ground truth. The columns include the number of seed files (#S) obtained with each algorithm, and the number of bugs found (#B) with the optimal scheduling strategy.

6.2.1 Which Algorithm Performed Best?

Table 2 shows the full breakdown of the reduced sets computed by each algorithm with the optimal scheduling algorithm. Columns 1 and 2 show the file type and program we are analyzing, while columns 3 and 4 show the total number of crashes and unique bugs (identified by stack hash) found during the ground truth experiment. The next six columns show two main statistics (in subcolumns) for each of the seed selection algorithms: 1) the size of the set k (#S), and 2) the number of bugs (#B) identified with optimal scheduling. All set cover algorithms (Peach Set, Unweighted Minset, Time Minset, Size Minset) were allowed to compute a full-cover, i.e., select as many files as required to cover all blocks. The other two algorithms (Random Set and Hot Set) were restricted to sets of size $k = 10$.

Bug Distribution and Exploitability. The fuzzing campaign found bugs in 10/13 configurations of ⟨program, file type⟩, as shown in table 2. In 9/10 configurations we found less than 100 bugs, with one exception: `mp3gain`. We investigated the outlier further, and discovered that our fuzzing campaign identified an exploitable stack overflow vulnerability—the mangled stack trace can create duplicates in the stack hash algorithm. We verified the bug is exploitable and notified the developers, who promptly fixed the issue.

Reduced Set Size. Table 2 reflects the ability of the set cover algorithms to reduce the original dataset of 100 files. As expected, Unweighted Minset is the best in terms of reduction ability, with 278 files for obtaining full cover. Time Minset requires slightly more files (288). Size Minset and Peach Set require almost twice as many files to obtain full cover (406 and 462 respectively).

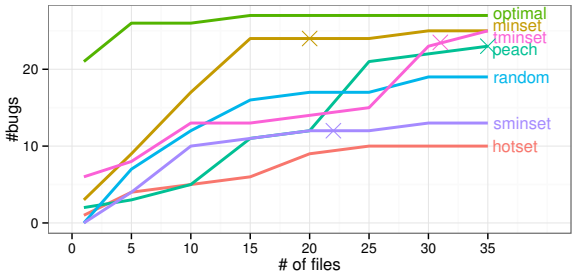

Figure 4: Number of bugs found by different seed selection algorithms with optimal scheduling.

Bug Finding. The Peach Set algorithm finds the highest number of bugs (295), followed by Unweighted Minset (255), Size Minset (182) and Time Minset (170). Hot Set and Random Set find substantially fewer bugs when restricted to subsets of size up to 10. We emphasize again that bug counts are measured under optimal scheduling and thus size of the reduced set is analogous to the performance of the selection algorithm (the highest number of bugs will be found when all seeds are selected). Thus, to compare sets of seeds in terms of bug-finding ability we need a head to head comparison where sets have the same size k.

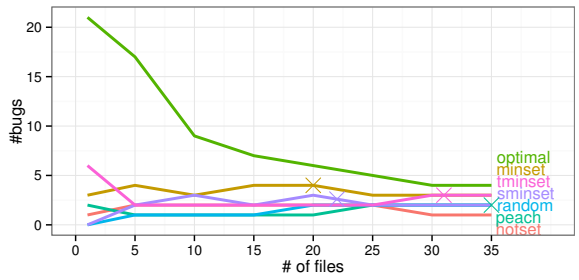

Figure 5: Number of bugs found by different seed selection algorithms with Round-Robin.

Figure 4 shows all selection algorithms and how they perform in terms of average number of bugs found as a function of the parameter k—the size of the seed file set. The "×" symbols represent the size after which each algorithm achieves a full cover (after that point extra files are added sorted by the metric of the selection algorithm, e,g,, by coverage in UNWEIGHTED MINSET). As witnessed in the comparison against RANDOM SET, UNWEIGHTED MINSET consistently performs better than other seed selection algorithms. TIME MINSET and PEACH SET also eventually converge to the performance of UNWEIGHTED MINSET under optimal scheduling, closely followed by random. HOT SET performs the worst, showing that spending time exploring *all* seeds can be wasteful. We also note, that after obtaining full cover (at 20 seed files), UNWEIGHTED MINSET's performance does not improve at the same rate—showing that adding new files that do not increase code coverage is not beneficial (even with optimal scheduling).

We performed an additional simulation, where all reduced sets were run with Round-Robin as the scheduling algorithm. Figure 5 shows the performance of each algorithm as a function of the parameter k. Again, we notice that that UNWEIGHTED MINSET is outperforming the other algorithms. More interestingly, we also note that UNWEIGHTED MINSET's performance actually *drops* after obtaining full cover. This shows that minimizing the number of seeds is important; adding more seeds in Round-Robin seems to hurt performance for all algorithms.

Conclusion: UNWEIGHTED MINSET performed best. UNWEIGHTED MINSET outperformed all other algorithms in our experiments, both for optimal and Round-Robin scheduling. This experiment confirms conventional wisdom that suggests collecting seeds with good coverage for successful fuzzing. More importantly, it also shows that computing a minimal cover with an approximation with a proven competitiveness ratio (UNWEIGHTED MINSET) is better than using an algorithm with no guaranteed competitive ratio (PEACH SET).

File	Application	FULL SET	UNWEIGHTED MINSET (k=10)
PDF	xpdf	53%	70%
	mupdf	83%	90%

	convert	2%	10%

Table 3: Probability that a seed will produce a bug in 12 hours of fuzzing.

6.2.2 Are reduced seed sets better than a full set?

Hypothesis 4 tests the premise of using a reduced data set. Will a reduced set of seeds find more bugs than the full set? We simulated a fuzzing campaign with the full set, and with different reduced sets. We compare the number of bugs found by each technique.

Using the optimal scheduling, the full set will *always* find more, or the same amount of bugs, than any subsets of seeds. Indeed, the potential schedules of the full set is a superset of the potentiel schedules of any reduced set. The optimal schedule of a reduced set of seeds is a valid schedule of the full set, but the optimal schedule of the full set might not be a valid schedule of a reduced set. Hypothesis 4 is therefore false under the optimal scheduling. We use a Round-Robin schedule to answer this question more realistically.

The "×" symbols on Figure 5 shows the unpadded size of the different selection algorithms. For those sizes, UNWEIGHTED MINSET found 4 bugs on average, and the other MINSET algorithms found between 2.5 and 3 bugs. Fuzzing with the full set uncovered only 1 unique bug on average.

We also measure the quality of a set of seeds by looking at the average seed quality contained in that set. Our hypothesis is that a reduced set increases the average seed quality compared to the full set. To measure quality, we computed the probability of a seed producing a bug after fuzzing it for 12 hours, when the seed is picked from the full set or the UNWEIGHTED MINSET. Table 3 lists the

results of this experiment. The UNWEIGHTED MINSET had a higher seed quality than the full set in 7 cases, while the opposite was true in 3 cases. They were tied on the 3 remaining cases.

Conclusion: Fuzzing with a reduced sets is more efficient in practice. The UNWEIGHTED MINSET outperformed the full set in our two experiments. Our data demonstrates that using seed selection techniques is beneficial to fuzzing campaigns.

6.3 Are Reduced Sets Reusable Across Programs?

We showed that seed selection algorithms improve fuzzing in terms of bug-finding performance. However, performing the data reduction may be computationally expensive; for instance, all set cover algorithms require collecting coverage information for all the seeds. Is it more profitable to invest time computing the minset to fuzz an efficient reduced set, or to simply fuzz the full set of seeds for the full time budget? In other words, is the seed selection worth the effort to be performed online?

We answer that question by presenting parts of our dataset. For example, our JPG bucket contains 530,727 distinct files crawled from the web. Our PIN tool requires 55 seconds (on average based on the 10 applications listed in Table 2) to compute code coverage for a single seed. Collecting coverage statistics for all our JPG files would take 368 CPU-days. For fuzzing campaigns shorter than a year, there would not be enough time to compute code coverage, let alone finding more bugs than the full set.

The result above indicates that, while seed selection techniques help improve the performance of fuzzing, their benefits may not outweigh the costs. It is impractical to spend a CPU year of computation to perform a separate seed selection for every new application that needs fuzzing, thus indicating that Hypothesis 2 does not hold.

However, recomputing the reduced set for *every application* may not be necessary. Instead, we can compute a reduced set for every *file type*. Our intuition is a reduced set that is of high-quality for application A should also be high-quality for application B—assuming they accept the same file type. Thus, precomputing reduced sets for popular file types *once*, would allow us to instantly select a high-quality set of seed files to start fuzzing. To test transferability of reduced sets (Hypothesis 3), we measure seed quality by computing code coverage achieved by a MINSET across programs.

Do Reduced Sets Transfer Coverage? Using the seed files from our ground truth experiment (§ 6.1) we measured the cumulative code coverage achieved in each configuration (program and file format) with reduced UNWEIGHTED MINSETs computed on all other configurations (for a total of $13 \times 13 \times 100$ coverage measurements). All measurements were performed on a c1.medium instance on amazon.

Figure 6 is a heat map summarizing our results. The configurations on the bottom (x-axis) represent all computed UNWEIGHTED MINSETs, while the configurations on the left (y-axis) represent the configurations tested. Darker colors indicate that the selected UNWEIGHTED MINSET obtains higher coverage. For example, if we select the `pdf.mupdf` MINSET from the x-axis, we can see how it performs on all the other configurations on the y-axis. For instance, we notice that `pdf.mupdf` MINSET performs noticeably better on 5 configurations: `pdf.mupdf` (expected since this is the configuration on which we computed the MINSET), `pdf.xpdf` and `pdf.pdf2svg` (expected since these applications also accept `pdfs`), and interestingly `png.convert` and `gif.convert`. Initially we were surprised that a PDF MINSET would perform so well on `convert`; it turns out that this result is not surprising since `convert` can also process PDF files. Similar patterns can be similarly explained—for example, GIF MINSETs are performing *better* than MP3 MINSETs for `mplayer`, simply because `mplayer` can render GIF images.

The heat map allows us to see two clear patterns:

1. High coverage indicates the application accepts a file type. For instance, by following the row of the `gif.eog` configuration we can immediately see that `eog` accepts GIF, JPG, and PNG files, while it does not process MP3s or PDFs. This is exactly the same pattern we are exploiting in our file type inference algorithm (§ 6.4).

2. Coverage transfers across applications that process the same file type. For example, we clearly see the PDF cluster forming across all PDF configurations, despite differences in implementations. While `xpdf` and `pdf2svg` both use the `poppler` library for processing PDFs, `mupdf` has a completely independent implementation. Nevertheless, `mupdf`'s MINSET performs well on `xpdf` and vice versa. Our data shows that similar clusters appear throughout configurations of the same file type, suggesting that we can reuse MINSETs across applications that accept the same file type (Hypothesis 3).

Conclusion: Reduced sets are transferable. Our data suggests that reduced sets can be transferred to programs parsing the same file types with respect to code coverage. Therefore, it is necessary to compute only one reduced set per file type.

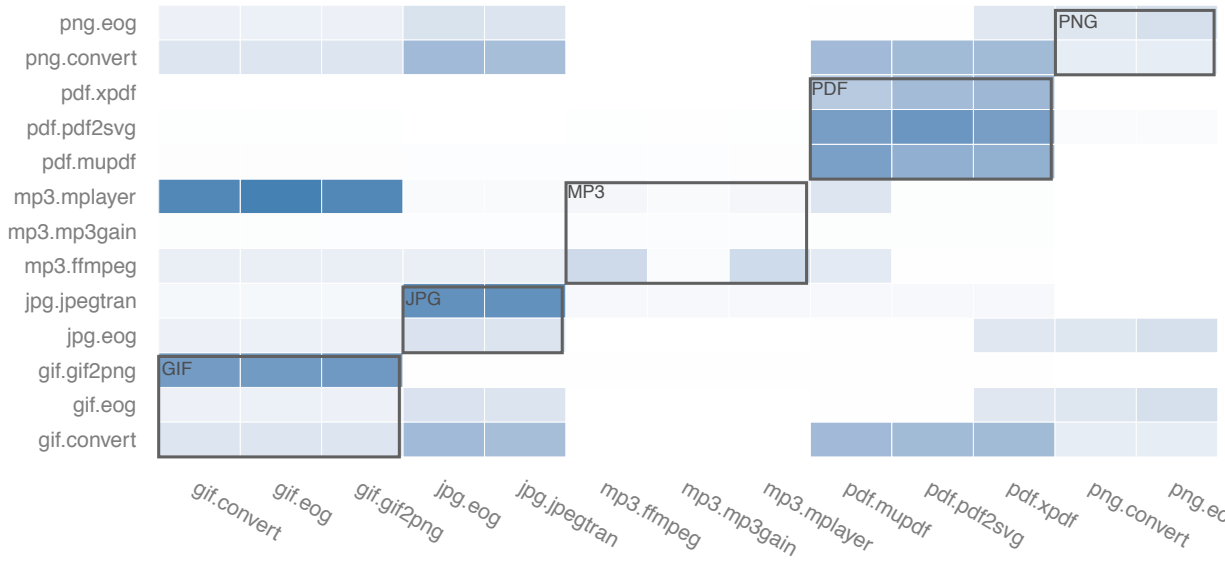

Figure 6: Transferability of UNWEIGHTED MINSET coverage across configurations. The base configurations, on which the reduced sets were computed, are on the bottom; the tested configurations are on the left. Darker colors indicate higher coverage.

6.4 Inferring File Types

In this experiment we ran our algorithm to automatically infer file types for our 10 applications over a large body of diverse file types (88 in total including AVI, MP3, MKV and so forth). We then manually verified the inferred file type, and measured accuracy. We report an error if a reported file type is not recognized by the target application. Table 6.4 summarizes our results. Our file type inference algorithm successfully infers file types for every program except `mp3gain`, where the file type inferred was CBR (Comic Book Reader), instead of MP3.

We manually examined why `mp3gain` shows higher code coverage for CBR files. It turns out that our sample CBR file is larger than 15 MB, and it happens to have a valid MP3 frame header signature in the middle of the file. Since `mp3gain` searches for a valid MP3 frame header regardless of the entire file format, it is possible to misinterpret an input file as a valid MP3 file. In other words, this is probably not a false positive, because `mp3gain` indeed takes in the CBR file and outputs a modified CBR file, which is the expected behavior of the program.

Program	Inferred File Type	Success
convert	svg	✓
eog	png	✓

7 Discussion & Future Work

Input Types. The focus of this paper is on file-parsing applications. Thus, we do not target applications that use command line arguments as their input sources (e.g., /bin/echo), or applications that receive input from the network (e.g., /usr/bin/wget). File-based vulnerabilities represent a significant attack vector, since remote attacks can be carried out by simply sending an attachment to the victim over the network.

Handling argument inputs for applications is straightforward: we can extend our fuzzing framework to randomly generate arguments to the `exec` system call. Treating network applications would be more elaborate since we would have to update our seed database to include network packets for various protocol types. One potential extension is to utilize automatic protocol reversing [3, 7]. We leave it as future work to support more input types.

Statistical Significance. We have performed initial hypothesis testing based on the data. Currently, using UNWEIGHTED MINSET is assumed to outperform other al-

gorithms. Using our data (see Figure 3), we were able to show that UNWEIGHTED MINSET is at least as good as random with high probability. However, the data does not show with statistical significance that UNWEIGHTED MINSET is strictly better. Fuzzing longer and with more seed files and programs may yield more datapoints that would allow a stronger conclusion—at the cost of a much more costly ground truth computation: an additional seed file requires 12 hours of extra fuzzing hours for each application. We leave fuzzing for more than 650 days as future work.

Command Line Inference. Currently, COVERSET uses several heuristics to infer command line arguments. We believe that command line inference is an important first step to fully automate the entire fuzzing process. For example, COVERSET currently does not handle dependent arguments, e.g., when option `A` is valid only when option `B` is also selected. Developing systematic and effective approaches for deriving command line arguments—e.g., based on white-box techniques—is a possible direction for future work.

8 Related Work

In early 90s, Miller et al. [21] introduced the term fuzzing. Since then, it has become one of the most widely-deployed technique for finding bugs. There are two major categories in fuzzing based on its ability to examine the internal of the software under test: (1) black-box fuzzing [20], and (2) white-box fuzzing [13, 14]. In this paper, we use black-box mutational fuzzing as the underlying technique for our data reduction algorithms.

Coverage-driven seed selection is not new. Several papers and security practitioners use similar heuristics to select seeds for fuzzing [1, 8, 9, 11, 22, 23, 26]. FuzzSim by Woo et al. [29] is the closest work from academia, where they tackle a seed scheduling problem using multi-armed bandit algorithms. Our paper differs from their approach in that we are not developing an online scheduling algorithm, but an offline data-driven seed selection approach. Therefore, our seed selection is complementary—when it is used as a preprocessing step—to the FuzzSim scheduling algorithm.

There are several previous works on recovering input formats, which involves dynamic taint analysis [3, 7]. Our goal is being able to run fuzzing with appropriate seed files, but not recovering the semantics of file format. Accommodating more precise file format inference techniques is out of the scope of this paper.

9 Conclusion

In this paper we designed and evaluated six seed selection techniques. In addition, we formulated the optimal ex post facto seed selection scheduling problem as an integer linear programming problem to measure the quality of seed selection algorithms. We performed over 650 days worth of fuzzing to determine ground truth values and evaluated each algorithm. We found 240 new bugs. Our results suggest how best to use seed selection algorithms to maximize the number of bugs found.

Abstract

Encryption schemes where the ciphertext must abide by a specified format have diverse applications, ranging from in-place encryption in databases to per-message encryption of network traffic for censorship circumvention. Despite this, a unifying framework for deploying such encryption schemes has not been developed. One consequence of this is that current schemes are ad-hoc; another is a requirement for expert knowledge that can disuade one from using encryption at all.

We present a general-purpose library (called libfte) that aids engineers in the development and deployment of format-preserving encryption (FPE) and format-transforming encryption (FTE) schemes. It incorporates a new algorithmic approach for performing FPE/FTE using the nondeterministic finite-state automata (NFA) representation of a regular expression when specifying formats. This approach was previously considered unworkable, and our approach closes this open problem. We evaluate libfte and show that, compared to other encryption solutions, it introduces negligible latency overhead, and can *decrease* diskspace usage by as much as 62.5% when used for simultaneous encryption and compression in a PostgreSQL database (both relative to conventional encryption mechanisms). In the censorship circumvention setting we show that, using regular-expression formats lifted from the Snort IDS, libfte can reduce client/server memory requirements by as much as 30%.

1 Introduction

Both in practice and in the academic literature, we see an increasing number of applications demanding encryption schemes whose ciphertexts abide by specific formatting requirements. A small industry has emerged around the need for in-place encryption of credit-card numbers, and other personal and financial data. In the case of credit-card numbers, this means taking in a string of 16 decimal digits as plaintext and returning a string of 16 decimal digits as ciphertext. This is an example of *format-preserving encryption* (FPE). NIST is now considering proposals for standardized FPE schemes, such as the FFX mode-of-operation [7], which is already used in some commercial settings [3]. On a totally different front, a recent paper [11] builds a *format-transforming encryption* scheme. It takes in plaintext bit strings (formatted or not) and returns ciphertexts formatted to be indistinguishable, from the point of view of several state-of-the-art network monitoring tools, from real HTTP, SMTP, SMB or other network protocol messages. This FTE scheme is now part of the Tor Project's Browser Bundle, and is being integrated into other anti-censorship systems.

It seems clear that FPE and FTE have great potential for other applications, too. Unfortunately, developers will find a daunting collection of design choices and engineering challenges when they try to use existing FPE or FTE schemes in new applications, or to instantiate entirely new schemes. To begin with, there isn't a standard way to specify the formats that plaintexts or ciphertexts must respect. There are no established guidelines, and certainly no automated tools, to help developers understand whether they should be targeting deterministic schemes or randomized ones, or how their chosen formats might affect runtime performance and memory usage. (In the case of FTE, it can be difficult to tell if a given input and output format will result in a scheme that operates properly.) There are no established APIs, and no reference implementations or open-source libraries to aid development.

Making FPE/FTE More Approachable: libfte. In this work, we offer a unifying framework for building and deploying FPE and FTE schemes. We design and implement an algorithm library, libfte, and include in it developer-assistance tools. A paramount goal of

our effort is *ease-of-use*: our library exposes an interface in which formats for plaintexts and ciphertexts are easily specified via Perl-compliant regular expressions (regexes), and it relieves the programmer of the burdens of making good algorithm and parameter choices.

Some of what we do is to make existing algorithms (e.g., FFX) significantly easier to use. But some of the engineering and deployment challenges demand entirely new approaches to both FPE and FTE. Perhaps most notably, we solve an open problem regarding how to build regular-expression-based schemes using a regex's nondeterministic finite automaton (NFA) representation, as opposed to its DFA representation. This is desirable because it can lead to significantly more space-efficient schemes, but the approach was previously thought to be unworkable [5, 11]. We dispel this thought, and experimentally observe the resulting boost in efficiency.

To summarize the main contributions of this work, we:

- *Design and implement a library and toolkit* to make development and deployment easy. The libfte library exposes simple interfaces for performing FPE/FTE over regex formats specified by the user. We provide a configuration tool that guides developers towards good choices for the algorithms that will instantiate the scheme, and that provides concrete feedback on expected offline and online performance and memory usage.
- *Develop new FTE schemes* that take regular-expression formats, but can work directly with their NFA representation. This was previously thought to be an unworkable approach [5], due to a PSPACE-hardness result, but we show how to side-step this via a new encoding primitive called *relaxed ranking*. The result is FTE schemes that handle a larger class of regexes, and impose smaller offline/online memory requirements.
- *Detail a general, theoretical framework* that captures existing FPE/FTE schemes as special cases, and surfaces potentially useful new constructions, e.g., deterministic FTE that encrypts and compresses simultaneously. Due to space constraints, the formalisms appear mostly in the full version [16].

In addition, the libfte library will be made publicly available as free and open-source software[1], with APIs for Python, C++ and JavaScript.

Applications. We exercise libfte by applying it to a variety of application settings. Table 1 gives a summary of the diversity of formats required across these various applications.

We first show how to use libfte to perform FPE of SQL database fields, a classic motivational setting for FPE, but one that has (to the best of our knowledge) never been reported upon. We show that performance loss compared to conventional encryption is negligible. We also show how to leverage the flexibility of libfte to *improve* performance, by using a (deterministic) FTE scheme that simultaneously encrypts and compresses fields (in a provably secure manner).

We then use libfte to build a proof-of-concept browser plugin that encrypts form data on websites such as Yahoo! Contacts. This uses a variety of FPE and FTE schemes, and allows one to abide by a variety of format restriction checks performed by the website.

Finally, we show that our NFA-based algorithms in libfte enable significant memory savings, specifically for the case of using FTE in the network-monitor-avoidance setting [11]. Using a corpus of 3,458 regular expressions from the Snort monitor we show that we can reduce memory consumption of this FTE application by 30%.

Deployment Setting	Examples	
	Type	Constraint
Databases	credit card number	16-digit string
	datefield	YYYYMMDD
	account balance	32-bit integers
Web Forms	email address	contains @ symbol, ends with {.com,...}
	year, month, day	YYYY, MM, DD
	URL	starts with http(s)
Network Monitors	HTTP GET request	"GET /..."
	Browser X	"...User-Agent: X ..."
	SSH traffic	"SSH-..."

Table 1: Example deployment settings and constraints for FPE/FTE schemes.

2 Previous Approaches and Challenges

We review in more detail some of the main results in the areas of format-preserving and format-transforming encryption, and then discuss some of the challenges presented when one attempts to implement and use these in practice. As we shall see, existing tools fall short for the types of applications we target. Table 2 provides a summary.

Format-preserving encryption. In many settings the format of a plaintext and its encryption must be the same, and the tool used to achieve this is format-preserving encryption (FPE). Work on FPE predates its name, with various special cases such as length-preserving encryption of bit strings for disk-sector encryption (c.f., [14, 15]), ciphers for integral sets [8], and elastic block ciphers [10] including de novo constructions such as the hasty pudding cipher [21]. For an overview of work on

Paper	Builds	Formats	Schemes	Implementation	Comments
[7]	FPE	slice of Σ^*	deterministic	none	proposed NIST standard
[5]	FPE	slice of chosen regular language	deterministic	none	first FPE paper, theory only, requires regex-to-DFA conversion
[11]	FTE	slice of chosen regular language	randomized	open source, but domain specific	input format fixed as bitstrings, control of output format, requires regex-to-DFA conversion
This Work	**FPE/ FTE**	**range-slice of chosen regular language**	**deterministic/ randomized**	**open source, configuration toolchain, non domain specific**	**control of input and output format, NFA and DFA ranking, regex-to-DFA conversion not required**

Table 2: Analysis of prior works, and a comparison of features.

FPE, see Rogaway [20].

FPE was first given a formal cryptographic treatment by Bellare, Ristenpart, Rogaway and Spies (BRRS) [5]. In their work, BRRS suggested an approach to FPE called the "rank-encipher-unrank" construction. First, they show how to build a cipher that maps $\mathbb{Z}_N$ to $\mathbb{Z}_N$, for an arbitrary fixed number N. (Recall that $\mathbb{Z}_N = \{0, 1, \ldots N-1\}$.) Now say that X is a set of strings that all fit some specified format, and one desires an encryption scheme mapping X to X. A classic algorithm due to Goldberg and Sipser (GS) [12] shows that, given a DFA for X, there exists an efficiently computable function $\mathsf{rank} : X \to \mathbb{Z}_N$, where $|X| = N$ and $\mathsf{rank}(x)$ is defined to be its position (its "rank") in the shortlex ordering of X. In addition, rank has an efficiently computable inverse $\mathsf{unrank} : \mathbb{Z}_N \to X$, so that $\mathsf{unrank}_L(i)$ is the i-th string in the ordering of L. Then to encrypt a string $x \in X$: (1) rank the input x to yield a number $a \leftarrow \mathsf{rank}(x)$, (2) encipher a, giving a new number b, then (3) unrank b to yield the ciphertext $y \leftarrow \mathsf{unrank}(b)$, which is an element of X.

BRRS focus on FPE for sets X that are a *slice* of a language L, that is $X = L \cap \Sigma^n$ for some n and where Σ is the alphabet of L. Relatedly, we define a *range-slice* of a language L as $X = L \cap (\Sigma^n \cup \Sigma^{n+1} \cup \cdots \cup \Sigma^m)$, for $n \leq m$. The latter is superior because it offers greater flexibility, although not explored by BRRS. Still, extending BRRS to an FPE scheme over the entire (regular) language is possible, by establishing a total ranking one slice at a time. The main disadvantage of the BRRS scheme is that it requires a DFA to represent the set X. For most users, this is an unnatural way to specify languages, or slices thereof.

We quickly note that the BRRS algorithm may be susceptible to timing-based side-channel attacks, since rank is not constant time. Timing information may therefore leak partial information about plaintexts. We leave to future work exploration of this potential security issue, which extends to libfte and other non-constant-time message encodings as well.

The FFX scheme. Bellare, Rogaway, and Spies [7] specify the FFX mode of operation, which is a specific kind of FPE scheme and is based on the BRRS work [5]. FFX takes a parameter $2 \leq r \leq 2^{16}$, the radix, and encrypts a plaintext $P \in L = \bigcup_\ell \{0, 1, \ldots, r-1\}^\ell$ to a ciphertext in L with $|L| = |P|$. The length ℓ ranges between a minimum value of 2 (or 10, if $r \geq 10$) and $2^{32} - 1$. For example, FFX[10] enciphers strings of decimal digits to (same length) strings of decimal digits; FFX[8] does likewise for octal strings. In addition, FFX has an extra "tweak" input, making it a length-preserving tweakable cipher, in the sense of [17]. The tweak allows FFX to support associated data.

We are aware of no public, open-source implementations of FFX, though there do exist proprietary ones [3]. Even given such an implementation, the formats supported by FFX are not as general as we might like. For example, the scheme does not support domain $\mathbb{Z}_N$ when N is not expressible as r^ℓ for the supported radices r. One can rectify this using cycle walking [8] but the burden is on developers to properly do so, hindering usability. Moreover, the user is left to determine how best to map more general formats into the set of formats that FFX supports.

Format-transforming encryption. Dyer, Coull, Ristenpart and Shrimpton (DCRS) [11] introduced the notion of format-*transforming* encryption, and gave a purpose-built scheme that mapped bitstring plaintexts to ciphertexts belonging to a specified regular language. Their FTE scheme was built to force protocol misidentification in state of the art deep-packet-inspection (DPI) systems used for Internet censorship.

The DCRS scheme is randomized, which lets it target strong privacy goals for the plaintexts (namely, semantic security [13]), and also naturally aligns with using standard encryption schemes as building blocks. The scheme itself is similar in spirit to BRRS: the plaintext bitstring is encrypted using an authenticated encryption scheme, the resulting intermediate ciphertext interpreted as a number, and this number is then unranked into the target language. Like BRRS, this scheme works on slices of a given regular language.

DCRS observe that regular expressions provide a friendlier programming interface for specifying inputs. But to use the GS scheme for ranking/unranking, they must first convert the given regular expression to an NFA and then from an NFA to a DFA. The last step often leads to a large blowup in the number of states, sometimes rendering the process completely intractable. (Examples of such regexs, and the associated NFA and DFA sizes, are given in Table 6 in Section 6.) Even when the process is tractable, the precomputed tables that DCRS and BRRS use to implement ranking require space that scales linearly in the number of states in the DFA. Many of the formats used by DCRS require several megabytes of memory; in one case, 383 MB. This is prohibitive for many applications, especially if one wants to keep several potential formats in memory.

Thus, in many instances it would be preferable to use the NFA representation of the given regex, but BRRS showed that ranking given just the NFA representation of a regular language is PSPACE-hard. Building any FPE or FTE scheme that works directly from an NFA has remained an open problem.

We also note that developers might hope for a general purpose FTE scheme, that takes arbitrary regular expressions for the input and output formats, and that can be built from existing deterministic cryptographic primitives (e.g., wideblock tweakable blockciphers) or randomized ones (e.g., authenticated encryption schemes). But actually instantiating such a scheme presents an array of algorithmic and engineering choices; in the current state of affairs, expert knowledge is required.

Summary. While a number of approaches to FPE and FTE exist, there is a gap between theory and developer-friendly tools. Implementations are non-existent, and even expert developers encounter challenges when implementing schemes from the literature, including: understanding and managing memory requirements, developing a "good" construction, or engineering the plaintext/ciphertext format pair. Finally, there exist fundamental performance roadblocks when using some classes of regular expressions. This is compounded by the fact that, a priori, it isn't obvious when a given regex will raise these roadblocks.

3 Overview of libfte

To aid adoption and usage of FPE and FTE, we developed a set of tools known collectively as libfte. At a high level, libfte has two primary components (see Figure 3): a standalone tool called the *configuration assistant*, and a library of algorithms (implemented in a mixture of Python and C/C++) that exposes an API for encryption and decryption via a number of underlying FPE/FTE schemes. Loosely, the API takes a configuration, describing what algorithms to use, and some key inputs for those algorithms, while the assistant helps developers determine good configurations. Let us start by talking about the assistant.

Configuration assistant. A *format* is a tuple $\mathcal{F} = (R, \alpha, \beta)$, where R is a regular expression, and $\alpha \leq \beta$ are numbers. A format defines a set of strings $L(\mathcal{F}) = \{\ s \in L(R) \ \big|\ \alpha \leq |s| \leq \beta\ \}$, where $L(R)$ is the set of strings matched by R. Following traditional naming conventions, we call $L(\mathcal{F})$ the language of the format. Because of its wide-spread use, in libfte the input R is specified in Perl-Compatible Regular Expression syntax. However, we note that PCRE syntax allows expressions that have no equivalent, formal regular expression. For instance, PCRE expressions using $\backslash 1, \backslash 2, ...$ (where $\backslash 1$ is a back-reference to the first capture group; see [1]) are not even context free, let alone regular. Thus, libfte accepts expressions built from a subset of the full PCRE syntax.

Our configuration assistant takes as input two formats, one describing the format of plaintext strings ($\mathcal{F}_P$), and one describing the desired format of ciphertext strings ($\mathcal{F}_C$). It also accepts some "preference parameters", for example specifying the maximum memory footprint of any scheme considered by the assistant, but these are set to some reasonable default value if not specified. It then runs a battery of tests, in an effort to determine which configurations will result in FPE/FTE scheme that abide by the user's inputs. Concretely, the assistant outputs a table listing various possible configurations (some configurations may not be possible, given the user's input), along with information pertaining to expected performance and memory usage. Given the user's preferences, the table lists the best option first. In the case that no available configuration is possible, the assistant provides information as to why, so that the user can alter their inputs and try again.

The encryption API. The algorithm library exposes an encryption API that takes as input an *encryption configuration*, which consist of a plaintext format, a ciphertext format, and a configuration identifier. The latter is a string that specifies the desired methods for performing ranking, unranking, encryption and decryption. The library performs all necessary precomputations (initialize rankers, build look-up tables, etc.) in an initialization function and returns a handle to an object that can perform encryption and decryption, according to the specified configuration. Currently, ten configurations are supported by libfte (see Section 6 for descriptions).

Roadmap. In Sections 4 and 5 we describe in detail the algorithms that result in these configurations. In Section 4 we detail a new type of ranking algorithm, what

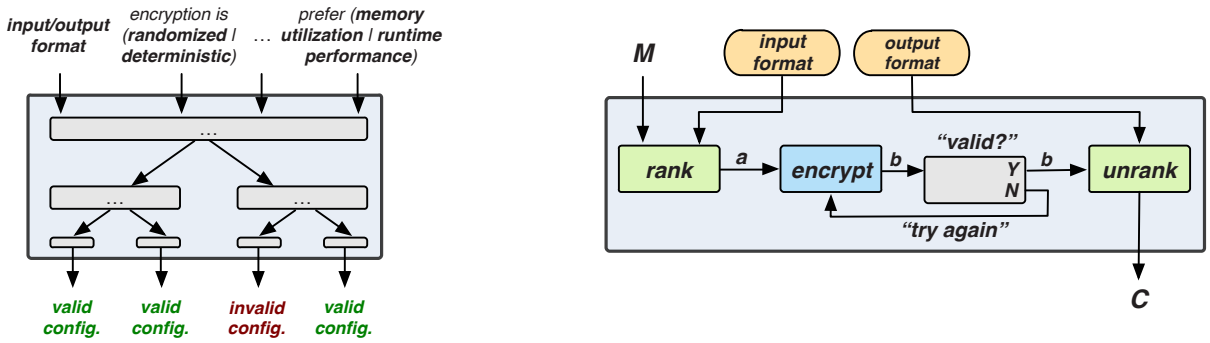

Figure 3: **Left:** The libfte configuration assistant (built against the library) helps users create formats that meet their specific performance requirements. The assistant takes an input/output format pair and uses a decision-tree process to determine if the formats are valid. If the formats are deemed valid, performance statistics are reported for the instantiated scheme(s). **Right:** The library implements APIs for FPE/FTE schemes. Shown is a diagram of the basic flow of our FPE/FTE schemes. As input it takes an input/output format and message M and returns a ciphertext C.

we call *relaxed ranking*, that allows us to work more directly with regular expressions (in particular, their equivalent NFAs), and sidestep the PSPACE-hardness obstacle. In Section 5, we lay out methods of combining relaxed ranking with standard cryptographic primitives to build both deterministic and randomized FPE and FTE schemes. For deterministic schemes, we leverage a technique called *cycle walking*, and for randomized schemes, we employ *rejection sampling*.

Then in Section 6 we describe specific instantiations of these schemes, and explain how the configuration assistant works in more detail. Finally, in Section 7 we show how these schemes can be put to work in three different use cases: database encryption, web form encryption, and network monitor circumvention.

4 Fast, Relaxed Ranking

The rank-encipher-unrank method for constructing FPE/FTE schemes needs efficient techniques for mapping strings in a regular language L to positive integers as well as computing the inverse operation (mapping positive integers back to strings in the language). Existing techniques are often impractical for two main reasons. First, the traditional DFA-based ranking requires the construction of a DFA corresponding to a regular expression. DFAs for some regular expressions can be very large. For instance, the minimum DFA for the regex $(a|b)^*a(a|b)\{20\}$ has $1 + 2^{21}$ states. Second, the numbers involved in ranking can be very large (for languages with many strings) and operations on these integers can therefore be computationally expensive. As an extreme example, ranking a $10,000$-byte long element accepted by the regex $.*$ requires numbers of up to $(2^8)^{10000}$ bits, or $10,000$ bytes. This section tackles these two challenges.

4.1 Relaxed Ranking

We introduce a framework for building FPE and FTE schemes directly from NFAs. The resulting algorithms will often use significantly less memory than the DFA approach, thus enabling general-purpose regex-based ranking in memory-constrained applications. For instance, the NFA for the regex $(a|b)^*a(a|b)\{20\}$ has 48 states.

A key insight is that we can circumvent the negative result about NFA ranking if we shift to a *relaxed ranking* approach, which we formally define in a moment. This will require, in turn, constructing FPE and FTE schemes given only relaxed ranking which we address in Section 5.

4.1.1 Relaxed Ranking Schemes

Informally, a relaxed ranking of a language $\mathcal{L}$ relaxes the requirement for a bijection from $\mathcal{L}$ to $\mathbb{Z}_{|\mathcal{L}|}$.

Formally, a *relaxed ranking scheme* for $\mathcal{L}$ is a pair of functions $\mathsf{Rank}_{\mathcal{L}}$ and $\mathsf{Unrank}_{\mathcal{L}}$, such that:

1. $\mathsf{Rank}_{\mathcal{L}} : \mathcal{L} \to \mathbb{Z}_i$ is injective, $i \geq |\mathcal{L}|$ (Note that we capitalize 'Rank' to distinguish relaxed ranking from ranking.)
2. $\mathsf{Unrank}_{\mathcal{L}} : \mathbb{Z}_i \to \mathcal{L}$ is surjective; and
3. For all $X \in \mathcal{L}$, $\mathsf{Unrank}_{\mathcal{L}}(\mathsf{Rank}_{\mathcal{L}}(X)) = X$.

The last condition means that we can correctly invert points in the image of $\mathcal{L}$, denoted $Img(\mathcal{L}) \subseteq \mathbb{Z}_i$. Note that a ranking is a relaxed ranking with $i = |\mathcal{L}|$.

DFA-based ranking revisited. As a thought experiment, one can view the traditional GS DFA-based ranking for regular languages as follows: let $\mathcal{I}$ be the set of all

accepting paths in a DFA. First, one maps a string $X \in \mathcal{L}$ to its accepting path $\pi_X \in \mathcal{I}$. Then, one maps π_X to an integer via an (exact) ranking. The composition of these two functions yields a ranking function for all strings in $\mathcal{L}$. In the DFA ranking algorithms of [5, 12], these two steps are merged.

A two-stage framework. We can use this two-step procedure to build efficient relaxed ranking algorithms. Suppose we desire to build a relaxed ranking function $\mathsf{Rank}_{\mathcal{L}}$ from a given set $\mathcal{L}$ into $\mathbb{Z}_i$. We first identify three components:

1. an *intermediate* set $\mathcal{I}$ for which we can efficiently perform ranking, i.e., there is an efficient algorithm for $\mathsf{rank}_{\mathcal{I}} : \mathcal{I} \to \mathbb{Z}_i$ where $i = |\mathcal{I}|$;
2. an injective function $\mathsf{map} : \mathcal{L} \to \mathcal{I}$; and
3. a surjective function $\mathsf{unmap}\colon \mathcal{I} \to \mathcal{L}$ such that for all $X \in \mathcal{L}$ it holds that $\mathsf{unmap}(\mathsf{map}(X)) = X$.

We then define

$$\begin{aligned} \mathsf{Rank}_{\mathcal{L}}(X) &= \mathsf{rank}_{\mathcal{I}}(\mathsf{map}(X)) \\ \mathsf{Unrank}_{\mathcal{L}}(Y) &= \mathsf{unmap}(\mathsf{unrank}_{\mathcal{I}}(Y)) \end{aligned}$$

Should unmap additionally be injective, then $\mathsf{Rank}_{\mathcal{L}}$ is a bijection, and we have (strict) ranking.

At first glance, this framework may seem to not have accomplished much as we rely on a strict ranking to realize it. But we will ensure that the language $\mathcal{I}$ allows for strict ranking, and so the framework allows us to transform the problem of ranking from a difficult set ($\mathcal{L}$) to an easier one ($\mathcal{I}$).

4.1.2 Relaxed Ranking Using NFAs

We construct relaxed ranking for NFAs using the approach above. We use as intermediate set $\mathcal{I}$ the set of all accepting paths in the NFA. To map into this set, for each string in $\mathcal{L}$ we deterministically pick an accepting path (a process called *parsing*). To rank on $\mathcal{I}$ we define a path ordering, and generalize the Goldberg-Sipser ranking algorithm for DFAs to count paths based on this ordering.

Recall that an NFA is a 5-tuple $\mathrm{M} = (Q, \Sigma, \delta, q_0, F)$, where Q is a finite set of states, Σ is the alphabet, $\delta \subseteq Q \times \Sigma \times Q$ is the transition relation[2], $q_0 \in Q$ is the start state, and $F \subseteq Q$ is the set of final (or accepting) states. If $(q, a, q') \in \delta$ then M may transition from state q to state q' when the current input symbol is a. We also write a transition $\tau = (q, a, q') \in \delta$ as $q \xrightarrow{a} q'$, where q is the source and q' is the destination of τ.

A *path* π in M is a sequence of transitions

$$q_{i_0} \xrightarrow{a_{j_1}} q_{i_1} \xrightarrow{a_{j_2}} q_{i_2} \cdots q_{i_{n-1}} \xrightarrow{a_{j_n}} q_{i_n} .$$

[2]We assume that there are no ϵ-transitions, but this is without loss of generality as there are standard methods to efficiently remove them from an NFA.

Path π can also be expressed as a sequence of transitions $\tau_1\tau_2 \cdots \tau_n$, where $n = |\pi|$ is the length of π. The suffix π^1 of the path π is $\tau_2 \cdots \tau_n$, and we have $\pi = \tau_1\pi^1$. The sequence of characters in the path is $\pi|_\Sigma = a_{j_1}a_{j_2}...a_{j_n}$.

The intermediate set $\mathcal{I}$. An accepting path is one that ends in an accepting state. Let $\mathrm{Acc}_{\mathrm{M}}(q)$ be the set of accepting paths starting from state q. We let $\mathcal{I} = \mathrm{Acc}_{\mathrm{M}}(q_0)$.

The functions map **and** unmap**.** We must map from $\mathcal{L}$ to $\mathcal{I}$ and back. The latter is simpler: define $\mathsf{unmap}(\pi)$ to be the word $\pi|_\Sigma$. This is fast to compute, in time linear in $|w|$. The forward direction $\mathsf{map}(w)$ requires a deterministic choice for an accepting path for w. This is called *parsing*. Any suitable parsing algorithm will work, but we note that the most obvious algorithms may be quite inefficient. For example, simply recording all accepting paths while running the NFA runs in time exponential in $|w|$ in the worst case.

Linear-time parsing. We now give the (to the best of our knowledge) first algorithm for determining a compact representation of all of an NFA's accepting paths for a string w. Then $\mathsf{map}(w)$ simply runs this algorithm for w and outputs the lexicographically least accepting path. Our algorithm constructs an implicit representation of a directed-acyclic graph (DAG) representing all accepting paths for w. The lexicographically least accepting path for w can then be found using a simple traversal of the DAG. Next we describe the algorithm in detail.

Let $\mathrm{M} = (Q, \Sigma, \delta, q_0, F)$ be an NFA, $Q' \subseteq Q$, and $c \in \Sigma$. We denote by $\delta(Q', c)$ the set of states q such that $(q', c, q) \in \delta$ for some $q' \in Q'$, and by $\delta^{-1}(Q', c)$ the set of states q such that $(q, c, q') \in \delta$ for some $q' \in Q'$.

Consider a string $w = c_1c_2...c_n$. Traditional NFA matching starts with a frontier of states $\mathcal{F}_0 = \{q_0\}$, and at every position k in w it computes $\mathcal{F}_k = \delta(\mathcal{F}_{k-1}, c_k)$. The string is accepted if $\mathcal{F}_n \cap F \neq \emptyset$. However, this does not allow easy recovery of an accepting path, even if all $\mathcal{F}_k$ sets are saved. The main reason for this is that there might be states in the frontiers that do not lead to an accepting state. To work around this, we also scan the input backwards, maintaining a backwards frontier set of states where $\mathcal{B}_n = F$, and $\mathcal{B}_{k-1} = \delta^{-1}(\mathcal{B}_k, c_k)$. Given the sequences $\{\mathcal{F}_k\}$ and $\{\mathcal{B}_k\}$, with $k = 0, ..., n$, we compute $\{\mathcal{S}_k\}$ where $\mathcal{S}_k = \mathcal{F}_k \cap \mathcal{B}_k$. The set $\mathcal{S}_k$ contains all states reachable from the start state following transitions on $c_1...c_k$ such that $c_{k+1}c_{k+2}...c_n$ is an accepting path. Together, $\{\mathcal{S}_k\}$ and the NFA transitions of the form (q, c_k, q') with $q \in \mathcal{S}_{k-1} \wedge q' \in \mathcal{S}_k$, form an implicit Direct Acyclic Graph (DAG) representation of all accepting paths for w. Finally, we traverse this DAG starting from $q_0 \in \mathcal{S}_0$ and following the lexicographically smallest transitions, which yields $\mathsf{map}(w)$.

NFA path ranking. All that remains is to give a strict

ranking algorithm for $\mathcal{I}$, the set of accepting paths in the NFA. Here, we can adapt techniques from the DFA-based ranking by Goldberg and Sipser. Their algorithm can be viewed as a recursive procedure for counting the number of accepting DFA paths that precede a given path in lexicographical order.

Let $T(q, n)$ be the number of paths of length n in $\mathrm{Acc}_{\mathrm{M}}(q)$. Note that, for all $q \in Q$ and $0 \leq i \leq n$, the value of $T(q, i)$ can be computed in polynomial time using a simple dynamic-programming algorithm.

Assume that the NFA transitions are enumerated according to a total ordering, and that $\tau \lessdot \tau'$ means that τ precedes τ' according to this order. The ordering on transitions induces a lexicographical ordering '$\prec$' on paths (which are sequences of transitions). Formally, if $\pi_1 = \tau_1\pi_1^1$ and $\pi_2 = \tau_2\pi_2^1$, then this order is:

$$\pi_1 \prec \pi_2 \iff \tau_1 \lessdot \tau_2 \vee \left(\tau_1 = \tau_2 \wedge \pi_1^1 \prec \pi_2^1\right) \quad (1)$$

Let $\mathsf{rank}(\pi)$ be the number of accepting paths $\pi' \prec \pi$ that precede π in the lexicographical order on paths. It follows that, $\mathsf{rank}(\epsilon) = 0$ (the rank of the empty string is 0), and for any $\pi = \tau\pi^1 \in \mathrm{Acc}_{\mathrm{M}}(q)$, we have:

$$\mathsf{rank}(\pi) = \mathsf{rank}(\pi^1) + \sum_{(q,c',q') \lessdot \tau} T(q', n-1) \quad (2)$$

Note that the sum is over transitions $\tau' = (q, c', q') \in \delta$ that precede τ in transition order, $\tau' \lessdot \tau$. In words, we are summing over all outgoing edges from q that lead to paths that are lexicographically smaller than the paths that follow the transition τ. Unrolling the recursion gives us an iterative procedure for ranking accepting paths of length n that can be efficiently implemented via dynamic programming.

To conclude, the relaxed ranking for a string w accepted by an NFA is $\mathsf{Rank}(w) = \mathsf{rank}(\mathsf{map}(w))$, and the reverse is $\mathsf{Unrank}(r) = \mathsf{unmap}(\mathsf{unrank}(r))$.

4.2 Large Integer DFA/NFA Optimization

We present a simple but effective optimization that speeds up both NFA and DFA-based ranking. In practice, ranking efficiency depends on how fast we evaluate the sum in equation (2), and this depends on the precise definition of the transition order. We define this order so that we can replace multiple large-integer additions with a single multiplication. Our experiments confirmed that this replacement indeed resulted in faster code.

Observe that equations (1) and (2) used for path ranking depend only on transition (edge) order and structure of the automaton. This observation is valid for both NFA and DFA. Previous, traditional, DFA ranking is given by these equations and standard lexicographical ordering, using character order: $(q, c', q') \lessdot (q, c'', q'') \Longleftrightarrow (c' < c'')$. In a DFA $c' = c'' \implies q' = q''$. But equation (1) does not have to use standard lexicographical ordering.

Our idea is to give *priority to states over characters.* We assume a state and character order given by an arbitrary but fixed enumeration of Q and Σ, and use the following order for transitions originating from the same state q: $(q, c', q') \lessdot (q, c'', q'')$ if-and-only-if $(q' < q'')$ or $q' = q''$ and $c' < c''$. This specific order allows for precomputation in equation (2). In equation (2) we can replace all the terms $T(q', n-1)$ which correspond to transitions $(q, c', q') \lessdot \tau$ with $n[q, q'] \times T(q', n-1)$, where the precomputed value $n[q, q']$ represents the number of transitions from q to q'. Similarly, all the terms corresponding to edges $\tau' = (q, c', q'')$, where $\tau' \lessdot \tau = (q, c'', q'')$, can be replaced by $r[q, c'', q''] \times T(q'', n-1)$, where $r[q, c'', q'']$ is the number of such transitions. These optimizations have benefit, because the numbers $T(q, n)$ can be very large multiple precision integers.

5 Building FTE Schemes

Now we turn to building FTE schemes, treating FPE in passing as a special case of FTE. We specifically give two methods for composing relaxed-ranking algorithms with an underlying cryptographic primitive to make an FTE scheme. For deterministic FTE, the cryptographic component is a tweakable cipher (e.g. FFX), and we call the composition *cycle-walking FTE*. For randomized FTE, the cryptographic component is an authenticated encryption scheme, and we call the composition method *rejection-sampling FTE.* (Impatient readers can look ahead to Figure 4 for the pseudocode.) We delay specific instantiations of the schemes until Section 6.1.

Informal FTE scheme syntax. We provide a formal treatment of FTE scheme syntax in the full version. We provide a simpler, more informal discussion of it here; this will suffice for what follows. An FTE scheme is a pair of algorithms $(\mathsf{Enc}, \mathsf{Dec})$. The FTE encryption algorithm Enc takes as inputs

- a key K
- a pair of formats $(\mathcal{F}_P, \mathcal{F}_C)$ that describe the language $L(\mathcal{F}_P)$ of plaintext inputs, and the language $L(\mathcal{F}_C)$ of ciphertext outputs
- a plaintext string $M \in L(\mathcal{F}_P)$
- associated data, and encryption parameters (both optional)

and outputs a ciphertext string $C \in L(\mathcal{F}_C)$, or a special "failure" symbol $\perp$. Associated data is data that must be bound to the underlying plaintext, but whose privacy is not required. (For example, metadata meant to provide context for the use or provenance of the plaintext.) We allow for encryption parameters to help enforce spe-

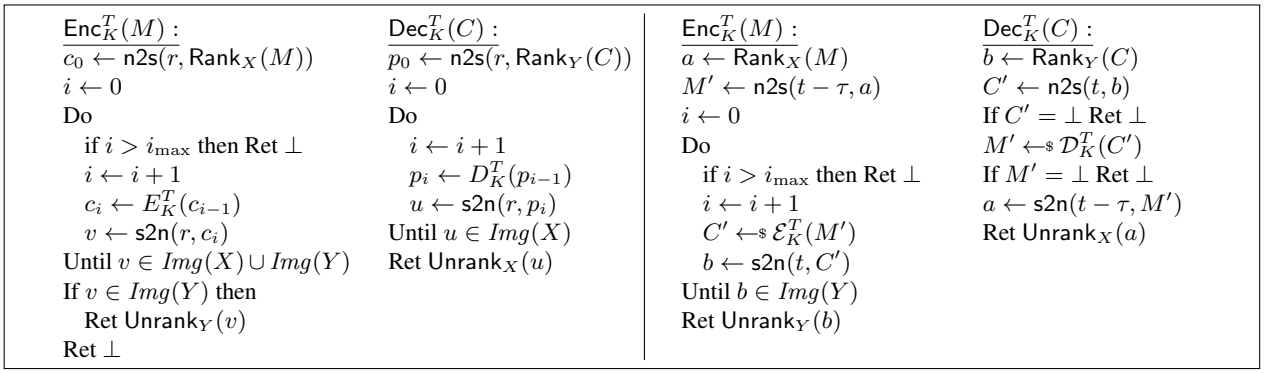

Figure 4: **Left:** Cycle-walking deterministic FTE. $\mathsf{n2s}(r, a)$ returns the string representing number a in radix r, and $\mathsf{s2n}(r, b)$ returns the number whose radix r representation is b. The parameter $i_{\max}$ determines the maximum number of iterations. **Right:** Rejection-sampling randomized FTE.

cific failure criteria, which will become clear when we describe our schemes. We write $\mathsf{Enc}_K^{T,P}(M)$ for FTE encryption of message M, under key K, using associated data T and parameters P. To ease the burden of notation (slightly), we typically do not explicitly list the parameters as inputs. The encryption algorithm may be randomized, meaning that fresh randomness is used for each encryption.

The FTE decryption algorithm Dec takes as input $(\mathcal{F}_P, \mathcal{F}_C), K$, a ciphertext C, and the associated data T (if any), and returns a plaintext M or $\perp$. The decryption algorithm is always deterministic.

Unlike conventional encryption schemes, we do not demand that $\mathsf{Enc}_K^{T,P}(M)$ always yield a valid ciphertext, or always yield $\perp$, when T, P and K are fixed. Instead, we allow encryption to "fail", with some small probability, to produce a ciphertext for a any given plaintext in its domain. Doing so will permit us to give simple and natural FTE schemes that would be ruled out otherwise.

In general, the formats can change during the lifetime of the key, even on a per-plaintext basis. (Of course, changes must be synchronized between parties.) When we talk about an FTE scheme being over some given formats, or their languages, we implicitly have in mind some notion of a format-session, during which the formats do not change.

5.1 Cycle-walking (deterministic) FTE

To build deterministic FTE schemes we take inspiration from BRRS rank-encrypt-unrank. However, accommodating format transformations and, especially, NFA-based language representations introduces new challenges.

To begin, let $X = L(\mathcal{F}_P)$ and $Y = L(\mathcal{F}_C)$. Assume that we perform relaxed ranking using the two-stage framework in Section 4.1.1, with the intermediate sets $\mathcal{I}(X)$ for X and $\mathcal{I}(Y)$ for Y. If Rank_X and Rank_Y are the corresponding relaxed-ranking functions, let $Img(X)$ be the image of X under Rank_X, and likewise $Img(Y)$ be the image of Y under Rank_Y. Define $N_X = |\mathcal{I}(X)|$ and $N_Y = |\mathcal{I}(Y)|$. (Recall that if we are using NFA-based ranking over either X or Y, these values can be significantly larger than $|X|$ or $|Y|$.) We assume that both N_X, N_Y are finite.

Say one has a tweakable cipher[3] E that natively supports strings over a variety of radices, e.g. FFX. (At a minimum, there are many constructions of secure tweakable ciphers that support radix 2, e.g. [9, 14, 15].) Now, fix integers $r \geq 2$ and $t \geq \lceil \max\{\log_r(N_X), \log_r(N_Y)\} \rceil$, so that a string of t symbols from $\{0, 1, \ldots, r-1\}$ suffices to represent the relaxed-rankings of X and Y. Then if E can encipher the set of strings $\{0, 1, \ldots, r-1\}^t$, we can encrypt a plaintext $M \in X$ as shown on the left side of Figure 4.

Cycle walking. A well-known fact about permutations is that they can be decomposed into a collection of disjoint cycles: starting from any element a in the domain of the permutation π, repeated application of π will result in a sequence of distinct values that eventually ends with a. Black and Rogaway [8] were the first to exploit this fact to build ciphers with non-standard domains, and we use it, too. For any fixed K and T, the mapping induced by E_K^T is a permutation. Thus, inside the Do-loop, the distinct strings $c_0, c_1 \leftarrow E_K^T(c_0)$, $c_2 \leftarrow E_K^T(E_K^T(c_0))$, and so on form a sequence that eventually must return to c_0. Intuitively, if we want a ciphertext that belongs to a particular subset $S \subseteq \{0, 1, \ldots, r-1\}^t$, we can walk the cycle until we hit a string $c_i \in S$.

There are, however, two important details to consider. The first is that encryption is not guaranteed to hit *any*

[3] If the FTE scheme does not need to support associated data, then the underlying cipher need not be tweakable, and references to T in the pseudocode can be dropped.

string $c_i \in S$. For example, if the subset is small, or the cycle is very short. So encryption must be equipped with test that tells it when this has happened, and $\perp$ should be returned. The second is that there must be a test that uniquely identifies the starting string c_0. This is because decryption should work by waking the cycle in reverse. Absent a test that uniquely identifies c_0, it may not be clear when the reverse cycle-walk should stop.

Our implementation deals with both of these issues. In particular, c_0 is the t-symbol string that results from relaxed-ranking our FTE plaintext input M. By definition, c_0 is a string that, when viewed as a radix-r integer, is in $Img(X)$. We desire to find a c_i that, when viewed as an integer, is in $Img(Y)$, since this is the set of integers that yield ciphertexts in Y that will be properly decrypted. Intuitively, the walk should halt on the first i for which this is true. But then, if any of $c_1, \ldots, c_{i-1}$ represent integers that are in $Img(X)$, proper decryption is not possible (because we do not know how many steps to go from c_i back to c_0). Thus our cycle-walking encryption checks, at each step, to see if the current walk should be terminated because decryption will not be possible, or because we have found a c_i that will yield a ciphertext Y that will decrypt properly. We also allow cycle-walking FTE to take a maximum-number-of-steps parameter $i_{\max}$, and encryption fails if that number of steps is exceeded.

Efficiency. The standard security assumption for a tweakable cipher is that, for any secret key K, and any associated data T, the mapping induced by E_K^T is indistinguishable from that of a random permutation. Modeling E_K^T as such, the expected number of steps before the cycle-walk terminates is at most $r^t/|Img(X) \cup Img(Y)|$ (a conservative bound) and never more than $i_{\max}$. Assuming the walk terminates before $i_{\max}$ steps, then the probability that the encryption succeeds is $p_s = |Img(Y)|/|Img(X) \cup Img(Y)|$. Since relaxed ranking is injective, $|Img(X)| = |X|$ and $|Img(Y)| = |Y|$, so $p_s \geq 1/(1 + |X|/|Y|)$. Thus we expect that p_s is quite close to 1 if $|Y| \gg |X|$.

Each step of the cycle-walk requires checking $v \in Img(X) \cup Img(Y)$, which can be done by checking $v \in Img(X)$ first (signaling termination of the walk), and then $v \in Img(Y)$ (signaling successful termination). A straightforward way to implement the last is to test if $v = \mathsf{Rank}_Y(\mathsf{Unrank}_Y(v))$ or, using our two-stage viewpoint on relaxed ranking, $\mathsf{map}(\mathsf{Unrank}(v)) = \mathsf{unrank}_{\mathcal{I}}(v)$, which may be faster. Checking $v \in Img(X)$ can be done likewise.

Recall that the NFA representation of a regex, unlike a DFA representation, may have many accepting paths for a given string in its language. This can lead to $N_X \gg |X| = Img(X)$ or $N_Y \gg |Y| = Img(Y)$, hence, potentially, $r^t \gg |Img(X) \cup Img(Y)|$. When this happens, the resulting in cycle-walking scheme may be prohibitively inefficient in some applications.

Simplifications. We note that the cycle-walking technique is used in [5], as well, but they restrict to the much simpler case that $X = Y$. More generally when we know that $Img(X) \subseteq Img(Y)$, we can simplify our construction. One may still need to cycle-walk in this case if $r^t > |Y|$. For example, say one desires to use $r = 2$ (binary strings) but the larger of $|X|, |Y|$ is not a power of two. But when $Img(X) \subseteq Img(Y)$ we know that, if the encryption cycle-walk terminates before $i_{\max}$ steps, then it always finds a point in $Img(Y)$, i.e. $p_s = 1$. Also, the expected number of steps is at most $r^t/|Img(Y)| = r^t/|Y|$, again modeling E_K^T as a random permutation. Finally, we note that the walk termination test can be simplified to $v \in Img(Y)$, and encryption can thereafter immediately return $\mathsf{Unrank}_Y(v)$.

Security. We mentioned, above, that the standard security assumption for a tweakable cipher is that, when the key K is secret, every associated data string T results in $E_K^T(\cdot)$ being indistinguishable from a random permutation. Under this assumption, it is not hard to see that the cycle-walking construction outputs (essentially) random elements of the set $Y = L(\mathcal{F}_c)$, when it does not output $\perp$. Intuitively, each $E_K^T(c_{i-1})$ in the cycle-walk is a random string (subject to permutivity), so the corresponding number v represented by the string is random, too. Thus, if $v \in Img(Y)$, it is a random element of this set, resulting in a random element of Y being chosen when v is unranked.

In the full version we formally define a security notion for deterministic FTE schemes, and give a theorem stating the security of our construction relative to this security notion.

5.2 Rejection-Sampling (randomized) FTE

We now turn our attention to building randomized FTE schemes. Let $\Pi = (\mathcal{K}, \mathcal{E}, \mathcal{D})$ be a conventional, randomized, authenticated-encryption scheme with support for associated data (AEAD). We assume that this scheme has a fixed ciphertext stretch τ; this is typical of in-use AEAD schemes. To build a randomized FTE scheme using a generalized ranking scheme, we use a rejection-sampling approach. Let t be the least integer such that both of the following are true: (1) $|\mathcal{I}(X)| \leq 2^{t-\tau}$, and (2) $|\mathcal{I}(Y)| \leq 2^t$. Then to encrypt $M \in X$, or decrypt $C \in Y$, under key K and associated data T, we do as shown on the right side of Figure 4.

A standard security assumption for AEAD schemes is that its ciphertexts are indistinguishable from strings (of the same length) that are uniformly random. Under this assumption, treating each C' as a random t-bit string, the

Sub-Component	Written in...	Lines of Code
Regular Expression Parser	C/C++/Flex/Bison	2,057
DFA Minimizer	C/C++	1,166
NFA/DFA Ranking	C/C++	2,752
FFX	C++	842
FPE/FTE	C++	870
Configuration Assistant	C++/Python	731

Table 5: The sub-components of libfte.

expected number of invocations of $\mathcal{E}_K^T$ is $2^t/|Img(Y)| = 2^t/|Y|$. (And certainly no more than $i_{\max}$.)

Under this standard security assumption, it is intuitive that any element of $Y = \mathcal{F}_c$ returned by our rejection-sampling FTE is a uniform one. If each C' is indistinguishable from a random string, then the corresponding number b represented by C' is random, too. Hence if $b \in Img(Y)$, then it is a random element of that set, and so the element of Y that results from unranking b will be random.

We give a formal security notion for randomized FTE, and a security theorem for rejection-sampling-based FTE, in the full version.

6 Realizing LibFTE

In Section 5 we explored strategies for constructing FPE/FTE schemes in theory. Now, let's concretely describe the schemes implemented in libfte.

Implementation. The libfte implementation is a hybrid of C, C++, Python, Flex and Bison. We present a detailed breakdown of the sub-components in Table 5. We engineered a custom regular expression parser because off-the-shelf solutions did not expose the appropriate data structures necessary to implement our NFA relaxed-ranking algorithm.

In addition to a native C++ interface, we also provide interfaces in Python and JavaScript for libfte. The Python interface is exposed through a manually-written wrapper around the C++ implementation. The JavaScript interface is provided through C++-to-JavaScript compilation.

6.1 Schemes Implemented in LibFTE

We use a shorthand notation to refer to types of libfte instantiations. As an example, T-ND-$ is a an F**T**E scheme that uses **N**FA-based ranking (Section 4.1) for the input format, and **D**FA-based ranking (Section 4.2) for the output format, and is randomized (**$**); T-ND denotes the same, but the scheme is deterministic. FPE constructions are similarly named, but begin with P.

For deterministic schemes (those without the final $) we use the cycle-walking construction, with FFX[2] as the underlying tweakable cipher. For randomized schemes, we use the rejection-sampling construction. As the underlying encryption scheme, we employ the Bellare-Rogaway "encode-then-encipher" paradigm [6], prepending the result of $\mathsf{Rank}_X(M)$ (interpreted as a fixed-length bitstring) with the appropriate number of random padding bits, and applying FFX[2] to this. Because our particular application of randomized FTE does not need support for associated data, the FFX tweak was fixed to an all-zeros string, and we do not need redundancy padding in our encode-then-encipher scheme.

We note that, although we fixed specific instantiations of FPE/FTE schemes for the sake of a concrete evaluation, there is no reason to restrict to these. In the randomized scheme, for example, one could use CTR-AES (with a random IV) and HMAC-SHA256 in an "encrypt-then-mac" composition [4, 18] (including any associated data in the mac-scope) for the underlying primitive.[4]

6.2 The LibFTE Configuration Assistant

We now turn our attention towards the implementation details of the libfte *configuration assistant*. We divide the internal workflow of the configuration assistant into three steps. First, we gather requirements from the user, this is done by the user passing parameters to a command-line interface. Then, we start with an initial set of all possible FPE/FTE schemes (i.e., P-xx, T-xx, T-xx-$) that one could instantiate, and use a decision tree algorithm to eliminate schemes from the initial set that do not satisfy user requirements. Finally, the configuration assistant analyzes the set of all schemes that were not eliminated in stage two, performs a battery of tests on them, and returns the results to the user. We provide a sample output of this tool in Figure 7.

Collecting requirements from the user. The command-line configuration assistant (see Figure 7) takes two required parameters, the input and output formats. In addition to the required parameters, the configuration assistant takes optional parameters, most notably: the memory threshold for the configuration assistant to determinize regexs, and the memory threshold for FPE/FTE scheme instantiation.

Identifying feasible schemes. Next, the configuration assistant's job is to eliminate schemes that fall outside the user-specified requirements. It starts with a set of all possible FPE/FTE schemes that one could construct (i.e.,

[4] One should keep in mind the interaction between the ciphertext length overheads of AEAD and the expected number of steps in rejection-sampling.

Scheme	Input/Output Format			DFA/NFA States	Memory Required	Encrypt (ms)	Decrypt (ms)
	R	α	β				
P-DD	`(a|b)*`	0	32	2	4KB	0.18	0.18
	`(a|b)*a(a|b){16}`	16	32	131,073	266MB	0.25	0.21
	`(a|a|b){16}(a|b)*`	16	32	18	36KB	0.19	0.18
	`(a|b){1024}`	1,024	1,024	1,026	34MB	1.2	1.2
P-NN	`(a|b)*`	0	32	3	6KB	0.36	0.35
	`(a|b)*a(a|b){16}`	16	32	36	73KB	0.61	0.60
	`(a|a|b){16}(a|b)*`	16	32	51	103KB	1,340	1,340
	`(a|b){1024}`	1,024	1,024	2,049	68MB	6.6	6.6

Table 6: Performance benchmarks for P-DD and P-NN constructions, based on our Python API. The regular expressions have been selected to highlight the strengths and weaknesses of the constructions. Recall that α and β are upper- and lowerbounds (respectively) on the length of strings used in a range slice.

```
$ ./configuration-assistant \
>  --input-format "(a|b)*a(a|b){16}" 0 32 \
>  --output-format "[0-9a-f]{16}" 0 16

==== Identifying valid schemes ====
WARNING: Memory threshold exceeded when
         building DFA for input format

...
```

Figure 7: A sample execution of our configuration assistant for building an FTE scheme. The tool failed to determinize the regex of the input format, and notifies the user that that T-ND, T-NN, T-ND-$ and T-NN-$ constructions are possible. Then reports on the performance of these schemes.

P-xx, T-xx, T-xx-$). If the DFA can't be built (within the user-specified memory thresholds) for the input format, then we eliminate P-Dx, T-Dx and T-Dx-$ schemes from consideration. We repeat this process for the output format. Then we perform a series of additional checks — involving the sizes of $L(\mathcal{F}_P)$, $L(\mathcal{F}_C)$, the sizes of the intermediate representations, the minimum ciphertext stretch of underlying cryptographic primitives, etc. — to cull away schemes that should not be considered further.

Evaluating feasible schemes. Finally, we consider the set of schemes that remain from the previous step. If there are none, we output an error. Otherwise, we iterate through the set of schemes and perform a series of functional and performance tests against them. We have fourteen quantitative tests, such as: the average time elapsed to perform encryption/decryption, the (estimated) probability that encryption returns $\perp$, and memory requirements. The final result of the tool is a table output to the user, each row of the table represents one scheme and the columns are results from the quantitative tests performed. The method for sorting (i.e., prefer memory utilization, prefer runtime performance, etc.) is a user-configurable parameter.

6.3 Performance

We conclude this section with benchmarks of our libfte implementation. All benchmarks were performed on Ubuntu 12.04, with an Intel Xeon E3-1220 at 3.10GHz and 32GB of memory. Numbers reported are an average over 1,000 trials for calls to our libfte Python API. For memory utilization of each scheme, we measure the memory required at runtime to use the specified formats. For encrypt benchmarks we select a random string in the language of the input format and measure the time it takes for encrypt to return a ciphertext. For decrypt benchmarks we select a random plaintext, encrypt it, then measure the time it takes for decrypt to recover the plaintext.

In Table 6 we have the performance of libfte for P-DD and P-NN schemes. Note that `(a|b)*a(a|b){16}` requires roughly four orders of magnitude less memory using a P-NN scheme, compared to a P-DD scheme. With the P-NN scheme for `(a|a|b){16}(a|b)*`, the high encrypt cost is completely dominated by cycle walking, we do roughly 720 FFX[2] encrypt calls per P-NN call. (The configuration assistant would inform the user of this, and the user would have the opportunity to re-write the expression as `(a|b){16}(a|b)*`.) For `(a|b)*`, the two constructions (i.e., P-DD, P-NN) require a comparable amount of memory but the P-DD construction is twice as fast for encryption/decryption.

Due to space constraints we omit benchmarks for T-xx and T-xx-$ schemes in this section, and defer their analysis to Section 7.

7 Exploring LibFTE Use Cases

We turn our attention to integrating libfte into third-party applications. Our goal is to show that libfte is easy to use, flexible, and in some cases *improves* performance, compared to other cryptographic solutions. In this section we consider three use cases: database encryption, web form encryption, and encryption using formats lifted from a network monitoring device.

7.1 Databases

We start with integration of libfte into a PostgreSQL database. For our database we used PostgreSQL 9.1 in its default configuration. Our server was Ubuntu 12.04 with an Intel Xeon E3-1220 v3 @ 3.10GHz and 32GB of memory. We use the pgcrypto library that is included in PostgreSQL's contrib directory as our baseline cryptographic library. We performed all tests with the PostgreSQL client and server on the same machine, such that network latency did not impact our performance results.

The integration of libfte into our database as PostgreSQL stored procedures required 53 lines of plpython code.

Pgbench is tool included with PostgreSQL to measure database performance. As input, pgbench takes a description of a database transaction and runs the transaction repeatedly, emulates concurrent users, and measures statistics such as transactions per second and response latency. We used pgbench's default database schema and transaction set for testing libfte's impact on PostgreSQL performance. The default pgbench testing schema simulates a simple bank and has four tables: accounts, tellers, branches, and history. The default transaction set for testing includes three query types: SELECT (S), UPDATE (U) and INSERT (I). There are three different transaction types that can be selected using pgbench: S, USI, and USUUI — for each transaction type the acronym represents the type and order of queries executed.

In order to test the performance impact libfte has on PostgreSQL, we created four configurations for populating and accessing data in the database:

- **PSQL:** The default configuration and schema used by the pgbench utility for its simple bank application. No encryption is employed.
- **+AES:** The default schema, with the following modifications: the balance columns in accounts, tellers, and branches are changed from type `integer` to type `bytea`. To secure these fields we use AES128 in ECB mode with PKCS padding.
- **+AE:** We use the same schema as **+AES**, but we change our encryption algorithm to pgcrypto's recommended encrypt function `pgp_sym_encrypt`, which provides privacy and integrity of data.
- **+FPE:** We use the default schema, but employ a libfte P-DD scheme with the format $R \leftarrow \backslash\text{-}[0\text{-}9]\{9\}$, $(R, 9, 10)$, to encrypt account balances (in accounts, tellers, and branches) in-place.

Account Balance Queries				
Transaction Type	**Transactions Per Second**			
	PSQL	+AES	+AE	+FPE
S	38,500	30,246	8,380	8,280
USI	2,380	2,259	1,580	1,540
USUUI	99.2	97.5	97.2	96.5

Table 8: A comparison of throughput (transactions/second) for our four database configurations.

We note that in our evaluation we did not have the option to compare libfte to a scheme that provides the same functionality or security, as no prior scheme exists. We compare to **+AES** because it provides a baseline performance that we would not expect libfte to exceed. The comparison to **+AE**, which provides privacy and integrity, can be used as a baseline for the performance of a cryptographic primitive implementation in a widely-used, mature database product.

Performance For each configuration and transaction type we executed pgbench for five minutes with 50 active customers, leaving all other pgbench parameters as default. In all configurations except PSQL, when performing modifications to the database we perform an encrypt when storing the account balance. When retrieving the account balance we recover the plaintext via a call to the decryption algorithm.

In Table 8 we have the have the benchmark results for transactions per second carried out by the server for our four database configurations and three transaction types. For the most complex transaction type (USUUI) our +FPE configuration reduces the number of transactions per seconds by only 0.8%, compared to the +AE configuration. For the simplest query type (S), +FPE reduces the transactions-per-second rate by only 1.1%, compared to +AE. Compared to the +AES configuration the +AE and +FPE reduce the transactions per second by roughly 72%. This is, in fact, not surprising as under the hood the +FPE configuration relies on FFX, which in turn calls AES at least ten times.

In Table 9 we have the average latency for each of the five different query types. This measures the amount of time elapsed between a client request and server response. Compared to the +AE configuration, +FPE introduces no substantial latency.

Simultaneous encryption and compression. As one final test, we deploy a T-DD scheme in our PostgreSQL

Account Balance Queries				
	Average Latency (ms)			
Query	PSQL	+AES	+AE	+FPE
(U) accounts	0.6	1.2	2.1	2.1
(S) accounts	0.4	0.5	1.0	1.0
(U) tellers	412	412	415	420
(U) branches	78	80	80	84
(I) history	0.2	0.2	0.2	0.2

Table 9: Average latency per query for each database configuration.

Credit Card Number Queries					
	PSQL	+AES	+AE	+FPECC	+FTECC
Table Size	50MB	65MB	112MB	50MB	**42MB**
Query Avg.	74ms	92ms	112ms	125ms	110ms

Table 10: FTE for simultaneous encryption and compression. The table size is the amount of space required on disk to store the table. We also present the average query time (over 1,000 trials) for selecting (and decrypting) 100 credit card numbers at random from 1 million records.

database to provide simultaneous privacy and compression. We augment the default pgbench database schema to add a new table for credit card numbers. This table has two columns: an account number of type `integer` and a credit card number field of type `bytea`. (Following the structure of the pgbench schema, we do not add any indexes to this table.) We start with the four configurations we presented in our initial benchmarks. However, we change our +FPE configuration to a P-DD scheme that encrypts 16-digit credit card number in-place and call this +FPECC. Then we introduce a new configuration, +FTECC, a T-DD scheme where our input format is a 16-digit credit card number and our output format is the set of all 7-byte strings.

In each configuration we populated our database with 1 million random credit card numbers. For each database configuration, we have a breakdown (Table 10) of the query cost to retrieve 100 credit card numbers at random (and decrypt, if required) as well as the total size of the new credit card table. Compared to the +AES and +AE configuration, our +FTECC configuration requires 35% and 62.5% less space, respectively. We note that it may be possible to employ additional compression in the PSQL, +FPECC settings (e.g., an int to bitstring conversion). However, such optimizations are not possible in the +AES and +AE configurations.

We also highlight that, with respect to query times (Table 10) our +FTECC configuration modestly outperforms the +AE configuration. Compared to +AES, +FTECC introduces a 19.5% increase in query cost.

7.2 Web Forms

Next, we present a Firefox extension powered by libfte. The job of this browser extension is to encrypt sensitive contact information, client-side, in a Yahoo address book contact form, prior to submission to the remote Yahoo servers.

Browser extension. We tested our libfte-extension with Firefox version 26, using our C++-to-JavaScript compiled libfte API. In addition to libfte , in roughly 200 lines of code, we implemented logic that was responsible for locating page elements to encrypt/decrypt. The Yahoo-specific logic was minimal and consisted of mappings between form fields and FPE/FTE schemes.

Fields were manually specified using unique identifiers (e.g., CSS id tags) and mapped to their corresponding P-DD FPE scheme in JavaScript. There are many options for determining what input/output formats to use for a given scheme. For this proof-of-concept we started with a set of formats we considered to be reasonable, then progressively relaxed/increased constraints on the formats appropriately until they were accepted by Yahoo's server-side validation. As a couple examples, we found that the email address field is required to have an @ symbol, and all dates are required to be valid date ranges. (e.g., month must between 1 and 12 inclusive) We expect that such constraints could be identified programmatically, at scale, using a browser automation tool such as Selenium [2].

Our Firefox extension exposes an "encrypt/decrypt" drop-down menu to the user. Prior to saving a new contact to their address book, the user can press the "encrypt" button to automatically libfte-encrypt all fields in the form. To recover the encrypted data, they user visits the page for a contact, then presses the libfte extension's decrypt button to recover the plaintext data. With further engineering efforts this encryption/decryption process could be transparent to the user. We present a screenshot of our extension in Figure 11.

7.3 Network Monitors

Finally, we turn our attention to building T-xx-$ schemes (as used in [11]) by lifting regular expressions from the Snort IDS [19]. As far as these authors are aware, this Snort IDS corpus of regular expressions is the largest and most diverse (publicly available) set of regexes used for deep-packet inspection.

In the initial exploration of FTE by Dyer et al. [11] a fundamental limitation to their construction was the need to perform a regex-to-DFA conversion for formats. Unfortunately, this creates a natural asymmetry: systems

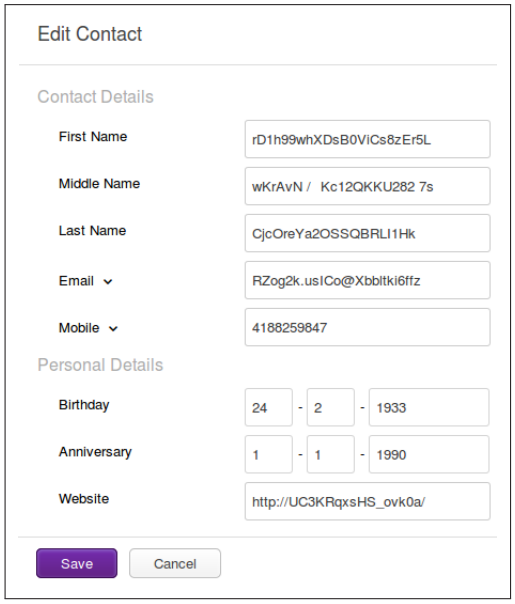

Figure 11: Screenshot from our Firefox Browser Extension that encrypts the data fields of our Yahoo address book, client-side, prior to transmission to the Yahoo servers.

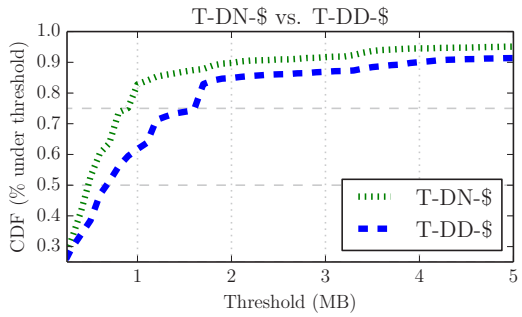

Figure 12: The CDF representing the fraction of the Snort corpus that can be instantiated for a given memory threshold. The CDF graph has a long tail and reaches 100% at 143MB for T-DN-$. We were unable to calculate the threshold for T-DD-$ to reach 100%, due to memory constraints on our test system.

such as Snort are able to perform network monitoring directly from an NFA representation, but the construction presented by Dyer et al. requires regex-to-DFA conversion. In this section we show that we've overcome this limitation — regular expressions that were intractable using the construction by Dyer et al. are no longer an obstacle, given our new NFA ranking algorithm.

Snort IDS regex corpus. To build our corpus, we started with the official Snort ruleset, version 2955, released Jan 14, 2014. Each rule in the ruleset contains a mixture of values, including static strings or regular expressions to match against traffic. From each rule we extracted all regular expressions (as defined by the `pcre` field) which resulted in 6,277 expressions. Of these, 3,458 regular expressions compiled with our regular expression parser[5]. For all regular expressions that compiled, if we were able to instantiate their precomputation table in memory, we were able to successfully utilize them for encryption.

Corpus evaluation. For each regular expression R in the Snort corpus we attempted to build a T-DD-$ and T-DN-$ scheme with an output format $\mathcal{F} \leftarrow (R, 0, 256)$, and input format that is a $\lfloor \log_2 |L(\mathcal{F})| \rfloor$-bit string. This choice of libfte scheme and α and β is motivated by the construction in [11].

In Figure 12 we plot the CDF of the fraction of the corpus that can be instantiated when constrained by a given memory threshold, for each scheme. At 1MB, roughly 60% of the corpus can be instantiated using T-DD-$ ranking, compared to roughly 85% of the corpus with T-DN-$ ranking. At 5MB, T-DN-$ is at roughly 97% and T-DD-$ is at roughly 92%. If we increase the threshold to 143MB (beyond the focus of the graph) we can instantiate 100% of the corpus using T-DN-$. Yet, at at threshold of 1GB, we are able to instantiate only 97.0% of the corpus using T-DD-$. In fact we were unable to construct some schemes (due to memory constraints) using T-DD-$, so we don't know the exact threshold required to reach 100% instantiation.

As a final test we measured the *total* memory utilization for instantiating the complete Snort corpus. Initially, we instantiated all regular expressions in the corpus using T-DD-$, which required a cumulative 8.8GB of memory. Then we considered a "best case" scenario, where, over the 97% of tractable regexs (those that we could construct a T-DD-$ scheme) we took the minimum of the T-DD-$ or T-DN-$ memory utilization. Using the best-case approach we reduced memory utilization to 6.2GB, a reduction of roughly 30%. The best-case scenario is, of course, biased against T-DN-$, as 3% of the corpus couldn't be instantiated with T-DD-$.

8 Conclusion

In this paper we presented a unifying approach for deploying format-preserving encryption (FPE) and format-transforming encryption (FTE) schemes. The approach is realized via a library we call libfte, which has two components: an offline configuration assistant to aid engineers in developing formats and understanding their system-level implications, and an API for instantiating

[5]We don't support greedy operators `*?` or case insensitivity `(?i...)`, which accounted for the majority of compilation failures. Greedy operators are used for parsing, not for language definition, and we do not support extended patterns of the form `(?...)` in general.

and deploying FPE/FTE schemes. In the development of libfte we overcame a number of obstacles. Most notably, we developed a new approach to perform FPE/FTE directly from the NFA representation of a regular expression, which was previously considered to be impractical. This significantly increases the expressiveness of regular languages for which FTE can be made useful in practice, and generally improves system efficiency, potentially making FTE a viable cryptographic option in contexts where it previously was not. We studied libfte performance empirically in several application contexts, finding that it typically introduces negligible performance overhead relative to conventional encryption. In some cases (e.g. simultaneous compressions and encryption) even enables substantial performance improvements.

Our work surfaces many avenues for future research. To name a few: investigate the security of libfte's algorithms (and FTE implementations, in general) in the face of side-channel attacks; integrate FTE into additional applications, and report on newly found algorithmic and engineering challenges; and explore efficiency improvements for specific classes of regular expressions that are in wide use. To promote further research and development, we will make libfte open source and publicly available at `https://libfte.org/`.

Ad-Hoc Secure Two-Party Computation on Mobile Devices using Hardware Tokens

Daniel Demmler, Thomas Schneider, and Michael Zohner

Technische Universität Darmstadt, Germany
{daniel.demmler,thomas.schneider,michael.zohner}@ec-spride.de

Abstract

Secure two-party computation allows two mutually distrusting parties to jointly compute an arbitrary function on their private inputs without revealing anything but the result. An interesting target for deploying secure computation protocols are mobile devices as they contain a lot of sensitive user data. However, their resource restriction makes the deployment of secure computation protocols a challenging task.

In this work, we optimize and implement the secure computation protocol by Goldreich-Micali-Wigderson (GMW) on mobile phones. To increase performance, we extend the protocol by a trusted hardware token (i.e., a smartcard). The trusted hardware token allows to pre-compute most of the workload in an initialization phase, which is executed locally on one device and can be pre-computed independently of the later communication partner. We develop and analyze a proof-of-concept implementation of generic secure two-party computation on Android smart phones making use of a microSD smartcard. Our use cases include private set intersection for finding shared contacts and private scheduling of a meeting with location preferences. For private set intersection, our token-aided implementation on mobile phones is up to two orders of magnitude faster than previous generic secure two-party computation protocols on mobile phones and even as fast as previous work on desktop computers.

1 Introduction

Secure two-party computation allows two parties to process their sensitive data in such a way that its privacy is protected. In the late eighties, Yao's garbled circuits protocol [Yao86] and the protocol of Goldreich-Micali-Wigderson (GMW) [GMW87] showed the feasibility of secure computation. However, secure computation was considered to be mostly of theoretical interest until the Fairplay framework [MNPS04] demonstrated that it is indeed practical. Since then, many optimizations have been proposed and several frameworks have implemented Yao's garbled circuits protocol (e.g., FastGC [HEKM11]) and the GMW protocol (e.g., the framework of [CHK+12]) on desktop PCs.

Motivated by the advances of secure computation on desktop PCs, researchers have started to investigate whether secure computation can also be performed in the mobile domain. Mobile devices, in particular smartphones, are an excellent environment for secure computation, since they accompany users in their daily lives and typically hold contact information, calendars, and photos. Users also store sensitive data, such as passwords or banking information on their devices. Moreover, typical smartphones are equipped with a multitude of sensors that collect a lot of sensitive information about their users' contexts. Therefore, it is of special importance to protect the privacy of data handled in the mobile domain.

In contrast to desktop PCs, mobile devices are rather limited in computational power, available memory, communication capabilities, and most notably battery life. Although mobile phones have seen an increase in processing speed over the past years, they are still about one order of magnitude slower than typical desktop computers when evaluating cryptographic primitives (cf. §5.4). These differences are due to the CPU architectures having a more restrictive instruction set and being optimized for low power consumption rather than performance, since mobile devices are battery-powered and lack active cooling. Moreover, the limited size of the main memory requires the programmer to carefully handle data objects in order to avoid costly garbage collections on Java-based Android smartphones. Network connections of mobile devices are almost exclusively established via wireless connections that have lower bandwidth and higher, often varying latency compared to wired connections. Tasks that are computationally in-

tensive or require long send/receive operations should be avoided when a mobile device is running on battery, as such tasks quickly drain the battery charge and thereby reduce the phone's standby time. Instead, such operations could be pre-computed when the mobile device is connected to a power source, which usually happens overnight. These limitations pose a big challenge for efficient secure computation and cause generic secure computation protocols to be several hundred times slower on mobile devices than on desktop PCs [HCE11], even in the semi-honest adversary model.

To enable secure two-party computation in the mobile domain, solutions have been developed that outsource secure computation to the cloud, e.g., [KMR12, Hua12, CMTB13]. However, recent events have shown that cloud service providers can be forced to give away data to third parties that are not necessarily trusted, such as foreign government agencies. Even if the employed protocols ensure that the cloud provider learns no information about the users' sensitive data, he can still learn and hence be forced to reveal meta-information such as the frequency of access, communication partners involved, the computed function, or the size of the inputs. Moreover, these server-aided approaches require the mobile device to be connected to the Internet which might not be possible in every situation or may cause additional costs.

An alternative solution, which we also use in this work, is to outsource expensive operations to a trusted hardware token that has very limited computational resources and is locally held by one of the communication partners.[1] Such hardware tokens are increasingly being adopted in practice, e.g., trusted platform modules (TPMs). Their adoption is particularly noteworthy on mobile devices in the form of smartcards that are the basis for subscriber identity modules (SIM cards), as well as for mobile payment or ticketing systems. A first approach for outsourcing Yao's garbled circuits protocol to such a trusted hardware token was proposed in [JKSS10]. However, this protocol requires the function to be known in advance and uses costly symmetric cryptographic operations during the online phase. We give an alternative solution that removes these drawbacks.

1.1 Outline and Our Contributions

In this work, we introduce a scheme for token-aided ad-hoc generic secure two-party computation on mobile devices based on the GMW protocol. After introducing preliminaries (§2) we detail our setting and trust assumptions that are similar to the ones in a TPM scenario (§3). We outline how a trusted hardware token can be used to shift major parts of the workload into an initialization phase that can be pre-computed on the token, independently of the later communication partner (§4), e.g., while the mobile device is charging. We thereby obtain a token-aided scheme that is well-suited for efficient and decentralized (ad-hoc) secure computation in the mobile domain. We implement and evaluate our scheme (§5) and demonstrate its performance using typical secure computation applications for mobile devices, such as securely scheduling a meeting with location preferences and privacy-preserving set intersection (§6). We compare our scheme to related work (§7) and conclude and present directions for future work (§8). More detailed, our contributions are as follows.

Token-Aided Ad-Hoc Secure Two-Party Computation on Mobile Devices (§4) We develop a token-aided secure computation protocol which offloads the main workload of the GMW protocol to a pre-computation phase by introducing a secure hardware token $\mathcal{T}$, held by one party $\mathcal{A}$ (cf. §3). $\mathcal{T}$ is issued by a trusted third party and provides correlated randomness [Hua12, Chap. 6] to both parties that is later used in the secure computation protocol. To prepare the secure computation, the other party $\mathcal{B}$ obtains seeds for his part of the correlated randomness from $\mathcal{T}$ via an encrypted channel. To further increase flexibility, we describe how to make the pre-computation independent of the size of the evaluated function $|f|$, at the cost of a $t \cdot \log_2 |f|$ factor communication overhead between $\mathcal{T}$ and $\mathcal{B}$, where t is the symmetric security parameter. In contrast to Yao-based approaches [MNPS04, JKSS10, HCE11, HEK12] and previous realizations of the GMW protocol [CHK+12, SZ13, ALSZ13], our protocol offers several benefits as summarized in Tab. 1 (cf. §4.5 for details).

Table 1: Comparison with related work.

Property	Yao [HCE11]	Token Yao [JKSS10]	GMW [CHK+12]	Ours §4
f unknown in init phase	✓	✗	✓	✓
ad-hoc communication $\ll t \cdot \lvert f \rvert$	✗	✓	✗	✓
$\ll \lvert f \rvert$ crypto operations in ad-hoc phase	✗	✗	✗	✓

Implementation (§5) We implement our token-aided protocol for semi-honest participants and evaluate its performance using two consumer-grade Android smartphones and an off-the-shelf smartcard. Thereby, we provide an estimate for the achievable runtime of generic se-

[1] This locality is also a security feature, as external adversaries either need to corrupt the token before it is shipped to the user or later get physical access to break into it.

cure computation in the mobile domain. Our implementation enables a developer to specify the functionality as a Boolean circuit, which can, for instance, be generated from a high-level specification language. We show that the performance of our token-aided pre-computation phase is comparable to interactively generating the correlated randomness using oblivious transfer.

Applications (§6) We demonstrate the practical feasibility of the GMW protocol on mobile devices by performing secure two-party computation on two smartphones using various privacy-preserving applications such as availability scheduling (§6.1), location-aware scheduling (§6.2), and set-intersection (§6.3). Most notably, for private set-intersection, our token-aided scheme outperforms related work that evaluates generic secure computation schemes on mobile devices [HCE11] by up to two orders of magnitude and has a performance that is comparable with secure computation schemes that are executed in a desktop environment [HEK12].

2 Preliminaries

In the following, we define our notation (§2.1) and the ad-hoc scenario (§2.2), and give an overview of oblivious transfer (§2.3) and the GMW protocol (§2.4). We describe Yao's garbled circuits in the full version [DSZ14].

2.1 Notation

We denote the two parties that participate in the secure computation as $\mathcal{A}$ and $\mathcal{B}$. We use the standard notation for bitwise operations, i.e., $x \oplus y$ denotes bitwise XOR, $x \wedge y$ bitwise AND, and $x||y$ the concatenation of two bit strings x and y. We refer to the symmetric security parameter as t and the function to be evaluated as f.

2.2 Ad-Hoc Scenario

In an *ad-hoc* secure two-party computation scenario, two parties that do not necessarily know each other in advance want to spontaneously perform secure computation of an arbitrary function f on their private inputs x and y. Traditionally, secure computation protocols consist of two interactive phases: the *setup phase* (independent of x and y) and the *online phase*. We extend this setting by a local *init phase* as depicted in Fig. 1.

The init phase takes place at any time before the parties have identified each other and is used for preprocessing. In the setup phase, the parties have determined their communication partner, establish a communication channel, and know an upper bound on the function size $|f|$. In the online phase, the parties provide their private inputs x and y to the function f that they want to evaluate and begin the secure computation. The *ad-hoc time* is the combined time for setup and online phase.

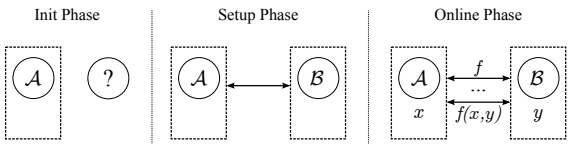

Figure 1: The three secure computation phases.

2.3 Oblivious Transfer

Oblivious transfer (OT) is a fundamental building block for secure computation. In an OT protocol [Rab81], the sender inputs two strings (s_0, s_1). The receiver inputs a bit $c \in \{0,1\}$ and obtains s_c as output without revealing to the sender which of the two messages he chose and without the receiver learning any information about s_{1-c}. OT protocols, such as [NP01], require public-key cryptography and make OT a relatively costly operation. OT extension [IKNP03] allows to increase the efficiency of OT by extending a small number of t base OTs to a large number $n \gg t$ of OTs whilst only using $\mathcal{O}(n)$ symmetric cryptographic operations. Optimizations to the OT extension protocol of [IKNP03] were suggested in [ALSZ13], which allow the parties to reduce the amount of data sent per OT. Moreover, [ALSZ13] describes a more efficient variant of the OT extension protocol for computing random OT, where the sender obtains two random values as output of the OT protocol.

2.4 The GMW Protocol

In the GMW protocol [GMW87], two (or more) parties compute a function f, represented as Boolean circuit on their private inputs by secret sharing their inputs using an XOR secret sharing scheme and evaluating f gate by gate. Each party can evaluate XOR gates locally by computing the XOR of the input shares. AND gates, on the other hand, require the parties to interact with each other by either evaluating an OT or by using a *multiplication triple* [Bea91] as shown in the full version [DSZ14]. Finally, all parties send the shares of the output wires to the party that shall obtain the function output. The main cost factors in GMW are the total number of AND gates in the circuit, called (multiplicative) size $|f|$, and the highest number of AND gates between any input wire and any output wire, called (multiplicative) depth $d(f)$.

Because an interactive OT is required for each AND gate, it was believed that GMW is very inefficient compared to Yao's garbled circuits. However, in [CHK+12] it was shown that by using OT extension [IKNP03] and OT pre-computation [Bea95] many OTs can be

pre-computed efficiently in an interactive setup phase. Thereby, all use of symmetric cryptographic operations is shifted to the setup phase, leaving only efficient one-time pad operations for the online phase. Additionally, the setup phase only requires an upper bound on $|f|$ to be known before the secure computation. Follow-up work of [SZ13] demonstrated that, by using OT to pre-compute multiplication triples in the setup phase, the online phase can be further sped up. Multiplication triples are random-looking bits a_i, b_i, and c_i, for $i \in \{\mathcal{A}, \mathcal{B}\}$, satisfying $(c_\mathcal{A} \oplus c_\mathcal{B}) = (a_\mathcal{A} \oplus a_\mathcal{B}) \wedge (b_\mathcal{A} \oplus b_\mathcal{B})$, that are held by the respective parties and used to mask private data during the secure computation. This masking is done very efficiently, since no cryptographic operations are required. In [ALSZ13] it was shown that multiplication triples can be generated interactively using two random OTs. [Hua12] proposed to let a trusted server generate the multiplication triples and send (a_i, b_i, c_i) to party i over a secure channel via the Internet. In our work, we propose to do this locally, without knowing the communication partner in advance.

3 Our Setting

In our setting, depicted in Fig. 2, we focus on efficient ad-hoc secure computation between two semi-honest (cf. §3.1) parties $\mathcal{A}$ and $\mathcal{B}$ who each hold a mobile device, which are approximately equally powerful but significantly weaker than typical desktop computer systems. The parties' devices are connected via a wireless network and are battery-powered.

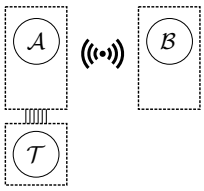

Figure 2: The parties involved in the secure computation.

$\mathcal{A}$ holds a general-purpose tamper-proof hardware token $\mathcal{T}$ that has very few computational resources. $\mathcal{T}$ is powered by $\mathcal{A}$, and its functionalities are limited to the standard functionalities described in §3.2. $\mathcal{A}$ and $\mathcal{T}$ are connected via a physical low-bandwidth connection and communicate via a fixed interface. $\mathcal{B}$ and $\mathcal{T}$ communicate via $\mathcal{A}$, i.e., every message that $\mathcal{B}$ and $\mathcal{T}$ exchange, is seen and relayed by $\mathcal{A}$. Note that this directly requires all communication between $\mathcal{B}$ and $\mathcal{T}$ to be encrypted such that it cannot be read by $\mathcal{A}$. We assume that $\mathcal{T}$ behaves semi-honestly, and is issued by a third party, external to and trusted by both $\mathcal{A}$ and $\mathcal{B}$ (cf. §3.2).

3.1 Adversary Model

We assume that both parties behave semi-honestly in the online phase, i.e., they follow the secure computation protocol, but may try to infer additional information about the other party's inputs from the observed messages. To the best of our knowledge, all previous work on secure computation between two mobile phones is based on the semi-honest model (cf. §7.1). The semi-honest model is suitable in scenarios where the parties want to prevent inadvertent information leakage and for devices where the software is controlled by a trusted party (e.g., business phones managed by an IT department) or where code attestation can be applied. Moreover, this model gives an estimate on the achievable performance of secure computation. We outline how to extend our protocol to malicious security in the full version [DSZ14].

3.2 Trusted Hardware Token

We use the term trusted hardware token $\mathcal{T}$ to refer to a tamper-proof, programmable device, such as a Java smartcard, that offers a restricted set of functionalities. Such functionalities include, for instance, hashing, symmetric and asymmetric encryption/decryption, secure storage and secure random number generation. A detailed summary of standard smartcard functionalities is given in [HL08]. The hardware token is passive, i.e., it cannot initiate a communication by itself and only responds to queries from its host. It contains both persistent and transient memory. $\mathcal{T}$ is physically protected against attacks and is securely erased if it is opened by force. Each token holds an asymmetric key pair, similar to an endorsement key used in TPMs [TCG13], where the public key is certified by a known trusted third party and allows unique identification of $\mathcal{T}$.

Tiny Trusted Third Party $\mathcal{T}$ acts as a tiny trusted third party that behaves semi-honestly. This assumption is similar to the TPM model that is widely used in desktop environments. $\mathcal{T}$ only provides correlated randomness that is later used in the secure computation and does never receive any of $\mathcal{A}$ or $\mathcal{B}$'s private inputs. We assume that only certified code is allowed to be executed on $\mathcal{T}$, and that $\mathcal{T}$ can only actively deviate from the protocol if the hardware token's manufacturer programmed it to be malicious. We assume the code certification was carried out by a trusted third party, and argue that both the manufacturer and the certification authority would face severe reputation loss if it was discovered that they built backdoors into their products. Moreover, we assume that neither $\mathcal{A}$ nor $\mathcal{B}$ colludes with the hardware token manufacturer. This non-collusion assumption is a common requirement for outsourced secure computation schemes

such as [Hua12, KMR12, CMTB13] and enables the construction of efficient protocols. Finally, note that, although $\mathcal{T}$ is in $\mathcal{A}$'s possession, $\mathcal{A}$ cannot easily corrupt $\mathcal{T}$ or obtain its internal information, since $\mathcal{T}$ is assumed to be tamper-proof and does not reveal internal secrets, i.e., the costs of an attack are higher than the benefits from breaking $\mathcal{T}$'s security. This assumption also holds if $\mathcal{A}$ colludes with or impersonates $\mathcal{B}$.

Protection Against Successful Hardware Attacks A malicious adversary could try to break into the hardware token. If such an attack is successful, the following standard countermeasures can be used to prevent further damage: A binding between token and key pair can be realized by using techniques such as physically uncloneable functions (PUFs), however, we are not aware of solutions that are available in commercial products. To bind a token to a certain mobile device or person, $\mathcal{T}$'s certificate could be personalized with one or multiple values that are unique per user and that can be verified over an off-band channel, such as the user's telephone number or the ID of the user's passport. Another line of defense can be certificate revocation lists (CRLs) that allow the users to check if a token is known to be compromised or malicious.

4 Token-aided Mobile GMW

In the following section, we give details on our token-aided GMW-based protocol on mobile devices. Our goal is to minimize the ad-hoc time, i.e., the time from establishing the communication channel between $\mathcal{A}$ and $\mathcal{B}$ until receiving the results of the secure computation. We consider the init phase to not be time critical, but we try to keep its computational overhead small.

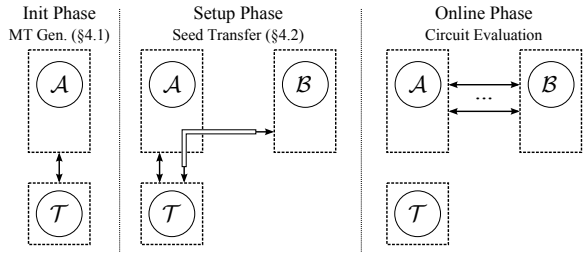

Figure 3: The three phases, workload distribution, and communication in our token-aided scheme.

An overview of our protocol is given in Fig. 3. The general idea is to let the hardware token generate multiplication triples from two (or more) seeds in the init phase that are independent of the later communication partner (§4.1). In the setup phase, $\mathcal{T}$ then sends one seed to $\mathcal{A}$ and the other seed over an encrypted channel to $\mathcal{B}$ (§4.2). The token thereby replaces the OT protocol in the setup phase and allows pre-computing the multiplication triples independently of the communication partner. The online phase of the GMW protocol remains unchanged. In order to overcome the restriction that the function size needs to be known in advance, we describe a method that pre-computes several multiplication triple sequences of different size and only adds a small communication overhead in the setup phase (§4.3). Finally, we analyze the security of our protocol (§4.4) and compare its performance to previous solutions (§4.5).

4.1 Multiplication Triple Pre-Computation in the Init Phase

In the original GMW protocol, $\mathcal{A}$ and $\mathcal{B}$ interactively compute their multiplication triples $(a^n_\mathcal{A}, b^n_\mathcal{A}, c^n_\mathcal{A})$ and $(a^n_\mathcal{B}, b^n_\mathcal{B}, c^n_\mathcal{B})$ in the setup phase using $2n$ random OT extensions (cf. §2.4). Instead, we avoid this overhead in the setup phase and let $\mathcal{T}$ pre-compute the multiplication triples in the init phase as shown in Fig. 4: $\mathcal{T}$ first *generates* random seeds and then *expands* these seeds internally into the multiplication triples and sends $c^n_\mathcal{A}$ to $\mathcal{A}$.

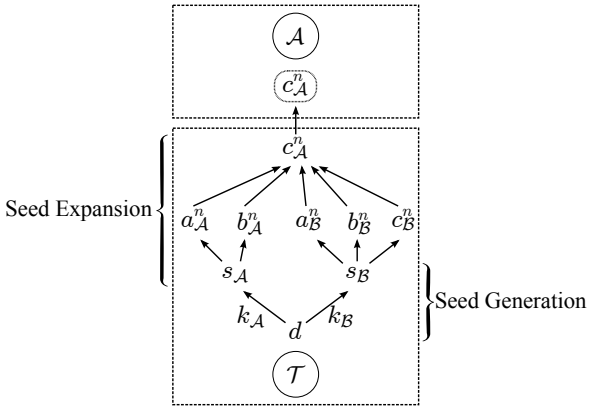

Figure 4: Multiplication triple pre-generation in the init phase between $\mathcal{A}$ and $\mathcal{T}$.

Seed Generation In the seed generation step, $\mathcal{T}$ generates two seeds $s_\mathcal{A} = G_{k_\mathcal{A}}(d)$ and $s_\mathcal{B} = G_{k_\mathcal{B}}(d)$ using a cryptographically strong Pseudo-Random Generator (PRG) G, two master keys $k_\mathcal{A}$ and $k_\mathcal{B}$, and a state value d, which is unique per multiplication triple sequence and can be instantiated with a counter. The two master keys $k_\mathcal{A}$ and $k_\mathcal{B}$ are constant for all multiplication triple sequences and have to be generated and stored only once. Thereby, $\mathcal{T}$ has to store only the unique state value d in its internal memory for every multiplication triple sequence. Note that the only values that will leave the internal memory of $\mathcal{T}$ are the seeds $s_\mathcal{A}$ and $s_\mathcal{B}$

that will be sent in the setup phase to $\mathcal{A}$ and $\mathcal{B}$, respectively (cf. §4.2). In order to ensure that $s_\mathcal{B}$ is not sent out twice, we require $s_\mathcal{A}$ to be queried before $s_\mathcal{B}$ and delete the state value d as soon as $s_\mathcal{B}$ has been sent out. A security analysis of this scheme is given in §4.4.

Seed Expansion The seed expansion step computes a valid multiplication triple sequence from the seeds $s_\mathcal{A}$ and $s_\mathcal{B}$ by computing $(a^n_\mathcal{A}, b^n_\mathcal{A}) = G_{s_\mathcal{A}}(d_\mathcal{A})$ and $(a^n_\mathcal{B}, b^n_\mathcal{B}, c^n_\mathcal{B}) = G_{s_\mathcal{B}}(d_\mathcal{B})$ and setting the remaining value $c^n_\mathcal{A} = (a^n_\mathcal{A} \oplus a^n_\mathcal{B}) \wedge (b^n_\mathcal{A} \oplus b^n_\mathcal{B}) \oplus c^n_\mathcal{B}$, where $d_\mathcal{A}$ and $d_\mathcal{B}$ are publicly known state values of $\mathcal{A}$ and $\mathcal{B}$, respectively. Due to the limited memory of the hardware token, the sequence $c^n_\mathcal{A}$ is computed block-wise such that $\mathcal{T}$ requires only a fixed amount of memory, independently of n, and each block is sent to $\mathcal{A}$, who stores it locally. Note that the values $(a^n_\mathcal{A}, b^n_\mathcal{A}, a^n_\mathcal{B}, b^n_\mathcal{B}, c^n_\mathcal{B})$ do not need to be stored, since they can be expanded from $s_\mathcal{A}$ and $s_\mathcal{B}$, respectively.

4.2 Seed Transfer in the Setup Phase

In the setup phase, the hardware token sends the seeds $s_\mathcal{A}$ and $s_\mathcal{B}$ to $\mathcal{A}$ and $\mathcal{B}$, respectively, and the parties generate their multiplication triples as depicted in Fig. 5. $\mathcal{A}$ obtains his seed $s_\mathcal{A}$ directly from $\mathcal{T}$ and can read the sequence $c^n_\mathcal{A}$, which was obtained in the init phase, from its internal flash storage. $\mathcal{B}$'s seed $s_\mathcal{B}$, on the other hand, cannot be sent in plaintext from $\mathcal{T}$ to $\mathcal{B}$ as the communication between the token and $\mathcal{B}$ is relayed over $\mathcal{A}$, which would allow $\mathcal{A}$ to intercept $s_\mathcal{B}$. We therefore require the communication between $\mathcal{B}$ and $\mathcal{T}$ to be encrypted and $\mathcal{T}$ to authenticate itself to $\mathcal{B}$ with a certificate.

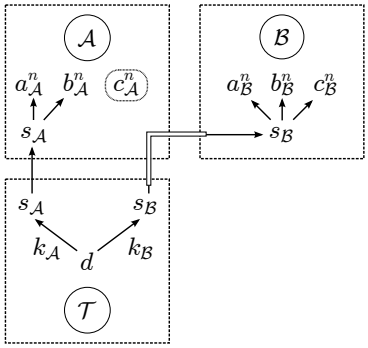

Figure 5: Seed transfer and seed expansion in the setup phase. $s_\mathcal{B}$ is sent from $\mathcal{T}$ to $\mathcal{B}$ over a secure channel.

An encrypted and one-way authenticated communication channel can be established using a key agreement protocol from a wide variety of choices (cf. [MvOV96]). We choose two protocols that allow us to handle different attacker models: For security against a malicious (active) $\mathcal{A}$ we use *TLS* [IET08] (with RSA for public-key crypto, AES for symmetric encryption, and HMAC as message authentication code) and for security against a semi-honest (passive) $\mathcal{A}$ we use KAS1-basic [NIS09] (with AES for symmetric encryption), cf. the full version [DSZ14] for details. Both schemes use $\mathcal{T}$'s public-key certificate that is signed by a trusted third party. For every new connection this certificate is verified by $\mathcal{B}$ and optionally checked against a CRL and/or is checked to be consistent with $\mathcal{A}$'s identity over an out-of-band channel to protect against hardware attacks (cf. §3.2).

4.3 Multiplication Triple Composition

The multiplication triple generation described until now requires the function size $n = |f|$ to be known beforehand. While this may be the case for some functions, e.g., for set intersection using bitwise AND (cf. §6.1), the size of other functions depends on the number of inputs, e.g., the number of contacts in the address book (cf. §6.3). The naive solution to not knowing n in advance would be to generate several multiplication triple sequences of fixed size ℓ in the init phase and send their $\lceil n/\ell \rceil$ seeds in the setup phase, when n is known. However, on average this approach wastes $\ell/2$ multiplication triples and requires to send $\lceil n/\ell \rceil$ multiplication triple seeds. Thus, a smaller ℓ results in fewer wasted multiplication triples but more communication overhead, while a higher ℓ results in more wasted multiplication triples but less communication. Since typical function sizes in secure computation range from millions [HEKM11] to even a billion AND gates [CMTB13], an appropriate ℓ is difficult to choose.

Instead of generating fixed-length blocks of multiplication triple sequences, we propose to generate m multiplication triple sequences $s_0, \ldots, s_{m-1}$ in the init phase, where s_i contains 2^i $(0 \leq i < m)$ multiplication triples. In the setup phase, we then send a set of multiplication triple seeds $\{s_k \,|\, n_k = 1\}$, where n_k is the k-th bit of n. This approach requires sending at most $\lceil \log_2 n \rceil$ seeds. As communication between $\mathcal{T}$ and $\mathcal{A}$ is the bottleneck in our implementation, we set the smallest size of a multiplication triple sequence such that it fits into one packet.

4.4 Security Analysis

In this section, we briefly analyze the security of our protocol for each of the three secure computation phases.

Init Phase In the init phase no private inputs are involved and $\mathcal{B}$ is unknown. Therefore, $\mathcal{A}$ can only try to manipulate the token, which is hard since the hardware token is tamper-proof. Moreover, $\mathcal{A}$ receives only its $c_\mathcal{A}$ shares that do not reveal anything about $\mathcal{B}$'s shares or $\mathcal{T}$'s internal state, due to the cryptographically strong PRG.

Setup Phase The only attack a malicious $\mathcal{A}$ could play in the setup phase, is to impersonate $\mathcal{B}$. This attack is prevented, since every seed s_B can only be queried once (cf. §4.1). The communication between the hardware token and $\mathcal{B}$ is done through an encrypted channel, so that $\mathcal{A}$ cannot get access to those messages. For active security, we use TLS and add a MAC to every packet to prevent modifications and avoid replay attacks. $\mathcal{B}$ cannot actively attack the token since all communication to the hardware token is controlled by $\mathcal{A}$. Obviously, any party can drop or ignore messages, but we exclude this simple denial of service attack from our system model since we assume both parties to be willing to participate in the secure computation. The seeds that each party obtains from the hardware token do also not reveal any additional information since they are directly output from a cryptographically strong PRG to which the hardware token's internal state is used as seed.

Online Phase The security for the online phase directly carries over from the GMW protocol, as we do not introduce any modifications to this phase.

4.5 Performance Comparison

We show that the asymptotic performance of our protocol improves over existing solutions. A summary is shown in Tab. 1 on page 2 and a more detailed comparison is given in the full version [DSZ14]. An experimental evaluation of our protocol is provided in §5.4 and its performance on applications is evaluated in §6.

Asymptotic Performance The init phase of our protocol is, unlike [JKSS10], independent of a concrete instance of f and can thus be pre-computed without knowing a communication partner. During the setup phase, the communication complexity of our protocol is only $O(t)$ (or $\mathcal{O}(t \cdot \log_2 |f|)$ if $|f|$ is unknown), which improves upon the communication of Yao's protocol and the GMW protocol [CHK+12, SZ13, ALSZ13] with $\mathcal{O}(t \cdot |f|)$ communication. Both parties have to do $\mathcal{O}(|f|/b)$ symmetric cryptographic operations to expand their seeds.[2] The online phase is the first phase where f needs to be known. Here, $\mathcal{A}$ and $\mathcal{B}$ send $\mathcal{O}(|f|)$ bits in $d(f)$ rounds, where $d(f)$ is the depth of f. The parties' computation complexity is negligible, as no cryptographic operations are evaluated. This is the biggest advantage over Yao's garbled circuits protocol [MNPS04, JKSS10, HCE11], where $\mathcal{O}(|f|)$ symmetric cryptographic operations have to be evaluated during the online phase.

[2] In our implementation, we instantiate the PRG G with AES-128-CTR, which has block size $b = 128$.

Concrete Performance For 80 bit security, the best known instantiation of Yao's garbled circuits protocol (resp. the GMW protocol) require per AND gate 240 bit (resp. 164 bit) communication and $4+1$ (resp. $12+0$) evaluations of symmetric cryptographic primitives in the setup + online phase. In comparison, our solution requires only 4 bit communication and $0.04+0$ fixed-key AES operations per AND gate.

5 Implementation

This section details the implementation of our scheme. We introduce the smartcard that we use to instantiate the hardware token (§5.1), give an overview of our Android implementation (§5.2), outline our benchmarking environment (§5.3), and experimentally compare the OT extension-based multiplication triple generation to our hardware token-based protocol (§5.4).

5.1 G&D Mobile Security Card

In our implementation we instantiate the trusted hardware token $\mathcal{T}$ with the Giesecke & Devrient (G&D) Mobile Security Card SE 1.0 (MSC). It is embedded into a microSD card that additionally contains 2 GB of separate flash memory. The MSC is based on an NXP SmartMX P5CD080 micro-controller that runs at a maximum frequency of 10 MHz, has 6 kB of RAM, 80 kB of persistent EEPROM, and is based on Java Card version 2.2.2. Note that an applet can only use 1,750 Bytes of the 6 kB RAM for transient storage. The MSC has co-processors for 3DES, AES and RSA that can be called from a Java Card applet, as well as native routines for MD5, SHA-1 and SHA256. The MSC runs the operating system G&D Sm@rtCafe Expert 5.0 which manages the installed Java Card applets, personalization data, and communication keys. The communication between the Android operating system and the MSC is done by a separate service via the SIMalliance Open Mobile API.

5.2 Architecture

The architecture of our implementation is depicted in Fig. 6. To support flexibility and extensibility, our modular architecture consists of the *Application* that specifies the functionality, the *GMWService* that performs secure computation, and the *MTService* that performs the multiplication triple generation and transfer. All communication between $\mathcal{A}$ and $\mathcal{T}$ is done via the MSC Smartcard Service supplied by G&D. The Application can be implemented by a designer and specifies the desired secure computation functionality as a Boolean circuit that can, for instance, be compiled from a high-level circuit description language such as the Secure Function

Definition Language (SFDL) [MNPS04, MLB12] or the Portable Circuit Format (PCF) [KMSB13].

The GMWService implements the GMW protocol and performs the secure computation, given a circuit description and corresponding inputs. The MTService generates the multiplication triples using either OT extension (*OT-Ext*) based on the memory efficient implementation of [HS13] including the optimizations from [ALSZ13] or, if one of the parties holds a hardware token, our token-aided protocol of §4. If a hardware token is present, the MTService manages the multiplication triple generation during the init phase by querying the token and storing the received $c_{\mathcal{A}}$ sequences. For the MSC, the multiplication triple generation on $\mathcal{T}$ is performed via a Java Card applet (*MT JC Applet*) that implements the functionality in §4.1 and is accessible through the Java Card interface. Our implementation can be installed as a regular Android app and does not require root access to the smartphone or a custom firmware.

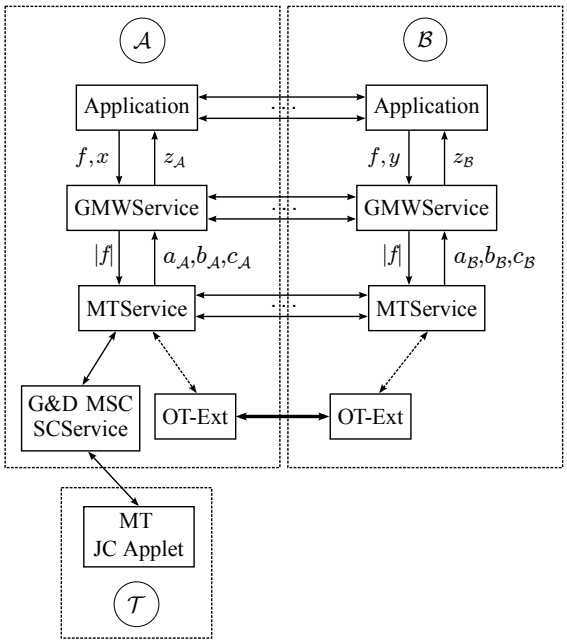

Figure 6: Modular architecture design.

Secure computation is performed by having an Application running on each smartphone, which specifies the function f both parties want to compute securely. From this function the Application generates a circuit description, which it sends to the GMWService. The GMWService interprets the circuit and queries the MTService for the required number of multiplication triples $|f|$. The MTServices on both smartphones then communicate with each other and check whether one of the smartphones holds a hardware token ($\mathcal{A}$ in Fig. 6). If so, both MTServices perform the seed transfer protocol (cf. §4.2), expand the obtained seeds ($\mathcal{A}$ loads the corresponding $c_{\mathcal{A}}$ sequences obtained in the init phase), and merge the obtained multiplication triple sequences (cf. §4.3). If no hardware token is present, the MTServices generate the multiplication triples by invoking OT extension. The MTService then provides the multiplication triples (a_i, b_i, c_i) for $i \in \{\mathcal{A}, \mathcal{B}\}$ to the GMWService. Finally, the Applications send their inputs x and y, respectively, to the GMWService, which performs the secure computation and returns the output $z_i = f(x,y)$.

5.3 Benchmarking Environment

For our mobile benchmarking environment we use two Samsung Galaxy S3's, which each have a 1.4 GHz ARM-Cortex-A9 Quad-Core CPU, 1 GB of RAM, 16 GB of internal flash memory, a mircoSD card slot, and run the Android operating system version 4.1.2 (Jelly Bean). For the communication between the smartphones, we use Wi-Fi direct. For the evaluation, we put the smartphones next to each other on a table. The G&D mobile security card is connected to the mircoSD card slot of one of the phones. We use the short-term security setting recommended by NIST [NIS12], i.e., a symmetric key size of 80 bits and a public key size of 1,024 bit with a 160 bit subgroup. We instantiated the pseudo-random generator G that is used for seed expansion (cf. §4.1) with AES-128 in CTR mode. The hardware token generates multiplication triple sequences of size 2^m for $11 \leq m \leq 24$. We used $m = 11$ as lower bound on the size, since 2,048 is the biggest size we can transfer from $\mathcal{T}$ to $\mathcal{A}$ with a single packet, and $m = 24$ as upper bound, since it was appropriate for our case studies in §6. Finally, we point out that our implementation is single-threaded and utilizes only one of the four available cores of our smartphones. We leave the extension to multiple threads as future work.

5.4 Performance Evaluation

First, we want to quantify the runtime differences between the mobile and the desktop environment. We measure the execution time for AES-128 in ECB mode for an identical single-threaded Java implementation in both domains. The smartphone version is running with 5.5 MB/s while the desktop version achieves 61.1 MB/s. The optimized AES-256 implementation of Truecrypt[3], written in C/C++ and assembly, achieves 143.1 MB/s on the same desktop machine, running without parallelization. For comparison, the smartcard (cf. §5.1) is running AES-128 at a maximum speed of 16.7 KB/s.

In the following we evaluate the performance of our token-based scheme (cf. §4) on smartphones, using TLS or KAS1-basic as key agreement protocol, and compare

[3] http://www.truecrypt.org

it to the OT extension based multiplication triple generation. In our evaluations we only include the time for init and setup phase, since the online phase is identical for both approaches. Results for the online phase are given in §6. All values are averaged over 10 measurements.

Fig. 7 gives an overview over the timings for the generation of 2^m ($11 \leq m \leq 24$) multiplication triples using either OT extension in the setup phase or the hardware token (§4.1) in the init phase. Additionally, the setup phase using TLS and KAS1-basic is depicted, which includes the seed transfer and the seed expansion of $\mathcal{B}$. We always assume the worst case number of seeds to be transferred, i.e., for 2^{24} multiplication triples, we transfer $24-10=14$ seeds (cf. §4.3). Both axes in Fig. 7 are given in a logarithmic scale.

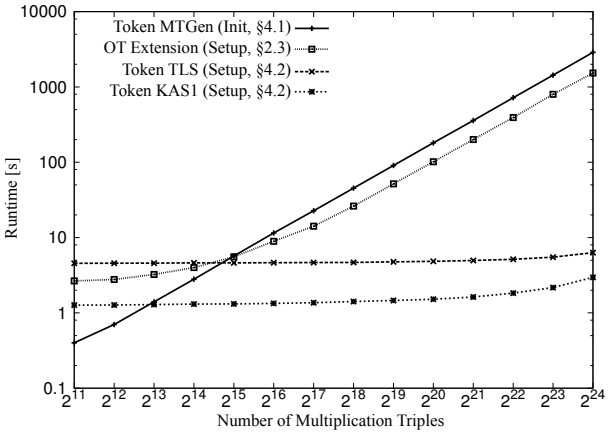

Figure 7: Performance evaluation of the multiplication triple generation and setup phase.

We observe that OT extension on mobile devices is able to generate 2^{24} multiplication triples in 1,529 s, corresponding to 10,971 multiplication triples per second. We ran the same code on two desktop PCs with a 2.5 GHz Intel Core2Quad CPU and 4 GB RAM, connected via Gigabit LAN and were able to compute 2^{24} multiplication triples in 139 s, which indicates a performance decrease of factor 11. While the performance decrease on mobile devices compared to desktop computers was significantly less than the factor of 1000 observed in [HCE11], it is still insufficient for efficiently computing complex functions such as private set-intersection, which typically requires millions of OTs.

In comparison, the multiplication triple generation of the hardware token during the init phase is able to generate 2^{24} multiplication triples in 2,883 s, corresponding to 5,819 multiplication triples per second. For the hardware token-based protocol we observe that the times for sending the seeds using the TLS and KAS1 key agreement protocols grow very slowly with the number of multiplication triples, since the amount of data to be encrypted and sent grows only with $\log_2 |f|$. Additionally, the TLS-based key agreement protocol (4.6 s for 2^{11} multiplication triples) is around factor 3 slower than the KAS1-based key agreement (1.3 s for 2^{11} multiplication triples).

The overall computation and communication workload of OT extension is substantially larger than in our token-based scheme, but its multiplication triple generation rate is not much faster. This can be explained by the faster processing power of the smartphones compared to that of $\mathcal{T}$ and the higher bandwidth of Wi-Fi direct compared to the relatively slow communication channel between $\mathcal{A}$ and $\mathcal{T}$. However, OT extension suffers from high energy consumption, due to the CPU utilization incurred by the symmetric cryptographic operations, as well as the Wi-Fi direct communication [PFW11].

We use PowerTutor[4] to measure the energy consumption of the smartphone's CPU for generating 2^{19} multiplication triples and compare the interactive evaluation of random OT extensions with our smartcard solution. Note that Fig. 8 only displays the CPU's energy consumption whereas the energy consumption of Wi-Fi and the smartcard is not included. However, we argue that the energy consumption of the smartcard is not a critical factor, since these operations can be performed when the phone is charging. The Wi-Fi connection, on the other hand, is required for OT during the setup phase, thus increasing the already high battery drain even further. Moreover, the OT computations have to be done on both devices simultaneously, draining both devices' batteries. Therefore, our token-based solution is particularly well-suited for the mobile domain, where energy consumption and battery lifetime are critical factors.

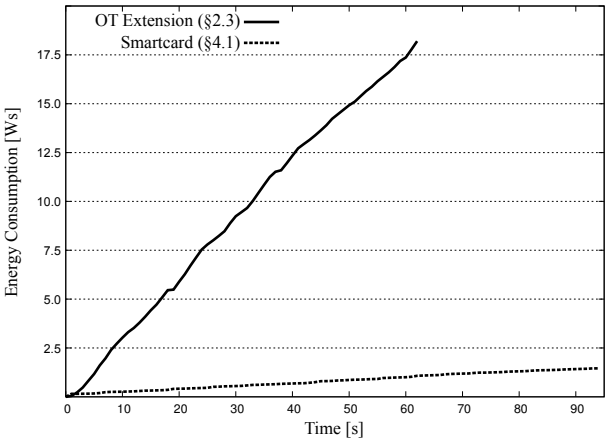

Figure 8: Accumulated smartphone CPU energy consumption during the generation of multiplication triples.

6 Applications

To evaluate the performance of our protocols, we use the mobile phones and setting as specified in §5.3 and consider the following privacy-preserving applications: availability scheduling (§6.1), location-aware scheduling (§6.2), and set intersection (§6.3). We implemented the applications and depict the performance results for an average of 10 iterations. We use KAS1-basic [NIS09] as key authentication scheme. We pre-generated the circuits using the framework of [SZ13], wrote them into a file, and read them on the smartphone. The time for reading the circuit file is included in the setup phase.

6.1 Availability Scheduling

Privacy-preserving availability scheduling is a common example for secure computation on mobile devices [HCC+01, BJH+11] and enables $\mathcal{A}$ and $\mathcal{B}$ to find a possible time slot for a meeting without disclosing their schedules to each other. To schedule a meeting, $\mathcal{A}$ and $\mathcal{B}$ specify a duration and time frame for the meeting. Each party $i \in \{\mathcal{A},\mathcal{B}\}$ then divides the time frame when the meeting can take place (e.g., a week) into n time slots $t_i^n = (t_{i,1},\ldots,t_{i,n})$ and denotes each time slot $t_{i,j} \in \{0,1\}$ as either free ($t_{i,j}=1$) or occupied ($t_{i,j}=0$). The parties compute their common availability t_{Avail}^n by computing the bitwise AND of their time slots, i.e., $t_{Avail}^n = t_{\mathcal{A}}^n \wedge t_{\mathcal{B}}^n$. Overall, this circuit has n AND gates and depth 1. Note that the bitwise AND circuit performs a general functionality and can, for instance, be used for privacy-preserving set intersection where elements are taken from a small domain [HEK12] or location matching [CADT13]. For our experiments, we set the time frames s.t. meetings can be scheduled between 8 am and 10 pm for one day divided into 15 minute slots ($n=56$ slots), one week divided into 15 minute slots ($n=392$ slots), and one month divided into 10 minute slots ($n=2{,}604$ slots). We depict our results in the upper half of Tab. 2.

The multiplication triple generation in the init phase can be performed in several hundred milliseconds, since it requires only one (for 56 and 392 time slots) or two (for 2,604 time slots) packet transfers between $\mathcal{T}$ and $\mathcal{A}$. The setup phase, more detailed the seed transfer protocol, is the main bottleneck in this application, as $\mathcal{T}$ has to perform asymmetric and symmetric cryptographic operations. Finally, the online phase requires only milliseconds but has a high variance, due to the communication over Wi-Fi direct and the small number of communication rounds that are performed in the online phase.

For comparison, we evaluated the same circuit using the mobile Yao implementation of [HCE11] on the same phones, which took factor 1.6 (for the day time frame) up to factor 12 (for the month time frame) longer, cf. Tab. 2.

Table 2: Performance for availability and location-aware scheduling. $|f|$ is the size of the circuit and $d(f)$ its depth. All values measured on smartphones (cf. §5.3).

Time Frame	Day	Week	Month
Availability Scheduling §6.1			
$\|f\|$ / $d(f)$	56 / 1	392 / 1	2,604 / 1
Init [s]	0.37 (±1.6%)	0.37 (±1.6%)	0.73 (±1.0%)
Setup [s]	1.3 (±13%)	1.3 (±13%)	1.3 (±13%)
Online [s]	0.002 (±150%)	0.003 (±167%)	0.007 (±129%)
Ad-Hoc [s]	1.3 (±13%)	1.3 (±13%)	1.3 (±13%)
Mobile Yao [HCE11]			
Ad-Hoc [s]	2.14 (±7.1%)	3.82 (±4.7%)	15.9 (±2.7%)
Location-Aware Scheduling §6.2			
$\|f\|$ / $d(f)$	39,864 / 69	280,605 / 87	1,872,206 / 106
Init [s]	6.9 (±0.3%)	48.5 (±0.2%)	319.6 (±0.5%)
Setup [s]	1.4 (±7.1%)	1.8 (±7.0%)	4.8 (±4.8%)
Online [s]	0.16 (±35%)	0.82 (±7.4%)	5.9 (±18%)
Ad-Hoc [s]	1.5 (±8.4%)	2.6 (±6.5%)	10.7 (±11%)

6.2 Location-Aware Scheduling

In the following we show that our system can be adapted to compute arbitrary and complex functions. We introduce the location-aware scheduling functionality which extends the availability scheduling of §6.1, s.t. the distance between the users is considered as well. The location-aware scheduling functionality takes into account the user's location in a time slot, computes the distance between the users, verifies if a meeting is feasible, and outputs the time slot in which the users have to travel the least distance to meet each other. We argue that this approach is practical, since such position information are often already included in the users' schedules.

In the location-aware scheduling scheme, we assume that the user $i \in \{\mathcal{A},\mathcal{B}\}$ also inputs the location of the previous appointment P_i and the next appointment N_i and the distances that he can reach from his previous appointment p_i and from his next appointment n_i (cf. Fig. 9 for an example). Such p_i and n_i can be computed in plaintext using the distance between P_i and N_i, the free time until the next appointment and the duration of the meeting. The minimal distance among all time slots where the reachable ranges for $\mathcal{A}$ and $\mathcal{B}$ overlap is selected as final result. If successful, the function outputs the identified time slot and for each user whether he should leave from the location of the previous or next appointment. A detailed description of the functionality is given in the full version [DSZ14]. We evaluate the scheme on the same number of time slots used in §6.1 (day, week, month) and depict the performance in the lower half of Tab. 2.

Compared to availability scheduling, the location-aware scheduling circuit is significantly bigger and requires more communication rounds. When performing the scheduling for a month, the circuit consists of 1.8 million instead of 2,604 AND gates for availability schedul-

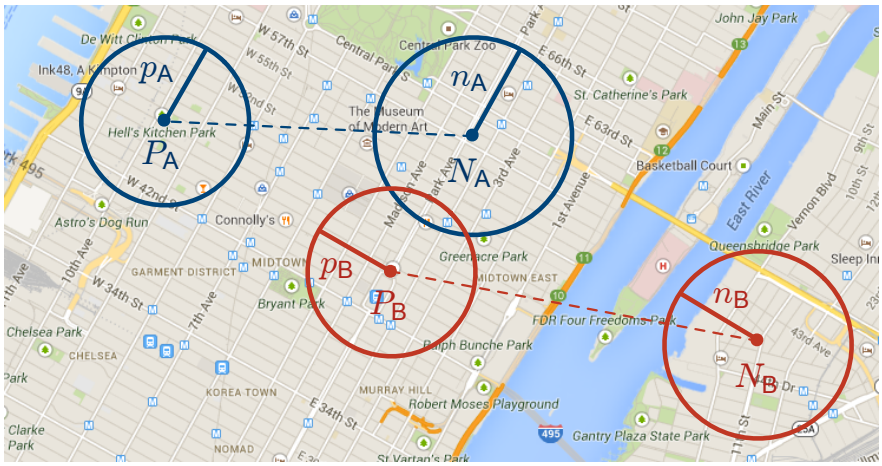

Figure 9: Location-aware scheduling for one time slot of $\mathcal{A}$ and $\mathcal{B}$ with previous locations $P_\mathcal{A}$ and $P_\mathcal{B}$, reachable distances from previous appointments $p_\mathcal{A}$ and $p_\mathcal{B}$, next locations $N_\mathcal{A}$ and $N_\mathcal{B}$ and corresponding reachable distances $n_\mathcal{A}$ and $n_\mathcal{B}$. The meeting can be scheduled between $N_\mathcal{A}$ and $P_\mathcal{B}$ as the reachable ranges overlap.

ing. The time for the init phase increases linearly with the number of AND gates and requires 319 s when performing scheduling for a month. The time for the setup phase is increased less, since the seed transfer grows only logarithmically in $|f|$ and the seed expansion is done efficiently. The online phase is also slowed down substantially (6 s for a month time frame), but is still practical.

6.3 Private Set Intersection

Private set intersection (PSI) is a widely studied problem in secure computation and can be used for example to find common contacts in users' address books [HCE11]. It enables two parties, each holding a set $S_\mathcal{A}$ and $S_\mathcal{B}$ with elements represented as σ-bit strings to determine which elements both have in common, i.e., $S_\mathcal{A} \cap S_\mathcal{B}$, without disclosing any other contents of their sets. While many special-purpose protocols for PSI exist, e.g., [CT10, CT12, CADT13], generic protocols mostly build on the work of [HEK12], where the Sort-Compare-Shuffle (SCS) circuit was outlined. The idea is to have both parties locally pre-sort their elements, privately merge them, check adjacent values for equality, and obliviously shuffle the resulting values to hide their order.

We implement the SCS-WN circuit of [HEK12] which uses a Waksman permutation network to randomly shuffle the resulting elements. We perform the comparison for bit sizes $\sigma \in \{24, 32, 160\}$ and compare the ad-hoc runtime of our protocol to the implementation of [HCE11] for $\sigma \in \{24, 32\}$. The results from [HEK12] are compared to ours for $\sigma \in \{32, 160\}$. The results are given in Fig. 10 and in Tab. 3. Note that [HCE11] and [HEK12] implement Yao's garbled circuits protocol using pipelining, whereas we use the GMW protocol.

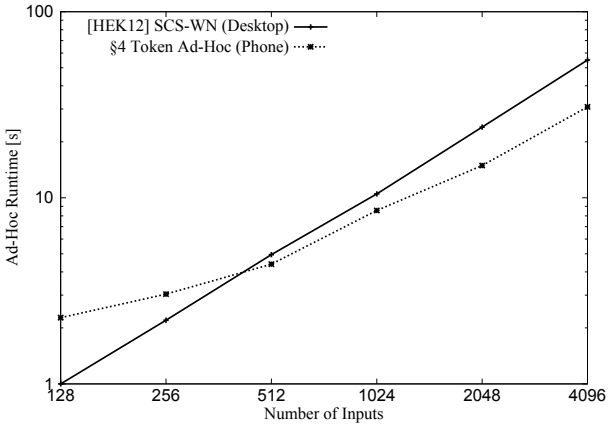

Figure 10: Private set intersection runtime for $\sigma = 32$ bit elements using our token-based protocol on two smartphones (§5.3) and [HEK12] on two desktop PCs.

For a fair comparison, we ran the code from [HCE11] on our Samsung Galaxy S3 smartphones and observed an approximate speedup of factor 2 compared to the measurements from their paper, that were made on older hardware (two Google Nexus One phones). Note that our performance results, as well as the values for the implementation of [HCE11] are benchmarked on mobile devices connected via Wi-Fi Direct, while [HEK12] is benchmarked on two desktop PCs (two Core2Duo E8400 3GHz PCs connected via 100 Mbps LAN).

From Fig. 10 we observe that, due to the seed transfer in our setup phase (cf. §4.2), the Yao's garbled circuits implementation of [HEK12] is faster for up to 256 inputs. However, the seed transfer time amortizes for larger inputs and our token-based scheme outperforms the imple-

Table 3: Ad-hoc runtime of private set intersection where each party inputs n values of σ bits, measured on identical mobile phones (§5.3). [HEK12] results are on PCs and taken from the paper (— indicates that no numbers were given).

Number of Inputs n		32	64	128	256	512	1,024
$\sigma = 24$bit	$\|f\|$	22,432	52,096	118,656	266,240	590,336	1,296,384
	Ours [s]	1.7 (±2.2%)	1.9 (±3.4%)	2.1 (±2.4%)	2.5 (±2.4%)	3.6 (±4.2%)	7.4 (±8.7%)
	[HCE11] [s]	30	68	161	410	1,052	3,010
$\sigma = 32$bit	$\|f\|$	30,368	70,528	160,640	360,448	799,232	1,755,136
	Ours [s]	1.7 (±2.7%)	1.9 (±3.5%)	2.3 (±7.7%)	3.0 (±18%)	4.4 (±9.8%)	8.5 (±20%)
	[HCE11] [s]	42	87	233	565	1,468	4,662
	[HEK12] [s]	—	—	1	2.2	4.95	10.5
$\sigma = 160$bit	$\|f\|$	156,768	364,096	829,312	1,860,864	4,126,208	9,061,376
	Ours [s]	2.2 (±8.8%)	2.7 (±16%)	4.0 (±1.9%)	7.0 (±1.9%)	14.3 (±2.9%)	28.7 (±1.4%)
	[HEK12] [s]	—	—	—	—	—	51.5

mentation of [HEK12], even though our implementation runs on substantially slower mobile phones while theirs is evaluated on two desktop PCs. From Tab. 3 we observe that our scheme outperforms the Yao's garbled circuits implementation of [HCE11], evaluated on identical mobile phones, by factor 18 for 32 inputs with $\sigma = 24$ bit and by up to factor 550 for 1,024 inputs with $\sigma = 32$ bit.

Finally, we compare the performance of our protocol to the PSI protocol of [CADT11,CADT13]. We use their reported numbers for pre-computed PSI on 20 input values and set the bit size $\sigma = 160$ in our protocol.[5] The protocol of [CADT11, CADT13] needs 3.7 s, while our ad-hoc runtime is only 2.1 s (±4.8%). Note, however, that their approach has only a constant number of rounds and can be sped up using multiple cores.

7 Related Work

We classify related work into three categories: secure function evaluation (§7.1), server-aided secure function evaluation (§7.2), and token-based cryptography (§7.3).

7.1 Generic Secure Function Evaluation

The foundations for secure function evaluation (SFE) were laid by Yao [Yao86] and Goldreich et al. [GMW87] who demonstrated that every function that is efficiently representable as Boolean circuit can be computed securely in polynomial time with multiple parties.

SFE Compiler A first compiler for specific secure two-party computation functionalities was presented in [MOR03]. The Fairplay framework [MNPS04] was the first efficient implementation of Yao's garbled circuits protocol [Yao86] for generic secure two-party computation and enabled a user to specify the function to be computed in a high-level language. The FastGC framework [HEKM11] improved on the results of Fairplay by evaluating functions with millions of Boolean gates in mere minutes using optimizations such as the free XOR technique [KS08] and pipelining. The FastGC framework has been used to implement various functions such as privacy-preserving set intersection [HEK12], genomic sequencing, or AES [HEKM11], and was optimized with respect to a low memory footprint in [HS13].

Next to Yao's garbled circuits protocol, the GMW protocol [GMW87] recently received increasing attention. The work of [CHK+12] efficiently implemented GMW in a setting with multiple parties. Subsequently, [SZ13] optimized GMW for the two-party setting and showed that GMW has advantages over Yao's garbled circuits protocol as it allows to pre-compute all symmetric cryptographic operations in a setup phase and that the workload can be split evenly among both parties.

SFE on Mobile Devices A recent line of research aims at making SFE available on mobile devices, such as smartphones. In [HCE11] the authors port the FastGC framework [HEKM11] to smartphones and observe a substantial performance reduction when compared to the desktop environment. They identify the slower processing speed and the high memory requirements as the main bottlenecks. Similarly, [CMSA12] ported the Fairplay framework [MNPS04] to smartphones. A compiler with smaller memory constraints than Fairplay was presented in [MLB12]. We emphasize that previous works on generic SFE on mobile devices use Yao's garbled circuits protocol, whereas our approach is based on GMW.

Several special-purpose protocols for mobile devices using homomorphic encryption were proposed in [BJH+11] (activity scheduling), [CDA11] (scheduling, interest sharing), and [CADT11,CADT13] (comparison, location-based tweets, common friends). In contrast to generic solutions, such custom-tailored protocols can be more efficient, but are restricted to specific functionalities. Their extension to new use cases is complex and usually requires new security proofs.

[5] Note that [CADT11,CADT13] also support bigger bit sizes, since they operate on 1,024-bit ElGamal ciphertexts.

7.2 Server-Aided SFE

One way to speed up generic secure computations on resource constrained devices is to outsource expensive operations to one or more servers. In [HS12] a system for fair server-aided secure two-party computation using two servers was introduced. SALUS [KMR12] is a system for fair SFE among multiple parties using a single server. A system that allows cloud-aided garbled circuits evaluation between one mobile device and a server was introduced in [CMTB13] and its efficiency was demonstrated on large-scale practical applications, such as a secure path finding algorithm. Both [CMTB13] and [KMR12] achieve security against malicious adversaries, but require at least one party to be a machine with more computing power than a mobile phone as it evaluates multiple garbled circuits. [Hua12] proposes that a trusted server generates multiplication triples that are sent to both parties over a secure channel, requiring $\mathcal{O}(|f|)$ bits communication. Instead, we propose to replace the server with a trusted hardware token and show that the communication to one party can be reduced to sub-linear complexity. Moreover, they achieve security against malicious adversaries based on [NNOB12]; we sketch how to extend our work to malicious security in the full version [DSZ14].

We consider this line of research as orthogonal to ours, since it focuses on outsourcing secure computations to a powerful but untrusted cloud server. In contrast, we focus on secure computation between two mobile devices where computations are outsourced to a trusted, but resource constrained smartcard locally held by one party.

7.3 Token-Based Cryptography

Another approach is to outsource computations to trusted hardware tokens, such as smartcards. These tokens are typically resource-constrained, but have the advantage of offering a tamper-proof trusted execution environment.

Setup Assumptions for UC Hardware tokens can be used as setup assumption for Canetti's universal composability (UC) framework, as they allow to construct UC commitments, with which in turn any secure computation functionality can be realized, e.g., [Kat07, DNW09, DKMQ11]. These works are mainly feasibility results and have not been implemented yet.

SFE in Plaintext As discussed in [HL08], the trivial solution to performing SFE using hardware tokens would be to have each party send its inputs over a secure channel to the token, which evaluates f and returns the output. A similar approach with multiple tokens, which additionally provides fault tolerance was given in [FFP+06].

When using the hardware token for plaintext evaluation, the performance of the time-critical online phase is limited by the performance of the token, which is typically very low. Moreover, this requires the token to hold all input values in memory, which quickly exceeds its very limited resources.[6] Alternatively, the token could use external secure memory to store inputs and intermediate values, e.g., [IS05, IS10], but this would require symmetric cryptographic operations in the online phase. Additionally, each new functionality would have to be implemented on the token, whereas our scheme is implemented only once and supports arbitrary functionalities.

Specific Functionalities An efficient protocol for private set-intersection using smartcards was presented in [HL08]. This protocol was extended to multiple untrusted hardware tokens in [FPS+11]. An anonymous credential protocol was presented in [BCGS09].

Outsourcing Oblivious Transfer There are several works that use hardware tokens to compute oblivious transfer (OT): [GT08] implemented non-interactive OT using an extension of a TPM, [Kol10] proposed OT secure in the malicious model using a stateless hardware token, and [DSV10] provided non-interactive OT in the malicious model using two hardware tokens.

We outsource the setup phase of the GMW protocol, which previously was done via OT, to the hardware token. Previous works on outsourcing n OTs require the hardware token to evaluate $\mathcal{O}(n)$ symmetric (or even asymmetric) cryptographic operations in the ad-hoc phase. In comparison, our scheme requires $\mathcal{T}$ to evaluate $\mathcal{O}(n/t)$ symmetric cryptographic operations in the init phase and only $\mathcal{O}(\log_2 n)$ symmetric cryptographic operations in the setup phase (cf. the full version [DSZ14]).

8 Conclusion and Future Work

In this work, we demonstrated that generic ad-hoc secure computation can be performed efficiently on mobile devices when aided by a trusted hardware token. We showed how to extend the GMW protocol by such a token, similar to a TPM, to which most costly cryptographic operations can be outsourced. Our scheme pre-computes most of the workload of GMW in an initialization phase, which is performed independently of the later communication partner and without knowing the function or its size in advance. This is particularly desirable as the pre-computation can happen at any time, e.g., when the device is connected to a

[6] The smartcard we use in our experiments has 1,750 Bytes of RAM, which would be completely filled if each party provided 300 inputs of 24 bits length in private set intersection (cf. §6.3).

power source, which happens regularly with modern smartphones. The remaining interactive ad-hoc phase is very efficient and can be executed in a few seconds, even for complex functionalities. We implemented several privacy-preserving applications that are typical for mobile devices (availability scheduling, location-aware scheduling, and set-intersection) on off-the-shelf smartphones using a general-purpose smartcard and showed that their execution times are truly practical. We found that the performance of our scheme is two orders of magnitude faster than that of other generic secure two-party computation schemes on mobile devices and comparable to the performance of similar schemes in the semi-honest adversary model implemented on desktop PCs.

We see several interesting directions for future research. As our scheme is based on the GMW protocol, it can easily be extended to more than two parties, e.g., for securely scheduling a meeting, cf. [CHK+12]. Moreover, our scheme can be modified to also provide security against malicious parties, cf. [Hua12] (we provide more details in the full version [DSZ14]). Another direction might be equipping both mobile devices with a hardware token to further improve efficiency and/or security.

ZØ: An Optimizing Distributing Zero-Knowledge Compiler

Matthew Fredrikson
University of Wisconsin

Benjamin Livshits
Microsoft Research

Abstract

Traditionally, confidentiality and integrity have been two desirable design goals that are have been difficult to combine. *Zero-Knowledge Proofs of Knowledge* (ZKPK) offer a rigorous set of cryptographic mechanisms to balance these concerns. However, published uses of ZKPK have been difficult for regular developers to integrate into their code and, on top of that, have not been demonstrated to scale as required by most realistic applications.

This paper presents ZØ (pronounced "zee-not"), a compiler that consumes applications written in C# into code that automatically produces scalable zero-knowledge proofs of knowledge, while automatically splitting applications into distributed multi-tier code. ZØ builds detailed cost models and uses two existing zero-knowledge back-ends with varying performance characteristics to select the most efficient translation. Our case studies have been directly inspired by existing sophisticated widely-deployed commercial products that require both privacy and integrity. The performance delivered by ZØ is as much as 40× faster across six complex applications. We find that when applications are scaled to real-world settings, existing zero-knowledge compilers often produce code that fails to run or even *compile* in a reasonable amount of time. In these cases, ZØ is the only solution we know about that is able to provide an application that works at scale.

1 Introduction

As popular applications rely on personal, privacy-sensitive information about users, factors such as legal regulations, industry self-regulation, and a growing body of privacy-conscious users all pressure developers to respond to demands for privacy. Storing user's data in the cloud creates downsides for the application provider, both immediately and down the road. While policy measures such as DoNotTrack and anonymous advertising identifiers become increasingly popular, a recent trend explored in several research projects has been to move functionality to the *client* [13, 17, 37, 40]. Because execution happens on the client, such as a mobile device or even in the browser, this alone provides a degree of privacy in the computation: only relevant data, if any, is disclosed (to a server). However, in many cases, moving functionality to the client conflicts with a need for computational *integrity*: a malicious client can simply forge the results of a computation.

Traditionally, confidentiality and integrity have been two desirable design goals that are have been difficult to combine. *Zero-Knowledge Proofs of Knowledge* (ZKPK) offer a rigorous set of cryptographic mechanisms to balance these concerns, and recent theoretical developments suggest that they might translate well into practice. In the last several years, zero-knowledge approaches have received a fair bit of attention [23]. The premise of zero-knowledge computation is its promise of both privacy *and* integrity through the mechanism cryptographic proofs. However, published uses of ZKPK [4, 5, 7, 8, 19, 36] have been difficult for regular developers to integrate into their code and, on top of that, have not been demonstrated to scale, as required by most realistic applications.

Zero-knowledge example: pay as you drive insurance: A frequently mentioned application and a good example of where zero-knowledge techniques excel is the practice of *mileage metering* to bill for car insurance: pay as you drive auto insurance is an emerging scheme that involves paying a rate proportional to the number of miles driven, either linearly, or using several billing brackets [4, 38, 41]. Of course, given that the insurance company knows much about the customer, including their address, if daily mileage data is provided, much can be inferred about user's daily activities, where they shop, etc. [15, 29, 30]. The user in this scheme performs a calculation on their own data, but of course the insurance company wants to prevent cheating. Zero-knowledge proofs provide a way to ensure both privacy and integrity, which involves performing the billing computation on the user's hardware (on the *client*), perhaps, monthly, and providing the insurance company with 1) the final bill and 2) a proof of correctness of the accounting calculation, which can be verified by the insurance company (on the *server*) [4, 18, 35, 39].

What we did: In this paper, we present ZØ, a compiler that consumes applications written in a subset of C# into code that produces scalable zero-knowledge proofs of knowledge, while automatically splitting applications into distributed code, to be executed on two (or more)

execution tiers. We are building on very recent developments in zero-knowledge cryptographic techniques [16, 31], exposing to the developer the ability to take advantage of these advances. ZØ builds detailed cost models of the code regions that require ZKPK, and uses existing zero-knowledge back-ends with varying performance characteristics to select the most efficient translation, by formulating and solving constrained numeric optimization problems. Our cost modeling takes advantage of the strengths of both back-ends, while avoiding their weaknesses, both for local and global (distributed) optimization. Using a set of realistic applications that perform tasks such as distributed data mining and crowd-sourced data aggregation, we demonstrate ZØ's ability to produce privacy-preserving code which runs significantly faster than previously possible.

High-level goals: ZØ aims to provide an attractive combination of high-level goals of *privacy*, *integrity*, *expressiveness*, and *performance*. While the first two goals are achieved through the use of zero-knowledge, to support ease of programming and expressiveness, ZØ accepts (a subset of) C#, a widely-used general purpose language as input that can run in many settings. Of course, we are not tied to C# and could support another high-level language such as JavaScript, Java, or C++. Our use of a general-purpose language allows developers to include hundreds or thousands of lines of C# or other .NET code, allowing the construction of full-featured GUI-based distributed applications that support zero-knowledge instead of small examples written in a domain-specific language.

To enable distributed programming wherever .NET code can run, ZØ supports automatic tier-splitting, inspired by distributing compilers such as GWT [20] and Volta [24]. We primarily target client-server computations (two tiers), although other options such as P2P are also supported by ZØ. Code produced by ZØ can be run on desktops, in the cloud, on mobile devices (Windows Phone) and on the web (Silverlight).

Applications: Much of the inspiration for ZØ came from our desire to be able to use ZKPK techniques to build applications directly analogous to some widely-deployed commercial products, as opposed to toy benchmarks. In our studies detailed in Section 7, we show how they can be (re-)built in a privacy- and integrity-preserving way. For example, our FitBit study was inspired by wireless activity tracking devices manufactured by FitBit (`fitbit.com`) and Earndit (`earndit.com`). The Slice study was inspired by purchase tracking software from Slice, Inc. (`slice.com`). The study Waze app was inspired by Waze, a popular crowd-sourced, real-time traffic app for mobile platforms (`waze.com`).

Contributions: We make these contributions:

- This paper proposes ZØ, a distributing compiler that allows developers to create highly performant, large distributed applications, while preserving both privacy and integrity. ZØ uses precisely calibrated *cost models* to choose which underlying zero-knowledge back-end to employ. Based on the cost model, ZØ statically determines the appropriate *splitting perimeter* for the application to achieve best performance and rewrites it to be run on multiple tiers.
- **Developer**: ZØ is designed to be easily accessible to a regular developer; to this end, we expose zero-knowledge functionality via LINQ, language-integrated-queries built into .NET. We demonstrate the expressiveness of the ZØ approach by developing six case studies directly inspired by commercial applications which we hope will become benchmarks for zero-knowledge tools, ranging from personal fitness tracking (Fitbit) to crowd-sourced traffic-based routing (Waze), to personalized shopping scenarios.
- **Cost modeling**: We develop cost models for the individual back-ends, allowing us to perform global cross-tier optimizations. Our cost-fitting models provide an excellent match with the observed performance, with R^2 scores between .98 and .99.
- **Speedup**: We evaluate ZØ on six complex real-life large-scale applications of zero knowledge, focusing on latency and throughput of zero-knowledge tasks. Our global optimizer is fast, completing in under 3 seconds on all programs. ZØ produces code that achieves as much as 40× speedups compared to state-of-the art zero-knowledge systems. We also find that ZØ is able to effectively optimize *across tiers* in a distributed application: while the code it generates may be slower on one tier (we observed one case that was 2× slower for the server), the savings at other tiers are always greater (e.g., 4× faster on the client).
- **Scale**: At scale, existing zero-knowledge compilers often produce code that fails to run in a reasonable amount of time, or exhaust system resources during compilation. In these cases, ZØ is the *only* solution that is able to provide a working application.

Paper Organization: The rest of the paper is organized as follows. Section 2 provides motivating examples and some background on zero-knowledge. Section 3 gives an overview of the ZØ approach. Section 5 describes the ZØ compiler implementation. Section 4 talks about cost models and both local and global optimizations ZØ performs. Section 5 describes ZØ implementation. Section 6 discusses how ZØ translates C# into ZK proof-generating code. Section 7 presents six case studies. Section 8 describes our experimental evaluation. Related work is discussed in Section 10 and Section 11 concludes the paper. The PDF version of this paper has

Figure 1: Example application: a personalized retail loyalty card.

an with additional diagrams to supplement the main text.

2 Background

To explain the goals of ZØ concretely, we will demonstrate its functionality on a smartphone application with conflicting privacy and integrity needs.

2.1 Example: Retail Loyalty Card

Figure 1 shows the ZØ code for a personalized retail loyalty card mobile app, with functionality similar to Safeway's "Just for U" application or Walgreens' iOS application. Each time the customer reaches the check-out line, this application interacts with the retail terminal in a bi-directional exchange of information. The exchange takes place using the phone's built-in NFC sensor.

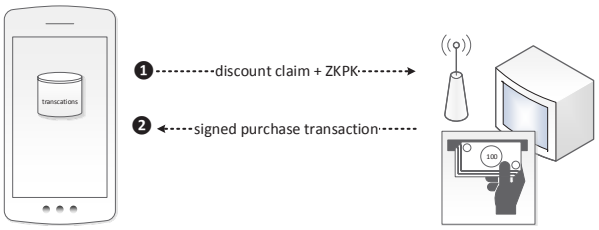

Figure 2: Personalized loyalty card application.

First, the application sends a *discount claim* to the retail terminal, pertaining to the items the customer is about to purchase. This discount is computed based on the customer's previous purchases, using personalization to provide enhanced value and incentive for the customer. Zero-knowledge proofs are supplied to ensure the privacy of the customer's shopping history, without sacrificing the trustworthiness of their discount claim.

Second, the terminal sends a list of purchases to the client, corresponding to the current check-out transaction. This list, along with the customer's other previous purchases, will be stored in a client-side database used to compute a discount the next time the user shops with this retailer.

Application Code: Figure 1 contains C# code for computing the core functionality of this application: using the customer's purchase history to produce a discount, and sending that discount to the retail terminal. It is important to notice that this is standard C#, capable of seamless incorporation into larger bodies of C# code. In fact, ZØ extends the standard C# compiler, and only applies specialized reasoning to classes that inherit from ZØ's `DistributedRuntime` class. All of the UI and external library code can remain in the application, without affecting the performance and functionality of ZØ. This allows ZØ to scale to large applications with arbitrary legacy dependencies, provided that the sections requiring zero-knowledge reasoning are localized and moderate in size. Several important points bear mentioning.

First, of the four functions, two of them, which we call *worker functions*, contain *location annotations*: `GetDiscounts` is constrained to execute on the client (e.g., the user's smartphone), and `ApplyDiscount` to `External` (e.g., the retail terminal). ZØ generates separate object code for each of these locations, and inserts code to handle the network transfer and data marshalling for any dependencies between these two functions. In order to streamline the code generated by ZØ, the worker functions must always return `void` or `IEnumerable` ob-

jects, which ZØ's underlying runtime is optimized to quickly marshall and transfer.

Second, the target functionality is computed from the main function `DoWork`, which is called after `Initialize`. `Initialize` gives the application an opportunity to prepare the class's local state by reading sensors, buffering data, etc., and can contain arbitrary C# code. `DoWork` is more constrained: it can contain a sequence of calls to worker functions, with no intermediate local computations, branching statements, or loop statements. This allows ZØ to efficiently compute the dependencies between different tiers. In this case, ZØ determines that the return value of `GetDiscounts` (computed on the smartphone) is always used by `ApplyDiscount` (computed on the retail terminal), and inserts code to package and send, or receive and unpack, the necessary data as well as any accompanying zero-knowledge proofs.

Third, the main code is located in `GetDiscounts`, which takes a list of the user's previous purchases (`history`), the user's current check-out items (`items`), and a finite-state transducer (`automata` and `transducer`), and produces a discount dollar value for transfer to the retail terminal. The transducer is produced by the retailer, and is designed to associate past purchases to items that the customer may be interested in buying in the future; the details of designing the transducer are beyond the scope of this work. `GetDiscounts` begins by checking that the purchases are given in ascending order, by their ID numbers; this is a simple optimization that allows the retailer to minimize the size of the transducer. This check is performed using LINQ's `Aggregate` operator, and ZØ's `check` function, which behaves like an assertion. It then proceeds to traverse the transducer's finite-state machine using the customer's shopping history, effectively loading the history into the transducer's memory in preparation for emitting discount values.

Finally, the customer's current items are processed by traversing the finite-state machine, starting in the final state of the previous traversal, and summing the output of the transducer relation. The final sum is returned to `DoWork` as a discount claim.

Zero-knowledge: The entirety of `GetDiscounts` is computed in zero-knowledge, as indicated by the `ZeroKnoweldgeBegin`() and `ZeroKnowledgeEnd`() annotations. Notice that each statement of this method consists of a LINQ query, giving the computation an overall functional form, without using language features such as references, loops, or conditionals. This is necessary to accommodate faithful translation into code that produces zero-knowledge proofs using the zero-knowledge backends discussed in Section 2.2. However, the programmer is still able to express computations in this fragment of standard C#, without dealing with the overhead of inter-language binding between the engines and the main program, and without needing to learn the different input languages understood by each engine.

Finally, a few subtle details of this code bear mentioning. Two of the class variable declarations, `shophist` and `items`, have location annotations that tell ZØ that they should not leave the customer's smartphone without first being processed by zero-knowledge code. This gives the programmer an extra degree of assurance of the code's privacy properties, letting her treat the zero-knowledge code regions like *declassifiers* with additional integrity guarantees. Finally, notice that the parameters to `GetDiscounts` contain `MaxSize` attribute annotations. These optional size annotations allow the ZØ compiler to do precise cost modeling, as explained in Section 4.

2.2 Zero-Knowledge Back-ends

ZØ relies on two zero-knowledge back-ends, Pinocchio [31] and ZQL [16], to produce code that balances privacy and integrity. Each of these back-ends takes an expression, in the form of executable code in a high-level source language, and produces object code that computes the expression over dynamically-provided inputs while building zero-knowledge proofs for the expression on the given input. These engines have very different characteristics that affect performance and usability in different ways, which we outline here.

Pinocchio: Pinocchio utilizes a novel underlying computation model, *Quadratic Arithmetic Polynomials*, to evaluate an expression and produce zero-knowledge proofs [31]. For some computations, it yields performance gains several orders of magnitude beyond previous systems that gave similar functionality, producing proofs of a *constant size* regardless of the size or structure of the target expression.

The expression language supported by Pinocchio is a strict subset of C, and the object created for evaluation is an *arithmetic circuit* [31]. The fact that the target circuit must be finite, and cannot encode *side-effects*, imposes necessary conditions on the parts of C that are available. Loops and conditionals are "unrolled" during compilation, so all loops must have static bounds. Likewise, pointers and array indices must be compile-time constants, or simple loop variables (as these are unrolled), thus simplifying cost modeling. For this paper we used a publicly released version of Pinoccio 0.4 obtained from the public distribution[1].

ZQL: ZQL utilizes several fairly recent advances in the theory of zero-knowledge proofs to produce efficient verified private code that operates over functional lists [16]. The underlying cryptographic machinery used by ZQL is more traditional than that of Pinocchio, relying heavily on homomorphic commitment schemes to provide its

[1] `https://vc.codeplex.com/downloads/get/714129`

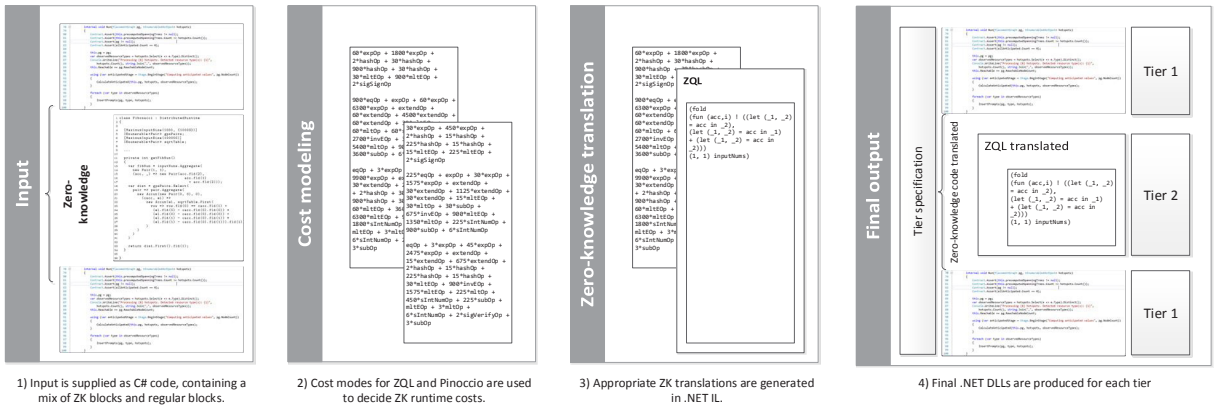

Figure 3: ZØ architecture. ZQL and Pinoccio are used as sample back-ends for illustrative purposes.

guarantees. The expression language supported by ZQL is a simple functional language without side effects, and limited operator support. In a nutshell, ZQL supports map and fold operations, as well as find operations over tuples of integers. Boolean expressions can only be used inside of find operations, and are currently limited to conjunctions of equality tests; all forms of inequality are not explicitly supported, although the authors plan to support these operations in future versions. In terms of arithmetic, addition, subtraction, and multiplication are supported. Finally, multiple operations can be sequenced using classic functional let bindings. Although these constructs might seem modest at first blush, the ability to perform table lookups using find allows for the evaluation of logic gates, and the list-based map and fold operations place no upper-bound on the size of the program's input, as in the case of Pinocchio. We obtained a version of ZQL from its authors.

3 Overview

Figure 3 shows the architecture of the ZØ compiler. The developer provides as input a set of C# source files, which may include arbitrary regions of legacy and library code as well as functionality targeted towards zero-knowledge proof generation. ZØ then enters a *cost modeling* stage, analyzing the zero-knowledge regions, building performance models that characterize the cost of providing zero-knowledge proof generation and verification code for each available zero-knowledge back-end. These models take the form of polynomials over the size of the input data to the zero-knowledge region in the original C# application. ZØ then compares the models to determine which engine the application should use for each C# statement in the region, and translates the C# code (depicted in the *zero-knowledge translation* stage of Figure 3) into expressions understood by the appropriate zero-knowledge engine. In the *final output* stage (Figure 3), ZØ decides how to split the application across tiers to maximize performance, given privacy annotations as well as relative *costs* for transmitting data and computing at each tier.

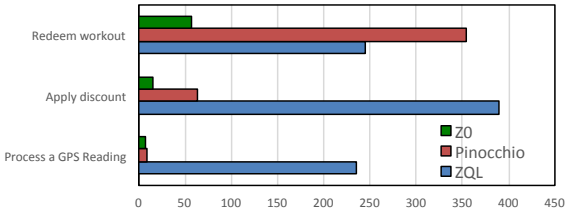

Figure 4: Comparison of times for several applications.

This translation yields a separate module which is callable from the original application, either as an *arithmetic circuit* (Pinocchio) or standard .NET bytecode (ZQL). Finally, ZØ partitions the original C# code, along with the zero-knowledge modules compiled in the previous step, into multiple applications to run at each *service tier*. During partitioning, ZØ inserts code to perform communication, synchronization, data marshaling, and zero-knowledge proof transfer in parallel to the original application code. The resulting modules are standard .NET bytecode that can be run on the proper tiers without the need for additional specialized software.

Optimization & cost models: Even apparently straightforward applications like the personalized loyalty card app discussed in Section 2.1 contain subtle characteristics that might make zero-knowledge proof generation expensive. It is often the case that one zero-knowledge engine offers significantly better performance for a particular statement, and selecting the appropriate engine for each computation in the zero-knowledge region means the difference between a scalable, low-latency implementation and one that requires hours or days to execute.

For the loyalty card application in Figure 1, it turns out that the inequality comparisons are better handled by Pinocchio, whereas the table lookups needed to execute the transducer are very inexpensive when performed by ZQL. A comparison of the times to perform the operation on the y-axis for several applications from Section 7 is shown in Figure 4. We can see dramatic differences in performance between the back-ends, with the ZØ approach out-performing either of the two back-ends. ZØ addresses these performance differences by building detailed performance models for each statement in the zero-knowledge region.

Distributed configuration: To support a variety of distributed scenarios, ZØ allows the developer to place code on several different tiers, which are specified using the following *tier labels*: Client (end-user's primary device), External (provider's servers), ClientShare (peer-to-peer nodes), and ClientResource (additional hosts owned by end-user). Tiers impose data confidentiality and integrity constraints, as ZØ makes assumptions about the *trust relationships* between tiers.

The figure in this paragraph shows these relationships; white cells indicate trust, and gray the opposite. At compile time, the user can modify the configuration by specifying *weights* on each tier label indicating the relative cost of computation at that tier, as well as the cost of communication between tiers. ZØ uses these weights during optimization to determine the best placement of code and data amongst the tiers, and are only necessary to fine-tune the performance of certain applications; they can be ignored and left at the default value of 1 by default. Data privacy constraints are given by the programmer by marking certain variables as *private* to a particular tier using the attribute [Private(T_L)], where T_L specifies the tier to which the data is considered private (e.g., Client, External, ...).

	C	CS	CR	E
C				
CS				
CR				
E				

Note that by design, these annotations are lightweight: they are only needed on (the few) variables that must be kept confidential. Most can be declared without any annotations at all.

When ZØ compiles the application and runs a global optimization described in Section 4.2 to place each worker method on a specific tier, privacy annotations are used in part to determine on which tiers a method may reside. These constraints are *hard*, meaning that a privacy annotation that requires a less performant compilation configuration will always be respected; if the privacy constraints conflict with each other, then compilation will not terminate early. Privacy annotations are propagated transitively using a local dataflow analysis, so that dependent variables have matching annotations.

Threat model: Because of its reliance on zero-knowledge back-ends, ZØ makes all of the assumptions needed for security by ZQL [16] and Pinocchio [31]. The result of ZØ compilation will be executed on one or more tiers. Privacy is violated when the trust relationships given in the previous section are violated. We assume that tiers cannot learn information by means other than direct communication, i.e. Server cannot obtain the list of purchases through side channels, for instance, unless it is directly shared by Client. Our applications that use secret sharing (Waze and Slice in Section 7) also assume that P2P clients do not collude.

4 Cost Models & Optimizations

This section discusses ZØ's cost modeling approach to optimizing zero-knowledge computations. As outlined in Section 3, in many cases one zero-knowledge engine will outperform the other on a particular computation by a significant factor, giving ZØ a key opportunity to optimize the code it produces. ZØ optimizes zero-knowledge regions by building detailed performance models that characterize the cost of building and verifying zero-knowledge proofs in each engine. We are able to accomplish this with reasonable accuracy because the execution depth of zero-knowledge regions is statically-bounded (a necessary condition imposed by the underlying engines), and the evaluation of zero-knowledge code universally relies on a few primitive operations. This allows ZØ to build static *cost models* as polynomials over the number of primitive operations each region must execute.

Section 4.1 discusses local optimizations within a given zero-knowledge region to decide which back-end to use. Section 4.2 proposes a split for the entire application designed for maximal performance.

4.1 Local Optimization

In order to build cost models for ZQL code, we execute the F# "object code" generated by ZQL's compiler *symbolically*. Symbolic data is represented by polynomials that characterize the size of the corresponding concrete data, or structured sets of polynomials in the case of structured data types. The symbolic operation for each ZQL operation accumulates terms on a polynomial that characterize the cost of that operation in terms of the size of its input data, and returns a new polynomial that characterizes the cost of producing of the result. Because the execution depth of iteration commands is always a polynomial function of the size of the inputs, and ZQL programs do not contain branching, accumulating a cost polynomial by symbolic execution necessarily accounts for *all* of the operations contained in a ZQL program.

Recall that Pinocchio compiles C code into a circuit, which is evaluated by a specialized runtime to produce and verify zero-knowledge proofs. The Pinocchio runtime executes roughly the same code to evaluate every

Figure 5: Absolute regression error (in seconds).

circuit, varying only on the number of times each operation is executed to handle every element of each input list and every operation in the circuit. We build a set of static polynomials that characterize the execution time of the runtime in terms of the size of the input circuit, i.e., the number of I/O wires and multiplication gates it contains. For example, the cost of the verification stage is given by the polynomial:

$$ExpMulB \times NInputs + 12 \times Pair + VerifyConst$$

In this polynomial, *ExpMulB* corresponds to the amount of time taken to complete a multi-Exponentiation on the Pinocchio's base elliptic curve, *NInputs* to the number of input wires in the circuit, *Pair* to the field pairing cost [31], and *VerifyConst* to a fixed setup cost for the verification stage. Similar polynomials are derived for the other stages of Pinocchio's runtime.

We use least-squares regression to derive coefficients for all models except those for Pinocchio's compute-stage model, which contains a non-linear term corresponding to the $O(n \cdot \log^2 n)$ runtime of polynomial interpolation. To cope with the non-linearity in Pinocchio's compute-stage model, we use the Gauss-Newton method [33] with at most 1,000 iterations and a randomly-chosen starting point.

Cost-fitting results: To derive the necessary coefficients for our models, we built a regression training application in ZØ consisting of several basic operations likely to appear in zero-knowledge applications. The training application takes as input a list of integers, and computes an aggregate sum, scalar product, second-degree polynomial, boolean mapping, and table lookup on the list. We compiled this application to use both all-ZQL and all-Pinocchio zero knowledge computations, and ran it ten times for each zero-knowledge engine using a fixed list size ($n = 100$). We performed regression to learn coefficients corresponding to the execution time of each primitive operation appearing in the cost model. We then compiled a representative subset of the applications described in Section 7 to use either all-ZQL or all-Pinocchio zero-knowledge computations, executed each zero-knowledge region ten times, and recorded the deviation between execution time predicted by the regression-trained cost models and the mean execution time observed over all experiments for a given application. Figure 5 presents the prediction error of the trained cost models in terms of the total zero-knowledge execution time in seconds. Note that the models derived for Pinocchio are generally more accurate in terms of relative error than those for ZQL, but the error in both cases is quite small: the greatest Pinocchio error is 0.39 seconds (on FitBit's key generation routine), while the greatest ZQL error is 1.81 seconds (on FitBit's prover routine). The coefficient of determination (R^2) for each performance model is at least 0.98, indicating a precise fit of the models to the execution time.

Summary: To summarize, ZØ is able to build performance models of zero-knowledge regions that predict actual execution time within tenths of a second in most cases, which provides ample accuracy to make a correct decision when selecting zero-knowledge engines at compile-time.

4.2 Global Optimization

ZØ builds cost polynomials to characterize the expense of each zero-knowledge operation in the target application. However, selecting the least expensive engine for each operation is oftentimes not as straightforward as evaluating each polynomial at a target input size and choosing the engine corresponding to the lesser value — it may be the case that a less expensive operation on the prover's side requires a more expensive operation on the verifier's side, and depending on the application computation may be more expensive for the verifier. Alternatively, there may be several ways to partition an application between tiers while preserving the privacy of variables at each tier, with each partition yielding a different trade-off between computation and communication cost. To address these concerns, ZØ performs *global optimization* on the application to balance the cost of computation and communication among differentiated tiers.

Performance of global optimization: We implemented our global optimization algorithm as part of the ZØ compiler. We use CCI2 to traverse the AST of the target code, and our cost modeler to generate the objective function.

Loyalty	38	0.01
Waze	263	2.65
Sice	230	2.14

Figure 6: Global optimization performance, showing solver time in seconds for the benchmarks in Section 7.

To perform the constrained optimization needed to find an optimal solution, we used the Nelder-Mead method [33] with at most 100 iterations. We looked for integer solutions over the full space of tier splittings.

The results are presented in Figure 6. Each application resulted in between 30 and 300 constraints, and the constraint solver found an optimal solution in under three seconds for all applications. Because Nelder-Mead is an

approximate numerical optimization algorithm, it is possible that it would return a *local* minimum.

However, we checked the solution returned for each application, and verified that it corresponded to the true global minimum. Figure 7 shows examples of ZØ-computed global splits for two representative applications.

5 Implementation

In order to make privacy analysis, zero-knowledge translation, and aggressive optimization feasible for the programmer, ZØ supports a subset of C# that includes certain LINQ (language integrated queries [34]) functionality and support for external code. To ensure that the external code does not interfere with the privacy, integrity, and optimization goals of ZØ, the contexts in which it is allowed are limited in some cases. The syntax accepted by ZØ is summarized in Figure 8.

The main program is structured into three parts: an initialization routine (InitBlock, contained in a method `Initialize`), the main body (MainBlock, contained in a method `DoWork`), and the worker methods (MethodDef). The initialization routine may consist of a sequence of arbitrary C# assignment statements, including calls to methods in external libraries not written in ZØ's input language. The main block consists of a sequence of method calls, assignment statements, and sleep statements. Each method call in the main body must be to a worker method defined in the ZØ application.

Zero-knowledge regions: The body of each worker method can contain calls to external methods, standard C# arithmetic and Boolean operations, and a subset of the standard LINQ data processing operations. Regions comprised of LINQ operations can be converted into zero-knowledge proof-generating object code using either available zero-knowledge engine (ZQL or Pinocchio). The supported LINQ operations include Select, Aggregate, First, and Zip. Select provides the ability to project the data in one list into a new list, while performing arithmetic and Boolean operations on each item in the original source list. Aggregate provides the ability to compute iterated functions over a list, maintaining an order-sensitive state through the iteration, which is eventually returned as the result of the operation. First provides the ability to perform searches over lists, using a programmer-defined predicate to determine which element of the list to match. Finally, Zip provides the ability to combine multiple lists, applying arithmetic and Boolean operations to each pair of items from the original source lists.

Zero-knowledge regions are specified by the programmer using a pair of methods ZeroKnowledgeBegin and ZeroKnowledgeEnd. Because zero-knowledge computations provide both integrity and privacy, these annotations serve a dual purpose. First, the programmer is denoting that the variables which are *live* [1] at the end of a zero-knowledge region are trusted across all tiers: the values have accompanying proofs that any tier can examine to verify that the computations in the zero-knowledge

region are performed correctly. Second, these regions serve to *declassify* private values that are used as inputs to a zero-knowledge region; this is in line with the approach taken by ZQL [16]. Because the inputs to zero-knowledge regions are kept private, except in cases where the computations are in some way invertible, the output values that depend on these inputs are considered public to all tiers.

Formal reasoning about composing proofs obtained from different zero-knowledge back-ends remains an avenue for future work. Because this work involves experimentation with very recent cryptographic tools, we are not aware of a readily-available composition theorem that would support reasoning about Pinocchio and ZQL.

Code splitting: ZØ partitions the given target application into code that runs on multiple tiers, inserting marshalling and synchronization code [20, 24] as necessary to ensure that the compiled functionality matches that specified in the original input program. The rewrite process is implemented as a bytecode-to-bytecode transformation within the CCI 2 rewriting framework for .NET [27]. We assume that the target tier for each method is provided as input to the compiler by the optimizer, as described in Section 4.2.

Code partitioning between tiers takes place at method granularity, and data partitioning is determined by the chosen code partition; data is transmitted between tiers on-demand, with all of the data represented by a variable used by a particular method being transmitted at once as it becomes available. Only worker methods can be split between different tiers, so all external code referenced by the application is present on each tier. This allows the compiler to avoid a potentially expensive deep-dependency analysis of the referenced external code, while keeping the dependency analysis of the target application localized to `DoWork`.

Runtime support: The architectural principle that guides ZØ's tier-splitting algorithm can be summarized as follows: *whenever possible, delegate the data communication and synchronization operations necessary to support functionality to a runtime API.* Each application compiled by ZØ is linked to a runtime library that provides an API for communicating data and synchronization between separate tiers. When the compiler performs tier splitting, rather than inlining complex code to perform the tasks, simple calls to this API are inserted to perform the "heavy lifting" of tier crossings at runtime.

6 Translating LINQ to Zero-Knowledge

Our compiler translates specified statements containing LinqExpr components in the worker methods into code that generates zero-knowledge proofs of knowledge. To accomplish this, ZØ relies on two *zero-knowledge back-ends*: ZQL [16] and Pinocchio [31]. Each back-end is itself a compiler, accepting as input an expression of a computation, and producing executable code to produce a zero-knowledge proof of the computation for a given set of inputs. As such, each back-end supports its own *expression language* with significantly different characteristics. The challenge addressed in this section is the translation of the common subset of LINQ supported by ZØ into the expression languages of these back-ends.

Figure 1 in the gives an overview of our back-end compilation process for ZQL and Pinocchio. The details differ widely for each back-end, converging only on the first and last steps which correspond to lifting low-level intermediate language code into a higher representation and inserting I/O marshaling instructions before and after the compiled object code. This divergence of functionality is necessary given the differences between the two expression languages: ZQL's expression language is essentially a small subset of pure standard ML, whereas Pinocchio's is a subset of C with restrictions on data types and loop bounds. Because the subset of LINQ functions supported by ZØ corresponds to a small core of functional expressions, translating from ZØ to Pinocchio is much more involved than to ZQL.

6.1 Pinocchio

The structure of C code is substantially different from the types of LINQ queries allowed by ZØ, and Pinocchio's additional restrictions make translation more complicated yet. First, all list sizes used in the Pinocchio expression must be statically-declared, and any operation over a list requires a static value to bound the corresponding loop statement. The LINQ commands in ZØ do not have these restrictions, so we must find a way to derive the needed information. Second, many expression forms in ZØ's LINQ commands have no corresponding expression form in C: they must be converted into statements whose side-effects are available as sub-expressions to enclosing expressions.

To perform translation to Pinocchio, ZØ follows a three-step process. First, static values for the size of each identifier that refers to a list value are derived using a constraint solver. The basis for this computation is a set of annotations provided by the developer, which indicate upper bounds on the sizes of certain input lists.

List Size Resolution: As previously discussed, Pinocchio requires static sizes for all lists and list operations, so our translation procedure requires a mapping from identifiers (for those that refer to list objects) to size constants. To produce such a mapping, we use a constraint resolution procedure over a set of bounding constraints generated by traversing the source expression. The rules for generating the constraints are given in Figure 9. Each rule is of the form $\Gamma, \textit{Syntactic Element} \Rightarrow \Gamma'$, where Γ

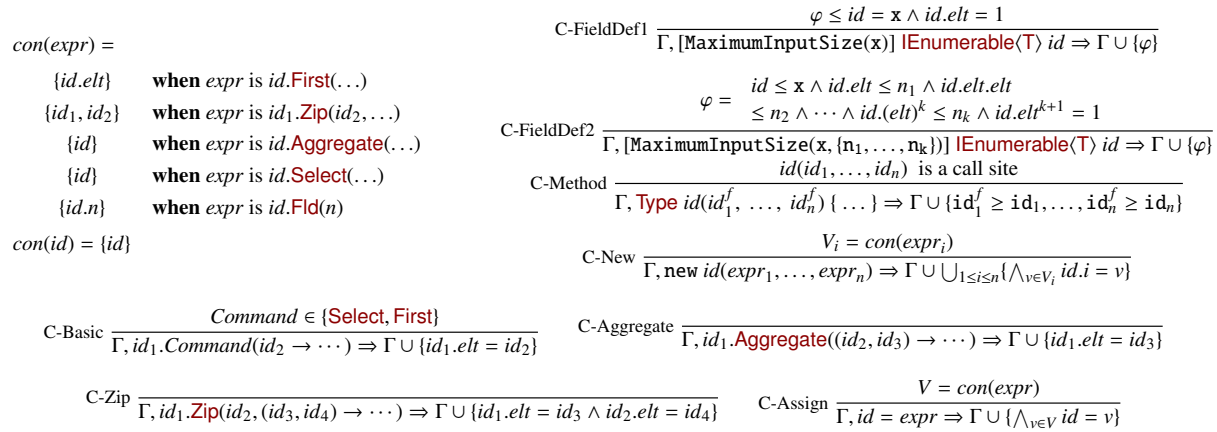

Figure 9: List size constraint generation rules. Γ is a set of constraints.

and Γ′ are sets of constraints. The constraints for each LINQ command are straightforward. The outcome of Select, Aggregate, and Zip operations has the same size as the input variable(s). The outcome of a First statement has the size of the elements contained in the input list.

The rules are invoked by a procedure that traverses each node of the program's AST, and performs syntactic matching on the entity represented by each node and the *Syntactic Element* of each rule. As the traversal proceeds, a list of constraints is maintained, and updated when rules match AST nodes. When the AST traversal completes, the set of constraints generated is passed to Z3 for resolution. If the constraints are satisfiable, Z3 will produce a model that associates constraint variables to integers that satisfy the original constraints. This model contains all of the information needed to derive the needed mapping between identifiers and list sizes.

Type Generation and Function Isolation: Pinocchio requires static sizes on all arrays and loop bounds. To accomplish this, ZØ creates a new `struct` type for each list with a distinct base type and size in the original program. Each new type has two fields: a static array and a constant defining the size.

Once types for each identifier are established, each sub-expression in the source statement is converted to a function body. To see the need for this step, consider the statement x.Select($el \rightarrow el$.Select(...)). C has no expression form for the functionality needed by the Select command, so both expressions must be converted into loop statements. Rather than placing the loop statements in the same method body and carefully managing side effects and sequencing with other sub-expressions, we isolate the emitted code for the inner Select in a separate function, and emit a call to the new function in its place in the context of the outer Select expression.

The statements generated for each LINQ command are straightforward translations of their defined behavior into basic C; in general, the input loop is iterated over, and the lambda passed to the command is invoked over each element. Field lookups, new object construction, and function calls are rewritten to their C equivalents.

6.2 ZQL

Recall that we only attempt to convert LinqStmt statements into zero-knowledge, so there are four primary functions to convert, in addition to a few additional expression forms. By no coincidence, the four primary LINQ functions correspond closely to the operations supported by ZQL. Figure 2 in the gives a set of rewrite rules that can be used to translate a LinqExpr to ZQL's expression language. Select, Aggregate, Zip, and First calls are translated to map, fold, map2, and find expressions. Lambda definitions and functions calls are translated compositionally, by first translating sub-expressions and then building a new construct in the target language. Object creation using new is translated into tuple construction. Recall that user-defined types in a ZØ program must expose a single constructor that assigns all fields of the type; field names are translated into a tuple order using the constructor signature. Similarly, field accesses using fld are translated into a let binding that returns the appropriate tuple component; the translation consults the target identifier's type constructor to deduce the number of fields in the type.

7 Motivating Case Studies

This section presents six case studies in ZØ, that are the focus of our experiments in Section 8. Similarly to [16], we assume that the sensor readings devices can are trusted and untampered with, and come signed by their producer, but the machine or mobile phone (Client tier) that performs the distance computation is not.

1) Walk for Charity with FitBit: Several programs exist for paying users for the amount of physical exercise they perform, either directly in the form of rewards, or indirectly by making charitable donations on their behalf,

such as `earndit.com`. This works by requiring users to log their exercise habits using a FitBit or other sensor device to measure the distance the user walks, runs, or bikes, and send the logs to a centralized server.

Privacy: The user may not want to reveal their *detailed physical activities* or *exercise route* to a relatively untrusted third party.

Integrity: The service is spending money on the basis of distance derived from sensor logs. If the distance computation can be subverted, the possibility for fraud arises, analogously to pay as you drive insurance [4, 38, 41].

Solution: Keep all sensor readings local to the user's machine (laptop or mobile device), perform the distance computation locally, on the client, send the result of the distance computation to the centralized third-party server. Use ZKPK to ensure that the distance computation is performed correctly. This approach is similar to what has been advocated for smart metering [35].

2) Supervised Studies in Social Sciences: Many scientific studies, especially in medical and social sciences, require subjects to wear sensors and undergo protocols that provide information about their physiological and psychological state. A study that seeks to understand the effect of common workplace events on worker's stress levels might require a participant to wear a galvanic skin response sensor and a camera to detect face-to-face interactions.

Privacy: Participants may have concerns about the use of their physiological measurements or, most prominently, the processing of images taken from their cameras.

Integrity: These studies typically involve payment given to subjects. Subjects concerned about their privacy, or those who simply do not want to wear intrusive sensor devices, have an incentive to *fake* their data.

Solution: Have all sensors associated with the study report readings to the subject's machine (desktop or mobile phone). This machine performs aggregate computations relevant to the actual study on the readings, reporting results and discarding the raw sensor readings. ZKPK is used to ensure that the readings are processed correctly.

3) Personalized Loyalty Cards: Many of today's large retailers such as Target, BestBuy, etc. use customer loyalty cards to encourage repeat visits. Typically, the customer must enroll in a loyalty program, and receive a card that can be applied to receive discounts in future visits. Recently, certain retailers (e.g., Safeway) have begun personalizing this process by using the customer's past purchase history (available because of the association between checkout and loyalty card) to create discounts available only to one particular customer. Depending on the retailer, these discounts can be sent to the customer's mobile phone, or applied automatically at checkout.

Privacy: Many people are not comfortable with a retailer tracking their purchases. This is most readily illustrated by a recent scandal with Target discovering that a teenage girl was pregnant before her parents did [14].

Integrity: Retailers offer discounts on the basis of past purchase history. If a customer could fake a purchase history, they might be able to obtain a discount for an item of their choosing. Moreover, having a reproducible strategy for "generating" discounts might create a serious problem for the retailer, similar to those experienced by some retailers that were overly generous in offering Groupons [32].

Solution: The solution is discussed in Section 2.1.

4) Crowd-sourced Traffic Statistics: Several mobile applications such as Waze (`waze.com`) and Google Maps provide traffic congestion information to end-users based on the combined GPS readings of the users.

Privacy: Users do not want to share their location with the app's servers, or the general public (in the case of a distributed protocol).

Integrity: The app needs reliable GPS readings from users to provide its core functionality. If users wish to "game" the system by providing fake GPS readings while receiving the end-product, the integrity of traffic data is compromised for everyone.

Solution: Let the users keep their GPS readings local, and take part in a distributed protocol to compute local density information for transmission to the app's central server. Clients represent their location on a map using a vector, represented as a set of secret shares, which can be added to the other clients' vector shares to derive the overall traffic density map. When each client sends their summed shares to the server, it can reconstruct the density map by combining the shares, as detailed in the appendix.

5) CNIDS: Collaborative intrusion detection (CNIDS) has long been a goal of security practitioners [25]. In the CNIDS scenario, multiple (distrustful) organizations share the results of their network intrusion detection sensors, to provide their peers with advanced warning about possible threats. A practical approach involves sharing IP blacklists: when an IP generates a valid NIDS alert on one organization's network, the IP is recorded and sent to the other participating organizations.

Privacy: NIDS operate on highly sensitive data — raw network traces. Organizations participating in CNIDS do not want to share their traces with other organizations, and in many cases, may be prohibited from doing so by law or organizational policy.

Integrity: Given the privacy concern and the benefits of participating, some organizations may want to freeload by suppressing their own NIDS alerts. Additionally, if

an adversary manages to compromise a participating network, it may choose to suppress or even generate false alerts, which may result in a denial of service for the targeted IP address.

Solution: Provide a ZKPK for the NIDS signature-matching process, to prove that a claimed intrusion is correct according to the signature. Note that this approach assumes that raw network data coming into the NIDS has not been tampered with, but that the machine performing the signature matching may not be trusted.

6) Slice: Organizing Shopping: Slice (`slice.com`) is a service that takes as input a user's past purchase history from their email mailbox, and provides various services using that data. One such service is product recommendation — given everybody's past purchase history, slice can build classifiers that predict a likely "next" purchase.

Privacy: Handing one's entire purchase history to a profit-driven third party has obvious privacy implications. So does the troubling need to share one's email credentials with Slice at the moment.

Integrity: A user, particularly one concerned about privacy, might provide fake data to Slice in order to obtain the useful classifier, which would pollute Slice's data for everyone and jeapordize Slice's ability to profit from the classifier.

Solution: Keep the user's purchase history local, and have the users take part in a distributed protocol in order to produce the classifier for Slice. Use ZKPK to ensure that no user is able to subvert the distributed classifier computation.

8 Experimental Evaluation

All experiments were performed on a Windows Server 2012 R2 machine with two 3.0 GHz 64-bit cores with 8 GB of RAM. All reported timing measurements correspond only to the zero-knowledge portion of the application's execution time, as this is the only portion that our compiler attempts to optimize.

The execution time of the ZK code is generally much higher that of the rest of the application, so focusing on these parts gives an accurate picture of the overall execution time. Each zero-knowledge proof generation and verification task was terminated after ten minutes. Our implementation uses 1,024-bit RSA keys for ZQL computations. Integers in Pinocchio circuits were configured to have 32-bits for comparison operations, and operate over a 245-bit field.

Figure 11 summarizes the key performance results from our experiments. We found that the ZØ-generated code gave significant performance benefits both in terms of computation time and proof size: up to 40× runtime speedup, with most proofs below 1 MB (the largest being ≈ 1.9 MB). Furthermore, we saw that global optimization is necessary to arrive at an ideal performance profile: some applications perform noticeably worse at one tier, but in each case the speedup at another tier was always greater. For example, the code ZØ generated for the Waze server ran ≈ 2× slower than Pinocchio's on average, but latency on the client tier was reduced ≈ 4×.

Scaling	ZØ scales to all application configurations. Others may time out or fail to compile in fewer than 20 minutes on some parameter settings: 100-byte traces (NIDS), >100 peers (Slice), large automata (Loyalty).
Latency	ZØ improves up to 40×, ≈ 5–13× on average
Proof size	ZØ almost always less than 1 MB, at most 1.5 MB. ZQL proofs can be tens or hundreds of MBs.
Global tradeoffs	ZØ may be slower at one tier (2× slower for Waze server), but savings at other tiers is always much greater (4× faster for Waze clients)

Figure 11: Performance summary.

Figure 12 shows the latency speedups across all applications. The average speedup delivered by ZØ is 3.3× compared to Pinocchio and 7.4× compared to ZQL.

Results: Space limitations do not allow us to present our measurements exhaustively. Instead, Figure 10 shows a sample of the runtime characteristics for our target applications. Rather than giving raw execution times, the results are broken into three categories: *throughput*, *latency*, and *proof size*. These metrics were selected to more clearly depict the impact of zero-knowledge techniques on each application.

Throughput: Figure 10(a)–(c) shows the results of three experiments involving throughput. Figure 10(a) shows the server's throughput for the Waze application, which corresponds to the number location updates per minute the server can handle as the number of users (n) increases. Notice that Pinocchio outpaces both the hybrid and ZQL compilations by about 2× on average. This is a result of the global optimization engine: verification in Pinocchio is very fast, whereas the time to construct a proof can be quite slow: in this case, the proof construction phase was up to 7× slower than the hybrid solution. This is critical, *as proof construction takes place on the client where resources are especially constrained for the application.* The discrepancy in resources is correctly used by ZØ to optimize for a lighter client workload at the expense of greater server overhead.

Figure 10(b) shows the number of random forest construction queries per minute the Slice server is able to handle, as the number of participating peers increases. As with Waze the Pinocchio solution dominates the ZØ solution at all data points because of the greater expensive of constructing proofs on the client, where the Pinocchio solution is up to 4× slower than ZØ.

Figure 10(c) shows the number of intrusion alerts per minute the collaborative NIDS server can handle as the number of bytes in the intrusion trace increases. Notice

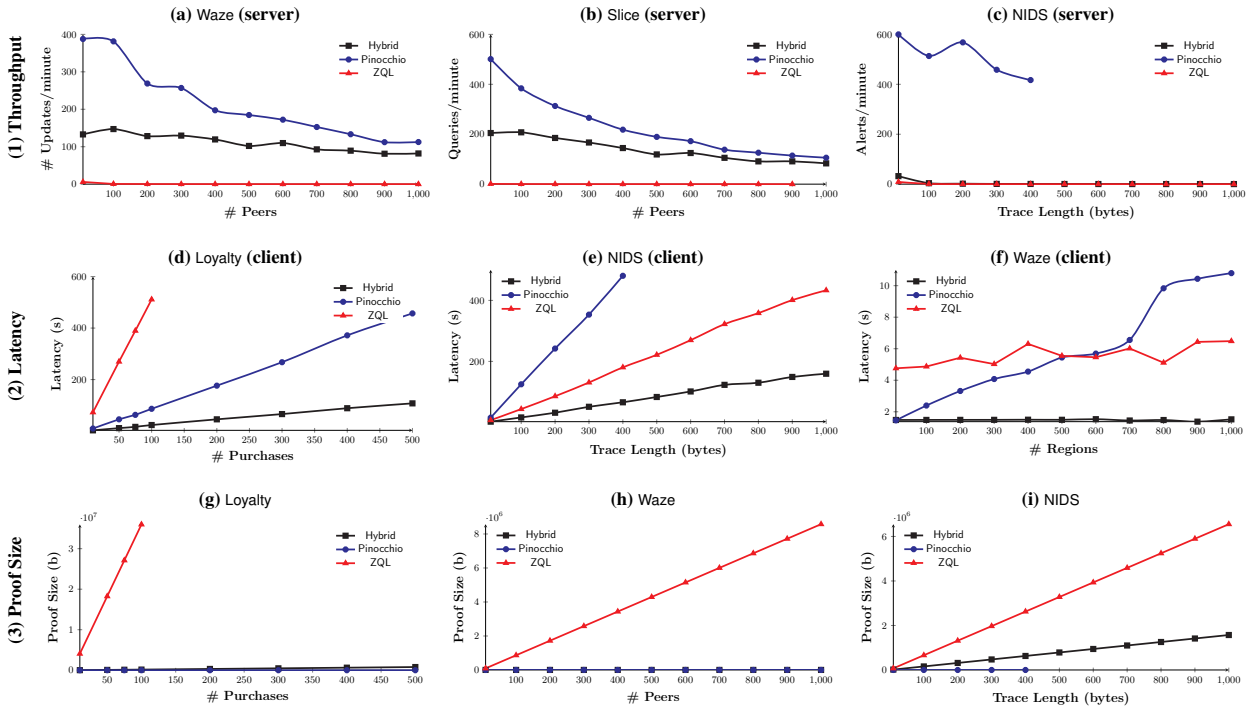

Figure 10: (1) Throughput, (2) latency, and (3) proof size for a characteristic sample of application functionality.

that Pinocchio outperforms at a few small data points, but fails to scale to any larger points. This is not because the server-side component is unable to scale, but rather the client timed out at these settings. For the remaining points, the ZØ solution outperforms the others by about 4×, and is the only solution that is able to scale to even the modest intrusion trace length of 1 KB.

Latency: Figure 10(d)–(f) shows the results of three experiments involving latency. Latency is always measured in seconds, and has a uniform upper bound of 600 seconds, which corresponds to our experimental timeout.

Figure 10(d) shows the latency of the client side of the Loyalty application as the number of purchases used to personalize discounts (n) increases. The ZØ solution far outpaces both alternatives at all data points (4–22× improvement). These experiments were performed for an automaton with about 75 edges. We found that when we scaled the automaton to more realistic sizes (a few thousand edges), the ZØ solution was the only one capable of completing *any* number of purchases before timing out, and the Pinocchio compiler timed out after 20 minutes. For longer purchase histories, the ZØ solution completes in just over 1.5 minutes, which is ample time if the application is location-aware and begins proving a set of discounts when the user enters the store.

	Pinocchio		ZQL	
	Mean	Max	Mean	Max
FitBit	6.4	6.6	4.5	4.7
Study	1.0	1.0	39.7	40.3
Loyalty	4.1	4.2	10.1	21.8
Waze	4.0	7.1	4.3	4.7
CNIDS	5.3	7.3	2.7	2.7
Slice	2.5	4.1	8.1	12.9
Mean	**3.3**		**7.4**	

Figure 12: Latency speedup factors for each application; averages use geometric mean for proportional speedup.

Figure 10(e) shows the NIDS client's latency to demonstrate that a single intrusion is present in a trace. Pinocchio times out at all points beyond 300 bytes, whereas ZØ is about 2.7× faster than ZQL. Otherwise, we see that as long as intrusions are spaced more than two-and-a-half minutes (159 seconds) apart, the NIDS client has enough time to build proofs for each intrusion trace.

Figure 10(f) shows the latency of the Waze client to send traffic statistics for a single location query as the size of the map (n) increases. First notice that the ZØ solution is essentially constant, not varying by more than 1.5 seconds between any two data points. The other solutions require as much as 4–7× as long to process a query on the client, which will limit the quality (i.e., recency) of the statistics the server is able to gather over time. Second, notice that at about $n = 700$, ZQL becomes more performant than Pinocchio. This is because as the map increases, the size of the lookup table needed to encode the regions increases. Pinocchio is not able to perform lookups as quickly as ZQL, so the portion of the computation needed for lookups becomes more significant at higher values of n. ZQL performs worse at lower values because most of the computation corresponds to the multiplications needed to compute secret

shares, which it does not complete as quickly as Pinocchio.

Proof Size: Figure 10(g)–(i) shows the results of experiments involving the size of the zero-knowledge proof in various applications. We always measure in bytes, and do not display a curve for the Pinocchio solutions, as it is constant across input size and is usually too small to distinguish on the same scale as the ZQL and ZØ solutions. Figure 10(g) shows the proof size for the Loyalty application as the number of past purchases (n) varies. While the Pinocchio solution of course dominates the others by this metric (864 bytes), as we know from previous experiments (Figure 10(d)) it does not scale in terms of Latency. The ZØ proof size remains nearly constant, always under 500 KB, whereas the ZQL solution requires at least three megabytes (to perform the inequality checks at the beginning), and finishes at about 100 megabytes. Note that we obtained the point at $n = 300$ despite the timeout, by letting the prover run for longer in this single instance. Because the Loyalty application needs to communicate this proof wirelessly to a POS terminal, size is crucial, and the ZØ solution offers the best overall characteristics in terms of size and latency.

Figure 10(h) shows the proof size for the Waze application as the number of peers varies. Again, Pinocchio dominates (2 KB), but the tradeoff in latency for this proof size is quite high (Figure 10(f)). The ZØ proof size remains constant at around 5 KB because the only processing done by ZQL is table lookups, which have a constant proof size. The ZQL solution requires 20 megabytes for 2,500 clients, and 8 megabytes for 1,000 clients, making it untenable given that the clients need to transmit proofs frequently over cellular networks.

Figure 10(i) shows the proof size for the NIDS application as the intrusion trace length increases. The Pinocchio proof is about 1 KB, but again the tradeoff in latency makes this characteristic mostly irrelevant. The sizes for the ZØ and ZQL solutions are both linear, with the ZØ solution offering a savings of about 4× at all data points. This is a significant savings, considering that false positives may be frequent, so the client may need to send proofs to the server almost continuously.

9 Limitations and Future Work

Proof of security: The main piece of outstanding work for ZØ is a formal argument of security. Because ZØ composes non-interactive zero-knowledge proofs from distinct back-ends, the security guarantees given by the original back-ends do not necessarily readily translate to the final optimized code produced by the compiler. In future work, we hope to characterize a unified threat model that encompasses those of both back-ends, as well as a composition theorem that demonstrates the safety of ZØ's modular compilation philosophy.

Optimization robustness: One concern is that a developer may unwittingly write code in a zero-knowledge block that ZØ compiles into very inefficient code. In general, ZØ's cost models should allow it to select the best back-end most of the time. In certain close cases, where the performance difference between back-ends is slight, discrepancies between ZØ's model coefficients and the characteristics of the target architecture may lead it to select the less-efficient back-end. However, as the difference between back-ends is small to begin with in such cases, the absolute performance penalty will likely be small as well.

As non-interactive zero-knowledge is still significantly more expensive than "normal" computation even in the best cases, the programmer must be careful not to place unnecessary statements inside of a zero-knowledge block. Additionally, if the programmer places inaccurate size annotations on data structures, i.e., annotations that are significantly larger than the average workloads encountered in practice, then the cost models used by ZØ during optimization might not characterize the actual performance requirements of the application; this can lead to sub-optimal performance.

Hardware integrity: Many of the applications discussed in this paper gather data from trusted hardware devices. The zero-knowledge facilities in ZØ ensure that the results of computations performed on such data can also be trusted, i.e., they were derived by the code originally intended by the application developer. However, zero-knowledge proofs might not provide all of the guarantees needed to realize an intended high-level security goal in some cases.

For example, nothing prevents a malicious user from "fooling" the FitBit application by physically manipulating the hardware to register more steps than were actually taken. In these cases, ZØ increases security by ensuring that attacks on the application code will not succeed, so that more-expensive hardware-layer attacks are necessary. Whether this makes an attack on a given application sufficiently difficult, or economically infeasible, is a point to be carefully considered as part of an end-to-end security strategy.

10 Related Work

Tier-Splitting and Language Methods: A number of compilers exist that enable automated tier-splitting in some form. In the context of web programming, Google Web Toolkit (GWT) [20], Volta [24], Links [11], and Hilda [43] are among the pioneering efforts. ZØ is closest to Volta and GWT, allowing developers to supply a single piece of code that is compiled into separate modules for the client and server. Unlike those projects, ZØ uses cost models of execution time and data size to derive an optimization problem whose solution represents

an ideal division of functionality between tiers.

Others have used tier splitting to provide security and privacy guarantees. SWIFT [10] builds on the JIF [28] language, incorporating security types for confidentiality and tier-splitting for web applications. To accomplish this, information flow constraints are embodied in an integer programming problem whose solution corresponds to a valid (e.g., secure) placement of code onto tiers that minimizes the number of messages that must be transferred. Unlike ZØ, SWIFT does not explicitly account for data size and transfer time when looking for a split that is likely to maximize performance.

Backes *et al.* [3] presented a compiler for distributed authorization policies written in Evidential DKAL [6], an authorization logic that supports signature-based proofs. The use of zero-knowledge proofs allows principals to prove access rights based on sensitive data without directly revealing its content. ZØ differs in its applicability: ZØ allows developers to use C# as part of a larger .NET application, whereas this work translates authorization logic formulas into cryptographic code.

Others have addressed the problem of untrusted client-side computation in various contexts [21, 22, 40, 42]. A similar notion of integrity was presented in Ripley [40], which prevents client-side cheating in web applications by efficiently replicating client-side computations on the server. Unlike ZØ, Ripley's mechanism does not preserve privacy.

Zero-Knowledge Proofs: Zero-Knowledge proofs of knowledge [5] have been extensively studied. Schemes have been developed for various types of relations and computations [7, 8, 19, 36]. Several projects have sought to provide zero-knowledge compilers [2, 3, 16, 26, 31] that take a proof goal and produce executable zero-knowledge code. The first set of zero-knowledge compilers [2, 3, 26] required specifications of cryptographic protocols [9], and so are difficult for non-cryptographers to use. The second generation [16, 31] are geared towards generating ZK code for general computations expressed in restricted high-level languages. Our work makes extensive use of these compilers to optimize zero-knowledge computation. There are a number of larger projects that incorporate zero-knowledge proofs in order to manage integrity without sacrificing privacy. Applications include privacy-preserving smart metering [35], random forest and hidden Markov model classification [12], and privacy-preserving automotive toll charges [4].

11 Conclusions

This paper paves the way for using zero-knowledge techniques for day-to-day programming. We have described the design and implementation of ZØ, a distributing zero-knowledge compiler which produces distributed applications that rely on ZKPK to provide simultaneous guarantees for privacy and integrity. We build on recent developments in zero-knowledge cryptographic techniques, exposing to the developer the ability to take advantage of these advances without requiring domain-specific knowledge or learning a new specialized language. Most of the heavy lifting is done by the compiler, including cost modeling to decide which zero-knowledge back-end to use and how to split the application for optimal performance, together with the actual code splitting.

Our cost-fitting models provide an excellent match with the observed performance, with R^2 scores at least and .98. Our global application optimizer is fast, completing in under 3 seconds on all programs. Our manual and experimental examination of program splits and back-end choices proposed by ZØ confirms that they are indeed optimal. Using six applications based on real-life commercial products, we show how ZØ makes it viable to use zero-knowledge technology. We observe performance improvements of over 40×. Perhaps most importantly, ZØ allowed many of the applications to scale to large data sizes with thousands of users while remaining practical in terms of computation time and data size. This means that applications which were not feasible using state-of-the-art zero-knowledge tools are now practical in realistic settings.

Acknowledgments

We thank the anonymous reviewers for their helpful comments. We thank the ZQL and Pinocchio developers for graciously providing code and support for our effort.

SDDR: Light-Weight, Secure Mobile Encounters

Matthew Lentz[†] Viktor Erdélyi[‡] Paarijaat Aditya[‡]
Elaine Shi[†] Peter Druschel[‡] Bobby Bhattacharjee[†]

[†]*University of Maryland* [‡]*MPI-SWS*

Abstract

Emerging mobile social apps use short-range radios to discover nearby devices and users. The device discovery protocol used by these apps must be highly energy-efficient since it runs frequently in the background. Also, a good protocol must enable secure communication (both during and after a period of device co-location), preserve user privacy (users must not be tracked by unauthorized third parties), while providing selective linkability (users can recognize friends when strangers cannot) and efficient silent revocation (users can permanently or temporarily cloak themselves from certain friends, unilaterally and without re-keying their entire friend set).

We introduce SDDR (Secure Device Discovery and Recognition), a protocol that provides *secure encounters* and satisfies all of the privacy requirements while remaining highly energy-efficient. We formally prove the correctness of SDDR, present a prototype implementation over Bluetooth, and show how existing frameworks, such as Haggle, can directly use SDDR. Our results show that the SDDR implementation, run continuously over a day, uses only ~10% of the battery capacity of a typical smartphone. This level of energy consumption is four orders of magnitude more efficient than prior cryptographic protocols with proven security, and one order of magnitude more efficient than prior (unproven) protocols designed specifically for energy-constrained devices.

1 Introduction

Mobile social applications discover nearby users and provide services based on user activity (what the user is doing) and context (who and what is nearby). Services provided include notifications when friends are nearby (Foursquare [6], Google Latitude [7]), deals from nearby stores (Foursquare), content sharing with nearby users (FireChat [5], Whisper [15], Haggle [50]), messaging for missed connections (SMILE [43], SmokeScreen [27]), lost and found (Tile [13], StickNFind [12]), sharing payments with nearby users (Venmo [14]). At their lowest layer, these applications all discover nearby devices; many also associate previously linked users to discovered devices and provide communication among presently or previously co-located devices.

Most commercially deployed solutions rely on a trusted cloud service [6, 7], which tracks users' activity and location, so that it can match co-located users and relay information among them. Discovery using a centralized matchmaking service forces users to disclose their whereabouts, perils of which have been extensively noted [16, 19, 24, 48, 52]. Instead of relying on centralized services, an alternate class of discovery protocols make use of local, short-range radio-to-radio communication [1, 9, 27, 50]. The common practice of using static identifier(s) in the discovery process [2] leaks information, since it allows an eavesdropper to track a user's locations and movements. To protect against such tracking, previous work [35–37] has suggested that ephemeral identifiers should be used in place of static ones. Simply replacing static identifiers with strictly random ephemeral identifiers is insufficient: while eliminating tracking, it also prevents friends (or users with prior trust relations) from recognizing each other when nearby.

In this paper, we describe a light-weight, energy-efficient cryptographic protocol for *secure encounters* called SDDR. At a high level, secure encounters provide the following properties: 1) discovering nearby devices, 2) mapping devices to known principals (if possible), and 3) enabling secure communication for encounter peers.

Device discovery and secure encounter SDDR performs a pair-wise exchange of a secret with each nearby device. The shared secret enables encounter peers to communicate securely during and after the encounter, anonymously and without trusting a third party (e.g., sharing related content with event participants).

Selective linkability and revocation Additionally, SDDR enables a user's device to be identifiable by specific other users, while revealing no linkable information to other devices. For instance, friends can agree to recog-

nize each others' devices, while third parties are unable to link and track devices upon repeat encounters. Moreover, users can efficiently and unilaterally revoke or suspend this linkability, for instance based on the current time or location (e.g., discoverable by colleagues only during work hours and on company premises).

Challenges: Energy efficiency and DoS resilience In theory, designing a protocol that satisfies the above functional and security requirements is straightforward. For example, an inefficient strawman scheme can be constructed using existing cryptographic primitives. Pairs of devices can perform a Diffie-Hellman key exchange to establish a shared secret, enabling the users to securely communicate. To support selective linkability, two users can participate in a standard Private Set Intersection (PSI) protocol. A user can allow (or disallow) a peer to recognize them in a future encounter by including (or excluding) a past shared encounter secret from the set.

However, as we will show in Section 6, using a full-fledged PSI protocol is impractical. Because the shared encounter secrets (i.e., elements in the set) are high-entropy values, it is possible to implement a secure PSI protocol through an efficient Bloom filter based construction. Unfortunately, even when using an efficient Bloom filter based PSI scheme, the above strawman scheme—implemented naively—has high energy consumption. Specifically, a naive implementation requires a device to wake up its CPU each time it receives a message from a nearby device, an expensive operation for energy-constrained mobile devices. The protocol would deplete the battery in crowded spaces (e.g., a subway train) where hundreds of devices may be within radio range. Furthermore, an attacker mounting a DoS attack could deplete the victim device's battery by frequently injecting messages to cause unnecessary wake ups.

1.1 Contributions

We designed, implemented, and formally proved the security of SDDR, a light-weight secure encounter protocol suitable for resource-constrained mobile devices. Our reference implementation source code (using Bluetooth 2.1 as the short-range radio) is available at http://www.cs.umd.edu/projects/ebn.

Achieving energy efficiency The main feature of SDDR is its *non-interactiveness*, i.e., the encounter protocol consists of periodic broadcasts of beacon messages, which enable both the key exchange and selective recognition. Because the SDDR protocol is non-interactive, the Bluetooth controller can be initialized so that it responds to discovery requests from peers with a beacon message, while the main CPU remains completely in the *idle state*. A device only needs to wake up its CPU when actively discovering nearby peers.

Our evaluation shows that such a non-interactive protocol allows us to improve the energy efficiency by at least 4 times in comparison with any interactive protocol (even if the interactive protocol performs no work), under a typical setting with 5 *new* devices nearby on average during *every* 60 second discovery interval. Under the same parameters, we show that an otherwise idle device running SDDR over Bluetooth 2.1 will operate for 9.3 *days* on a single charge.

First formal treatment of the problem We are the *first* (to the best of our knowledge) to provide a formal treatment of secure device discovery and recognition. We define a security model that captures the requirements of secure encounters and selective linkability, and prove that our solution is secure under the random oracle model (see Appendix A.3).

Applications over SDDR To demonstrate some of SDDR's capabilities, we have modified the Haggle mobile networking platform to use SDDR, enabling efficient and secure discovery and communication via Bluetooth for all Haggle apps. For demonstration, we have modified the PhotoShare app to enable private photo sharing among friends using SDDR selective linking.

Roadmap The remainder of the paper is organized as follows. We discuss related work in Section 2. Next, we review security requirements, formulate the problem and provide security definitions in Section 3. We present details of the SDDR discovery protocol in Section 4, followed by our reference Bluetooth implementation and evaluation results in Sections 5 and 6, respectively. We discuss the properties and implications of SDDR's encounter model in Section 7. We conclude in Section 8.

2 Related Work

Device discovery protocols Several device discovery protocols have been proposed; however, none simultaneously offer the full functionality and security offered by our SDDR protocol. Since SDDR provides secure device discovery and recognition for a large range of mobile encounter applications, it allows developers to focus on their application logic.

	Unlinkability	Selective Linkability	Efficient Revocability	No Trusted Party	Record Encounters
Bluetooth 4.0	✓	✓		✓	
SMILE	✓			✓	✓
SmokeScreen	✓	✓			✓
SDDR	✓	✓	✓	✓	✓

Table 1: Comparison of related device discovery and recognition protocols in terms of supported properties.

Bluetooth 4.0 (BT4) is the most recent version of the Bluetooth standard, introducing a new low-energy mode [3], as well as support for random MAC addresses to be used in communication. Building on top of the MAC address change support, BT4 adds a form of selective linkability in which paired (trusted) devices can recognize each other across MAC address changes, while remaining unlinkable to all other devices. Since BT4 uses a single shared key for all currently linkable users, it does not allow for efficient revocation of a subset of users. Further, BT4 does not natively support encounters with unlinkable devices.

SMILE [43] is a mobile "missed connections" application, which enables users to contact people they previously met, but for who they don't have contact information. The SMILE protocol creates an identifier and shared key with any set of devices that are within Bluetooth range at a given time. Users can subsequently exchange messages (encrypted with the shared key) anonymously through a cloud-based, untrusted mailbox associated with the identifier. Unlike SDDR, SMILE does not address selective linkability and revocation.

MeetUp [44] is an encounter-based social networking application that argues for (and uses) strong authentication within an encounter. This authentication comes in the form of exchanging signed certificates (from a trusted authority) attesting to a public key and picture of a user. However, we feel that in many applications, users should be unlinkable by default, and should not be required to distribute any identifiable information (e.g., public key, user picture) in an encounter. We discuss authentication in Section 4.4.

SmokeScreen [27], a system that allows friends to share presence while ensuring privacy, also implements a selectively linkable discovery protocol for encounter peers. In SmokeScreen's discovery protocol, devices periodically broadcast two types of messages: *clique signals* and *opaque identifiers*. Clique signals enable private presence sharing among friends, announcing the device's presence to all members of a mutually trusting clique. In comparison with SDDR, SmokeScreen requires a trusted third-party service and achieves slightly weaker security: an adversary can infer that two users belong to the same clique, since all users broadcast the same clique signal during each time epoch. Furthermore, SDDR can handle 35 nearby devices for the same energy as 3 devices in SmokeScreen. Additionally, SDDR supports efficient revocation of linked users, which is not possible with cliques in SmokeScreen.

SlyFi [35] is a link layer protocol for 802.11 networks that obfuscates MAC addresses and other information to prevent tracking by third parties. Unlike SDDR, SlyFi does not address selective linkability or revocation, nor does it negotiate shared keys among co-located devices. SDDR includes a Bluetooth MAC address change protocol similar to SlyFi's to prevent tracking.

Related protocols using Bloom filters Bloom filters [20] are a space-efficient probabilistic data structure for set membership. Bloom filters have been used in many cryptographic protocols [23], including (private) set-intersection and secure indexes. However, none of the protocols address the precise problem and security requirements of SDDR.

Secure indexes are data structures that allow queriers to perform membership tests for a given word in $O(1)$ time if they have knowledge of the associated secret. Secure indexes were first defined and formalized by Goh [33], who provided a practical implementation using Bloom filters. Similar work has focused on privacy-preserving searches over encrypted data [26] and databases [54] using Bloom filters. If applied to device recognition, all protocols would allow adversaries to track users due to the static Bloom filter content.

PrudentExposure [56] allows users to privately discover appropriate services, where the user and service belong to the same domain. To maintain user privacy, PrudentExposure relies on Bloom filters containing time-varying hashes of domain identities for intersecting the requested and available domains.

E-SmallTalker [55] and D-Card [25], which builds on E-SmallTalker, support social networking with nearby strangers (E-SmallTalker) and friends (D-Card). BCE [31] enables users to estimate the set of common friends with other users. These protocols would be insecure when applied to the device recognition problem, as none of the protocols use time-varying information in the Bloom filters, allowing users to be linked across multiple handshakes. Additionally, E-SmallTalker does not apply the Bloom Filter to high-entropy secrets, and thus is vulnerable to an offline dictionary attack.

Sun et al. [51] present a new way of building trust relationships between users by comparing spatiotemporal profiles (log of time and location pairs). In addition to a PSI-based scheme, they present another scheme using Bloom filters that trades off estimation accuracy and privacy in a user-defined manner. In SDDR, we avoid the privacy vs. accuracy trade off since the linkable users share a high-entropy secret as opposed to low-entropy time, location pairs.

Dong et al. [30] use *garbled* Bloom filters to create a practical PSI protocol that handles billions of set members. While more efficient than existing PSI protocols, it does not *scale down* when applied to small set sizes on resource-constrained devices. Because of its reliance on secret shares instead of bits in the Bloom filter, the smallest possible Bloom filter to handle a maximum of 256 items would be 17736 bytes — two orders of magnitude larger than what SDDR requires. In addition, the

communication cost of this interactive protocol increases linearly with the number of nearby devices.

Nagy et al. [45] use Bloom filters to provide a PSI protocol that allows users of online social networks (OSNs) to determine common friends while preserving user privacy. While their solution provides ample efficiency gains over standard PSI, saving an order of magnitude in communication and computation costs, several seconds per *interactive* exchange is too much when running on power-constrained devices in dense environments.

Authenticated key exchange Secure device discovery and recognition should not be confused with mutual authentication, or authenticated key exchange (AKE) protocols [21, 40]. SDDR aims to achieve device discovery and recognition; guaranteeing mutual authentication is not a goal of the basic SDDR protocol. As noted in Section 4.4, once Alice's device recognizes Bob's device, Alice can authenticate Bob by soliciting an explicit verification message from Bob; however, authentication will only be performed if desired by the higher-level application (or user). While secure device discovery and recognition can be achieved by executing an AKE protocol with each nearby device (for all possible shared secrets), such a scheme would be prohibitive in an environment with many nearby peers.

3 Problem Overview

In this section, we review the requirements for a secure encounter protocol, sketch a strawman design, and make observations that enable a practical protocol.

Devices executing a *secure encounter protocol* should detect nearby participating devices, and learn their current ephemeral network identifier. Additionally, each pair of nearby devices should generate a unique (except with negligible probability) shared secret key, known only to the pair. This key allows the devices to: 1) uniquely refer to a particular encounter; and, 2) authenticate each other as the peer in the encounter and securely communicate. The pair should learn no other information about each other; when the same pair of devices meet again, the shared secret and network identifiers exchanged should be unrelated.

By default, devices should remain unlinkable, meaning that no identifying information is exchanged. While unlinkability is appropriate between strangers' devices, friends may wish to enable their devices to recognize each other. A user who allows her device to be recognized by a friend during future discoveries is termed *selectively linkable* (or simply *linkable*) by that friend. When two devices discover each other, a *recognition protocol* should determine if the remote device corresponds to a linkable user. Selectively linkable users must share a unique secret value such that the devices can authenticate each other during the recognition protocol; we refer to this shared secret as the *link value*. Users can derive the link value from the shared secret established during a prior encounter, or using an out-of-band protocol.

In general, users may not wish to be recognizable by their entire set of friends at all times (e.g., Alice may only want her work colleagues to recognize her device while at work). Therefore, a user should be able to contextually (e.g., in terms of time, place, activity) filter the set of friends that can recognize them. This filtering requires that revocation of selective linkability be efficient (e.g., not require a group re-keying) and unilateral (e.g., not require communication). Additionally, the filtering may take place in one direction: Alice may want to not be recognizable by Bob, yet still want to recognize him. Therefore, we consider two distinct sets of link value: the set of advertiseIDs (i.e., who you are willing to be recognized by), and the set of listenIDs (i.e., who you want to recognize). Alice's device is able to recognize Bob's device if and only if their shared link value is in Bob's advertiseIDs and in Alice's listenIDs.

3.1 Security Requirements

We summarize the security requirements below:

Secure communication If Alice and Bob share an encounter, they are able to securely communicate using an untrusted communication channel, both during and after the encounter, and regardless of whether Alice and Bob have opted to selectively link their devices.

Unlinkability The information exchanged during a secure encounter reveals no identifying information about the participating devices, unless the devices have been explicitly linked. In particular, unlinked devices that encounter each other repeatedly are unable to associate their encounters with a previous encounter.

Selective linkability Alice and Bob can optionally agree to be linkable, and therefore able to recognize and authenticate each others' devices in subsequent discoveries.

Revocability Alice may, at any time, *unilaterally* revoke Bob's ability to recognize her.

3.2 Threat Model

We assume that user devices, including the operating system and any applications the user chooses to run, do not divulge information identifying or linking the device or user. Preventing such leaks is an orthogonal concern outside SDDR's threat model. User devices attempt to participate in the protocol with all nearby discovered devices, a subset of which could be controlled by attackers, who may all collude.

We do not consider radio fingerprinting attacks, which detect a device by its unique RF signature [22]. Such

attacks may require sophisticated radio hardware, and are outside our threat model.

3.3 Strawman Protocol

A strawman scheme using existing cryptographic tools, namely Diffie-Hellman [29] (DH) and Private Set Intersection [28, 39] (PSI), can meet the requisite security requirements outlined above. Upon detecting a device, the protocol performs a DH exchange to agree upon a shared secret key. By generating a new DH public and private key pair prior to each exchange, devices remain *unlinkable* across encounters.

To recognize selectively linkable devices, the protocol executes PSI over the devices' advertised and listen identifier sets. *Selective linkability* and *revocability* properties are satisfied by all PSI protocols; however, in order to preserve privacy, we require a PSI protocol that supports *unlinkability* across multiple executions.

While the DH+PSI strawman achieves the desired security properties, it is not practical when frequently run on resource constrained devices. As shown in Section 6, the computation and communication requirements of existing PSI constructions are prohibitively high.

3.4 Observations

In order to enable a practical protocol we rely on several observations:

First, *strict unlinkability* requires that two different discoveries between a pair of devices are unlinkable, regardless of how closely the discoveries are spaced in time. This property cannot be achieved with a non-interactive protocol, because it requires a change of ephemeral network ID and DH keys after each discovery. In order to use a non-interactive protocol, we must settle for the slightly weaker property of *long-term unlinkability*; devices may be linkable within a time epoch, but they remain unlinkable across epochs. For an epoch on the order of minutes, long-term unlinkability is sufficient in practice. It is important to note that epoch boundaries and durations do not require time synchronization; devices may choose when to change epochs independently.

Second, detecting selectively linked devices requires an intersection of the sets of advertised link values between a pair of devices. Even a simple, *insecure* intersection protocol would require the transmission of the complete sets during each pair-wise device discovery, which is too expensive. However, we note that in a large deployment, discoveries among strangers are far more common than discoveries among linked devices. Therefore, an over-approximation of the set intersection may suffice. False positives can be resolved when two presumed linkable devices attempt to authenticate each other using the shared link value.

Finally, we can take advantage of the fact that link values shared between users are high-entropy values taken from a large space, by design. General purpose PSI protocols, on the other hand, ensure security even when sets contain low-entropy values (e.g., dictionary words).

Using these observations, we present the SDDR protocol, which meets the security requirements with practical performance and energy efficiency.

4 SDDR Design

4.1 High-Level Protocol

Like the strawman protocol, SDDR uses DH to exchange a shared secret key with each nearby device; however, SDDR performs the exchange in a non-interactive manner. Periodically, each device broadcasts its DH public key and receives broadcasts from other nearby devices, computing all pair-wise shared secret keys.

SDDR divides time into epochs, during which the ephemeral network address, DH public/private key pair, and advertiseIDs set digest remain constant. Devices are unlinkable *across* epochs, thus preserving *long-term unlinkability*. To avoid expensive synchronous communication, epochs are not synchronized among devices. As a result, the DH computation may fail to produce a shared key if it occurs around an epoch change of either device in a pair. For instance, Alice receives Bob's broadcast in her epoch n, but Bob fails to receive Alice's broadcast until her epoch $n+1$, so he computes a different key. Because broadcasts occur more frequently than epoch changes (seconds versus minutes), however, the probability that a broadcast round yields a *shared* key quickly tends to one with every broadcast round.

Since the link identifiers shared between users are high-entropy values chosen from a large space (e.g., a shared key produced during a prior discovery), SDDR can recognize linkable devices by broadcasting salted hashes of their respective set of advertiseIDs. The DH public key is used as the salt; since the salt is different in each epoch, a device cannot be recognized by the bit-pattern in its Bloom filter across epochs, that ensuring long-term unlinkability. Each user then searches over the hashes using their own set of listenIDs, along with the corresponding salt value, in order to identify the listenID (if any) associated with the remote device.

However, the communication required for moderately-size sets (e.g., 256 advertiseIDs) is still too large for an efficient implementation in Bluetooth due to (pseudo-) broadcast message length constraints. By allowing the recognition protocol to *over-approximate* the actual intersection between the set of local listenIDs and remote advertiseIDs, SDDR can use a probabilistic set digest data structure to reduce the communication needed to determine the intersection. The size of the set digests can be parameterized based on the message size restrictions of

the radio standard used for communication. The choice affects performance only; false positives due to the use of set digests can be resolved using the shared link values, and therefore have no bearing on the protocol's security.

The *selective linkability* property is satisfied by the use of non-deterministic hashes of the link identifiers shared by two users, only allowing linkable users to recognize each other. The *revocation* is supported by the user's ability to add or remove link values from the set of advertiseIDs.

4.2 Formal Problem Definition

We divide the non-interactive SDDR protocol into two algorithms (GenBeacon and Recognize), which we formalize below:

$\mathsf{beacon} \leftarrow \mathsf{GenBeacon}(\mathsf{advertiseIDs})$

In each epoch, a device wishing to participate in peer encounters executes the GenBeacon algorithm, which takes as input the current set of advertiseIDs. The GenBeacon protocol outputs a message beacon, which the device then broadcasts to nearby devices.

$(sk, \mathsf{listenIDs}_{\mathrm{re}}, \mathsf{L}) \leftarrow \mathsf{Recognize}(\mathsf{beacon}_{\mathrm{re}}, \mathsf{listenIDs})$

Upon receiving a $\mathsf{beacon}_{\mathrm{re}}$ from a remote peer, a device executes the Recognize algorithm, which additionally takes in the current set of listenIDs. The Recognize algorithm outputs a secret key sk, the set of $\mathsf{listenIDs}_{\mathrm{re}}$ associated with the remote peer, and the link identifier L for this encounter.

4.3 Detailed Protocol Description

Next, we provide a detailed description of the SDDR protocol. Pseudo-code for the *GenBeacon* and *Recognize* algorithms is shown in Figure 1. In the protocol, as well as our implementation, we use Bloom filters as the probabilistic set digest data structure; however, other set digests (e.g. Matrix filters [46]) could be used instead.

Each user P_i starts by running GenBeacon in order to generate the beacon message to broadcast during the current epoch. GenBeacon first selects a random DH private key α_i, which corresponds to the DH public key g^{α_i}. Afterwards, GenBeacon computes the Bloom filter by hashing each advertiseID within AS_i (the set of advertiseIDs), using the DH public key as the salt. The resulting beacon contains the public key and the Bloom filter.

Each user P_i broadcasts their respective beacon during the epoch. After receiving a beacon from a remote user P_j, user P_i runs the Recognize algorithm. Recognize first computes the DH secret key dhk_{ij}, using the local user's DH private key and the remote user's DH public key (as contained in the beacon). Using the dhk_{ij} along with the local and remote DH public keys, Recognize computes the shared link identifier L_{ij}, which can optionally be used in case the two users wish to selectively link.

Additionally, Recognize computes the key sk_{ij} using the link identifier L_{ij}, which the two devices can use to authenticate each other as the peer associated with this encounter, and then securely communicate. Finally, Recognize queries the Bloom filter by hashing each listenID within LS_i (the set of listenIDs), using the remote user's DH public key as the salt, resulting in the set of matches M_j.

Recall that sk_{ij} may not be shared (i.e., $sk_{ij} \neq sk_{ji}$) in some cases when individual devices decide to change epochs. When a device attempts to communicate using such a key, the authentication will fail, and the device retries with a key produced in a subsequent discovery. Also, to make sure a valid link identifier is used, devices attempt to authenticate each other as part of the pairing process to selectively link.

Notation: Let $\mathsf{BF}\{S\}$ denote a Bloom filter encoding the set S. Let H_0, H_1, and H_2 denote independent hash functions later modeled as random oracles in the proof.

Inputs: Each user P_i has a set of listenIDs (LS_i) and a set of advertiseIDs (AS_i).

Outputs: For all users P_j, discovered by P_i, P_i outputs:

1. sk_{ij}: A shared secret key
2. $\mathsf{listenIDs}_{\mathrm{re}}$: Set of matching $\mathsf{listenID} \in LS_i$ associated with P_j
3. L_{ij}: A shared link identifier

Protocol: Each P_i performs the following steps:

$\underline{\mathsf{GenBeacon}(AS_i)}$

1. Select random $\alpha_i \in_R \mathbb{Z}_p$
2. Compute $\mathsf{BF}_i := \mathsf{BF}\{H_1(g^{\alpha_i}||x) : x \in AS_i\}$
3. Create $\mathsf{beacon}_i = (g^{\alpha_i}, \mathsf{BF}_i)$

Each user P_i broadcasts beacon_i***. For each user P_j that user P_i discovers, P_i runs*** Recognize.

$\underline{\mathsf{Recognize}(\mathsf{beacon}_j, LS_i)}$

1. Compute DH key $\mathsf{dhk}_{ij} = (g^{\alpha_j})^{\alpha_i}$
2. Compute link $\mathsf{L}_{ij} := \begin{cases} H_0(g^{\alpha_i}||g^{\alpha_j}||\mathsf{dhk}_{ij}) \text{ if } g^{\alpha_i} < g^{\alpha_j} \\ H_0(g^{\alpha_j}||g^{\alpha_i}||\mathsf{dhk}_{ij}) \text{ otherwise} \end{cases}$
3. Compute key $sk_{ij} := H_2(\mathsf{L}_{ij})$
4. Query for set $\mathsf{M}_j := \{x : x \in LS_i \wedge H_1(g^{\alpha_j}||x) \in \mathsf{BF}_j\}$

Figure 1: SDDR Non-Interactive Protocol.

Hiding Bloom filter load After receiving multiple Bloom filters, and calculating the distribution of the number of bits set, it is possible to determine the size of the remote user's set of advertiseIDs. This leaks information, which could be used to link devices across multiple epochs. To prevent this leak, the Bloom filters are padded to a global, uniform target number of elements N. Rather than computing actual hashes, we randomly

select $K*(N-|\mathsf{advertiseIDs}|)$ (not necessarily distinct) bits to set to 1, where K is the number of hash functions used in creating the Bloom filter.

4.4 Identification and Authentication

Identification and mutual authentication are not required by all applications, and hence are not a part of the basic SDDR protocol. However, identification and authentication can be achieved easily on top of SDDR as follows:

Identification Identification allows a user to associate a principal (e.g., "Bob") to a specific encounter through the use of out-of-band (OOB) mechanisms. As part of the identification procedure, the users agree on the link identifier (corresponding to the shared encounter) for the purpose of selective linkability. If Alice wishes to be recognizable by Bob in the future, she will insert the link identifier into her advertiseIDs; likewise, if she wishes to recognize Bob in the future, she will insert the link identifier into her listenIDs. However, choosing to enable (or revoke) recognizability is not part of the identification procedure, and can be performed any time by the user after the initial, one-time identification has taken place.

It is well known that achieving secure identification, resistant to man-in-the-middle (MITM) attacks, requires either an *a priori* shared secret or an OOB channel. Any manual authentication technique [32,41,42,53] (e.g., displaying and comparing pictures on both devices, generated from the link identifiers) allows Alice to securely identify Bob's device free of MITM attacks. Additionally, a technique not relying on OOB mechanisms has been proposed by Gollakota et al. [34] for 802.11, using tamper-evident messaging to detect and avoid MITM attacks. Note that many applications do not require identification, such as when users wish to (anonymously) share photos with other event participants.

Mutual authentication Mutual authentication bootstraps a secure and authenticated session between two peers using an *a priori* shared secret (e.g., the link identifier agreed upon as part of the identification procedure). Suppose that in a previous encounter, Alice and Bob participated in the identification procedure; additionally, both Alice and Bob elected to add the shared link identifier to both their advertiseIDs and listenIDs. Thus, in future encounters, Alice and Bob can now authenticate each other (free of MITM attacks). While the basic SDDR protocol does not provide authentication, it can easily be achieved by sending an explicit verification message. For example, a user can prove to a remote peer that they know the common link identifier L by simply sending the verification message $\langle \text{nonce}, H_3(L||\text{nonce}||\mathsf{dhk})\rangle$.

Alternatively, a user can execute a standard authenticated key exchange (AKE) protocol; however, in the case of SDDR, since a DH key is already exchanged, an explicit verification message is sufficient and cheaper than a standard AKE protocol. Mutual authentication only needs to be performed when requested by an application (or user), and thus is not part of the base SDDR protocol.

4.5 Suppressing Bloom filter false positives

The false positive probability of a Bloom filter, denoted as P_{fp}, is computed as a function of: the number of elements inserted (N), the size (in bits) of the Bloom filter (M), and the number of hash functions per element (K). Although Bose et al. [47] provide a more accurate (yet not closed form) solution, P_{fp} is closely approximated by the following formula:

$$P_{\mathsf{fp}} = \left(1 - \left[1 - \frac{1}{M}\right]^{KN}\right)^{K}$$

In the SDDR protocol, these false positives manifest themselves as selectively linkable principals associated with the remote device (and their current shared encounter). By default, false positives are not reduced over the course of an epoch, and only mutual authentication (see Section 4.4) will allow two peers to check if they are selectively linkable (resolving any false positives). Ideally, we want to provide a way for the matching set (M_j in the protocol) to converge towards the exact intersection of the remote peer's advertiseIDs and the user's listenIDs over time.

If one creates multiple Bloom filters, each using a unique set of hash functions (or salt value(s)), the intersection of the matching sets for the Bloom filters results in an overall matching set with a reduced false positive rate. Within a single epoch, a device can compute and distribute beacons with unique Bloom filters that evolve over time. Since beacons within the same epoch use the same DH public key, we modify Step 2 within the GenBeacon algorithm to additionally use an incrementing counter *count* as part of the salt:

$$\mathsf{BF}_i := \mathsf{BF}\{H_1(g^{\alpha_i}||x||\mathit{count}) : x \in AS_i\}$$

count increments each time a beacon is broadcast, and is reset to 0 at the start of every epoch. We use this extension as part of our implementation, as described in Section 5.

5 SDDR on Android

We have implemented the SDDR protocol on the Android platform as part of a system service. The codebase is written in C++ and runs with root privileges[1] . For development and evaluation, we use Samsung Galaxy

[1] SDDR requires root privileges to handle address changes, as well as to support efficient communication through Extended Inquiry Response (EIR) payloads.

Nexus phones running Android 4.1.2 [2] with the android-omap-tuna-3.0-jb-mr0 kernel. For our implementation, we selected to use Bluetooth for short-range radio communication; other short-range radios (e.g. WiFi, ZigBee) could also be used for this purpose. We selected Bluetooth 2.1 (BT2.1) over BT4 because a BT2.1 implementation closely mirrors the protocol as described; however, we designed a BT4 implementation for use in EnCore [17]. We use elliptic curve cryptography (ECC) due to the smaller key sizes relative to RSA, selecting the 192-bit curve as recommended by NIST [4].

We first describe the implementation of the major components of the SDDR protocol: discovery, handshake, and epoch change. Afterwards, we briefly describe the system service that we developed to allow all applications running on the device to take advantage of SDDR, without each independently managing discoveries. Finally, we discuss our integration of the system service with the open-source Haggle framework [8].

5.1 SDDR Protocol Components

Discovery In the protocol, a single beacon is broadcast throughout each epoch. In our implementation, since devices must wake up to discover nearby devices and receive their beacon messages, we break down each epoch into multiple discovery intervals. Using the protocol extension described in Section 4.5 to reduce Bloom filter false positives, we generate and broadcast a new beacon during every discovery interval.

There are two roles that devices can take on within the Bluetooth 2.1 discovery protocol: *discoverable* and *inquirer*. Every device always plays the role of *discoverable*, responding to incoming inquiry scans with information on how the *inquirer* can establish a connection (e.g., MAC address). By using the extended inquiry response (EIR) feature present in BT2.1, which includes an additional 240 byte payload added to the response, *discoverable* devices can transmit their beacon to the discoverer during the inquiry scan itself.

At the start of each discovery interval, a device additionally takes on the role of *inquirer*, performing an inquiry scan in order to collect and process beacon messages from nearby devices. In addition, the device will update its EIR payload with a new beacon message; this payload will be used as a response while *discoverable*.

Devices must only wake up when acting as a *inquirer*. Otherwise, while simply *discoverable*, only the Bluetooth controller (and not the main CPU) must be active; the controller wakes up every 1.28 seconds to listen and respond to inquiry scans from nearby devices.

[2]The Android 4.4 release would provide additional energy savings with respect to suspend and wakeup transitions due to the updated AlarmManager API.

Compute keys and recognize When a *inquirer* detects a new device, which could also be an epoch change by an existing device, it computes the shared secret for the current epoch using the local DH private key and the remote device's DH public key (embedded in the beacon). For each device: 1) for its first beacon, the *inquirer* queries the Bloom filter contained in the beacon using $H_1(g^{\alpha_i}||x||count)$ for each x in its set of listenIDs; 2) for subsequent beacons, the *inquirer* queries the Bloom filter only for each x previously determined to be in the intersection.

Periodic MAC address change SDDR ensures that the discovery and recognition protocol does not leak linkable information. However, the underlying Bluetooth packets have a static MAC address that can be used to track the device (and the user). As part of our Bluetooth implementation, we choose a random Bluetooth MAC address at the start of every epoch. BT2.1 does not provide a native interface for changing MAC addresses "on-the-fly"; therefore, we reset the Bluetooth controller each time the address is changed (once per epoch, nominally fifteen minutes). Unfortunately, this reset closes ongoing connections and invalidates existing device pairings; however, the BT4 specification supports changing the public (random) address for the device while maintaining the private address for paired devices.

5.2 SDDR Integration

We chose to implement the SDDR protocol as part of a system service on Android. The centralized service allows for greater energy efficiency as it can broadcasts discovery information to all applications via IPC mechanisms, as opposed to each application performing its own discovery. Currently, we allow applications to connect to the service via local Unix sockets. Applications receive messages for each discovered device, along with the shared secret and identity information (if selectively linkable) for SDDR-aware devices.

Haggle Haggle is a mobile communication platform for device-to-device radio communication, and supports a number of content sharing apps. A photo sharing app, for instance, shares with nearby devices photos whose textual attributes match a user's specified interests.

To demonstrate some of SDDR's capabilities, we have modified Haggle to use SDDR. This enables Haggle and its applications to communicate securely with nearby devices, without revealing any linkable information and without the risk of tracking by third parties. We have modified Haggle's photo sharing app to take advantage of SDDR's features. Users can add a special attribute to a photo, which narrows its visibility to a specified set of linkable user(s). If a photo carries this attribute, it is eligible for sharing only with devices of linkable users in

this set. Finally, when a photo is shared, it is encrypted with the shared key established by SDDR.

6 Experimental Results

In order to evaluate the design and implementation of SDDR, we first perform a comparison to the strawman protocol by focusing on the PSI portion in comparison to our Bloom filter-based approach. Secondly, we look at energy consumption both at the level of benchmarking individual operations within the SDDR (and other) protocols, as well as battery life consumption over the course of a day. Additionally, we attempt to analyze the scalability (and DoS resistance) of the SDDR protocol by extrapolating energy consumption results to a large number of devices. For a more application-level evaluation, we refer the reader to our work on EnCore [17], which includes a deployment with 35 users, using a BT4 implementation of SDDR.

6.1 Comparison with PSI

We measure the SDDR discovery protocol computation time while varying the number of linkable identifiers, and compare the elapsed time to that required for a PSI protocol. We use an implementation [11] of the JL10 scheme [38], one of the fastest schemes known-to-date. JL10 is secure and can be modified to achieve unlinkability across sessions. Both protocols are executed using a single core on the 1.2 GHz ARM Cortex-A9 processor.

Figure 2 shows the run times for each protocol; each bar is an average of 50 runs, with error bars denoting the 5^{th} and 95^{th} percentile values. We divide SDDR into two separate trials, varying the number of advertisements in order to achieve the specified false positive rates for each trial. Additional advertisements do not require much computation time because SDDR only uses the complete set of listen IDs for the first Bloom filter; afterwards, SDDR uses the matching set of listen IDs, which quickly converges towards the actual intersection.

Results show that SDDR is up to *four orders of magnitude* faster than standard PSI. The gain in performance is crucial for practical deployment, as these computations take place for every discovered device. In order to preserve user privacy against tracking, large maximum set sizes (128 to 256 entries) with random entry padding must be used with typical PSI protocols; alternatively, a size-hiding PSI scheme [18] can be used, but the performance in practice is worse than the scheme we used [10].

6.2 Energy Consumption

SDDR runs on resource-constrained devices, therefore we evaluate its energy consumption in detail. First, we look at microbenchmarks for the individual components of the protocol (e.g., discovery), as well as various idle states, which provide a baseline for energy consumption.

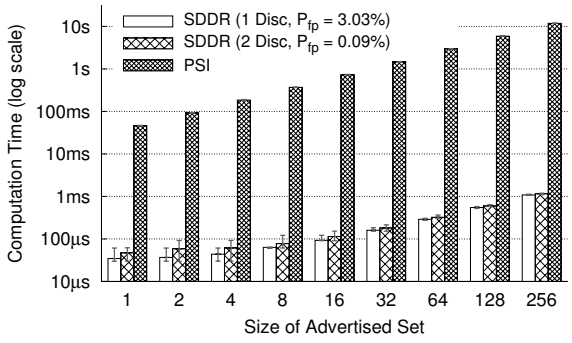

Figure 2: Protocol execution times of PSI versus SDDR for an encounter with varying sizes of advertised sets of link values. The "# disc" represents the number of discovery beacons used to compute the matching set, with P_{fp} as the associated false positive probability.

Second, we collect and analyze power traces of our protocol over several epochs in order to determine the battery life cost of frequently running our handshake protocol over the course of a day. Third, we estimate the reduction in battery consumption when in densely crowded areas, or under denial of service attacks, a device discovers the specification maximum of 255 devices per inquiry scan [3]. In order to monitor energy consumption over time, we use the BattOr [49] power monitor.

Microbenchmarks In Table 2, we outline the results from the microbenchmark experiments. We collect 25 data points for each experiment, and present the average values in the table above. We enable airplane mode on the device for each test, ensuring that all radio interfaces are disabled unless otherwise explicitly requested. Idle state requires very little power, as the device remains in suspended state with the main processor powered off. Since epoch changes require disabling and re-enabling the hardware Bluetooth controller, the controller requires several seconds to return to its working state. An epoch change requires 568mJ energy consumption — however, note that epoch changes are relatively infrequent (e.g., every fifteen minutes) compared to discovery.

Additionally, we collected power traces for various discovery and recognition protocols. When there are no nearby devices, the baseline discovery protocol in Bluetooth 2.1 costs 1363mJ per discovery. In comparison, our implementation of the SDDR protocol over Bluetooth 2.1 incurs only 7% additional energy cost while executing the recognition protocol with 5 nearby devices (and using 256 advertised and listen IDs). The implementation of the DH+PSI strawman over Bluetooth 2.1 requires much more energy per execution, over an order of magnitude greater than the baseline (43,335mJ compared to 1,363mJ). This is expected as the PSI protocol

Component	Avg. Power (mW)	Energy (mJ)
Idle	1.73	-
Bluetooth 2.1		
Discovery (0 Devices)	118	1,363
Incoming Connection	200	893
Discovery and Recognition (5 Devices, 256 Listen IDs)		
SDDR over BT2.1	124	1,464
DH+PSI over BT2.1	404	43,335
ResolveAddr in BT4.0	226	737
SDDR Epoch Change	178	568

Table 2: Average power and energy consumed by various components, or system states. Components which have energy consumption marked as '-' have no well defined duration.

State	Energy (J)	Battery (%)
Full Battery	23,328	100
Idle	150	0.64
Idle with Bluetooth	188	0.81
Running (5 Devices, 256 Listen IDs) (60s Discovery Interval)		
SDDR over BT2.1	2,511	10.76
ResolveAddr in BT4.0	1,260	5.40
DH+PSI over BT2.1	44,619	191.27
IncConn over BT2.1	9,143	39.19
(120s Discovery Interval)		
SDDR over BT2.1	1,300	5.57
ResolveAddr in BT4.0	718	3.08
DH+PSI over BT2.1	35,097	150.45

Table 3: Energy and battery life consumption for different states and protocol configurations over the course of one full day. A daily battery consumption of $p\%$ means that the battery would last $100/p$ days if the device runs the corresponding protocol and is otherwise idle.

is not as efficient as SDDR in terms of computation (See Figure 2) and communication, and it must execute an interactive protocol for each nearby device.

The ResolveAddr protocol, implemented as per the Bluetooth 4.0 specification, requires less energy (737mJ) compared to other schemes; however, it neither exchanges a session key, nor supports efficient revocation of the set of linked users [3]. ResolveAddr is optimized to support a limited feature set, and uses the efficient broadcast channels made available in Bluetooth 4.0.

In addition, as a point of comparison between interactive and non-interactive protocols, we collected power traces for a device waking up to handle an incoming connection over Bluetooth 2.1 (without performing any work). This incoming connection consumes an average of 893mJ, which is roughly 65% of the cost of an entire discovery operation. This connection cost scales linearly, which makes interactive protocols impractical for handling many nearby devices.

Reduction in battery life In order to gauge the reduction in battery life of frequently running a discovery and recognition protocol, we collected power traces for various protocol configurations with up to 5 nearby devices over the course of two epochs (30 minutes). For each protocol, we evaluate two different discovery intervals (60 and 120 seconds); existing applications, such as Haggle [8], use a 120 second interval. Since the energy consumption remains the same across two epochs, we extrapolate the energy consumed to a full day (24 hour period), as shown in Table 3.

The Samsung Galaxy Nexus battery has a capacity of 6.48Wh, which we convert to $23,328$J for the purpose of comparisons within the table. With 5 nearby devices, SDDR uses 5.57% of the battery life per day with a 120 second discovery interval; ResolveAddr uses slightly less than SDDR (around 3%), due to the reduced discovery costs. In comparison, the DH+PSI protocol consumes around 150% of the battery over the course of 24 hours. This means that the battery would completely drain within 16 hours, or within only 12.6 hours when using the 60 second discovery interval. IncConn provides a point of reference for the base-line battery life of an interactive protocol—without executing any protocol, it consumes around four times as much energy as SDDR.

As previously mentioned, we assume that each discovery returns 5 *new* nearby devices; in the case of SDDR, this requires computing the shared secret and using the complete set of listen IDs (instead of the matching set) to query the received Bloom filter. In practice, there will not always be 100% churn in nearby devices in each discovery period, meaning that these results are *conservative estimates* of actual energy consumption.

In order to provide a visual comparison between the protocols, we present snapshots of a single 120 second discovery interval for both the SDDR and DH+PSI protocols in Figure 3. These snapshots show the power consumed at each point in time; energy consumption is computed by integrating over a given interval of time. Both protocols initiate a discovery at around the 20 second mark. Since we designed the SDDR protocol to support non-interactive execution, SDDR over BT2.1 can take advantage of executing both the discovery and recognition portions at the same time. Unlike SDDR, the DH+PSI protocol must perform an interactive recognition protocol that takes longer than the discovery process itself, and must be performed individually with each nearby device. In the right half of the plot, both devices handle incoming discovery and recognition requests from nearby devices (5 for SDDR, and 1 for

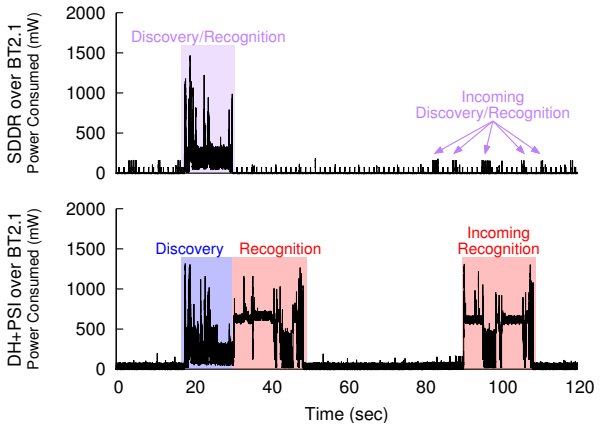

Figure 3: Power traces from running the SDDR and DH+PSI protocols (implemented over Bluetooth 2.1) for one discovery interval of 120 seconds.

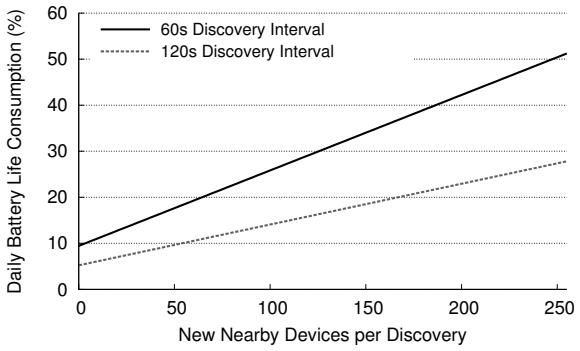

Figure 4: Estimated daily battery life consumption while running the SDDR protocol, for varying numbers of nearby devices.

DH+PSI). Even for the case of a single nearby device, DH+PSI is not practical.

Crowds and DoS attacks A frequently running protocol such as SDDR can potentially open up a new avenue of attack, whereby attackers can try to exhaust the battery of a victim device by forcing it to continually perform new discoveries. Even in benign scenarios, a device may legitimately perform many discoveries over a prolonged interval, e.g., when the user is at a stadium or an indoor auditorium, and the device encounters many other Bluetooth enabled devices. In this section, we experiment with these extreme scenarios, and show that SDDR does not adversely affect battery consumption, regardless of the number of peers it discovers. At the same time, SDDR is able to discover linked peers, and provide reasonable performance even in crowded spaces.

In order to study these worst-case scenarios for SDDR, we estimate the reduction in battery life assuming that there are 255 *new* device responses for every inquiry scan we perform. We use three components of energy consumption for our estimate: idle with Bluetooth running in discoverable mode (E_{BT}), epoch changes (E_{EC}), and discoveries (E_D). Each of these components represents the amount of energy consumed in mJ over the course of a full day (24 hours), and together represent the aggregate energy consumption while running the SDDR protocol:

$$E_{SDDR}(d,i) = E_{BT}(d,i) + E_{EC} + E_D(d,i) \quad (1)$$

$E_{BT}(d,i)$ and $E_D(d,i)$ vary with respect to the number of nearby devices (d), and the discovery interval in seconds (i). We measured the average energy consumption for cases of 1, 3, and 5 discovering devices, for discovery intervals of 60 and 120 seconds. Additionally, we use the results of the microbenchmarks from Table 2 to provide formulas for the energy consumed by epoch changes and discoveries. We assume a linear model, with respect to the number of nearby devices (d), for each i (either 60 or 120 seconds) in computing the formulas for $E_{BT}(d,i)$ and $E_D(d,i)$. The energy consumed by epoch changes (E_{EC}) does not vary with respect to d or i.

We validate Equation 1 by comparing its results to the measured values from Table 3. Without any nearby devices, our estimates are off by 1.96% and 0.66% for 60 and 120 second discovery intervals respectively. Likewise for the case of 5 devices, our estimates deviate from the measurement results by 4.61% and 1.74%.

The estimated daily battery life consumption for varying numbers of nearby devices is shown in Figure 4. Over the course of an entire day, running the SDDR protocol with a 120 second discovery interval consumes 27.82% battery life in this worst-case scenario.

Comparison with SmokeScreen We compare the performance of our protocol with SmokeScreen's discovery protocol [27]. SmokeScreen requires sending one clique signal per advertised ID, and does not use a set-digest data structure (e.g. Bloom filter) to aggregate them. In the authors' implementation, the clique signals are sent over a Bluetooth name request, which holds 248 bytes of data, i.e., roughly 4 clique signals. This makes SmokeScreen less scalable with larger advertised sets: 1) for more than 4 advertised IDs, the clique signals have to be sent over multiple Bluetooth name requests (increasing the discovery latency), and 2) sending multiple name requests for large advertised sets also lead to additional energy consumption. SDDR requires a constant amount of time to detect linkability to a given false positive rate, while SmokeScreen's detection time increases linearly with respect to the number of clique signals.

Since the SmokeScreen measurements were reported several years back, we re-evaluated the energy consumption for SmokeScreen on a recent device. In our measurement, we *conservatively* estimate the energy consump-

tion for SmokeScreen, by measuring only communication related, but not computation- or storage-related energy overhead. Our results suggest that in the case of one nearby device, SmokeScreen's communication consumes $1,628$mJ of energy; for three devices, this increases to $2,071$mJ. Unfortunately, the cost of performing a name request for each individual nearby device is prohibitively expensive. For the same amount of energy spent by SmokeScreen with 3 nearby devices, SDDR can discover and process 35 nearby devices (from Equation 1).

7 Discussion

In this section, we discuss properties and implications of the somewhat unique communication model provided by SDDR, which departs from the norm in two basic ways:

- SDDR decouples confidentiality from identity: encounter peers can communicate securely, even though they do not know each other, and cannot recognize each other during future encounters.
- Communication within SDDR is both defined and limited by radio range, which may not necessarily conform to application semantics.

7.1 Confidentiality without Identity

SDDR's secure encounter primitive provides, in effect, a per-encounter mutual pseudonym for the encounter peers, and an associated shared key. It enables the peers to name each other and communicate securely during their encounter, and at any time after their encounter via an untrusted rendez-vous service. The peers can name and authenticate each other as participants in a specific encounter and communicate securely, while remaining anonymous and unlinkable otherwise (assuming they do not reveal linkable information within their communication). Interestingly, if the users choose, this type of anonymous interaction during an encounter can form the basis for mutual identification and authentication.

Prior systems rely on anonymous or unlinkable encounters between peers, such as SMILE [43] which supports finding missed connections, and SmokeScreen [27] which allows two anonymous peers to exchange addresses for further communication (e.g., E-mail addresses) through the use of a trusted third party service.

7.2 Radio-Range Limited Communication

SDDR communication is limited to radio range, nominally 10 meters for Bluetooth 2.1 (50 meters for the latest Bluetooth 4.0 standard). From an application design point-of-view, range-limited communication may inhibit, but can also prove useful.

Without a third-party data repository or additional protocol mechanisms, e.g., a multi-hop structure, applications that provide notifications among devices beyond radio range cannot be implemented. For example, SDDR cannot be used to replicate the functionality of Google Latitude, which provides updates on friend locations independent of physical distance.

Yet another problem may be that the radio range is not limiting enough! For instance, consider an application that wants to create pairwise encounters and share a group secret only between users who are in the same room. Nothing within SDDR will prevent messages from being received outside the room, enabling a passive eavesdropper to learn the group secret. External mechanisms, in case of the room limited communication, possibly a fast attenuating ultrasound identification beacon are required to manage the impedance mismatch between application semantics and radio range. In general, application designers may choose to use SDDR for a base level of peer detection, and impose criteria that filters unwanted peers.

However, we note that radio range limited communication can have beneficial effects as well. In many situations, the Bluetooth radio range includes the attendees of a socially meaningful event—those with whom a user is likely to interact or share an experience.

Finally, the confidentiality and anonymity provided by SDDR may disproportionately empower abusive users, who could, e.g., spam or otherwise abuse those who are nearby. Here, radio range limited communication provides both a bound on abusive communication and a rudimentary form of accountability. If SDDR is used for malice, the victim is assured that the source of the communication is nearby. The victim could move, or provide evidence of misbehavior (received messages) to law-enforcement authorities. The physical proximity (either of the sender or an accomplice) required for communication within SDDR can potentially serve as a deterrent to abusive communication.

8 Conclusion

In this paper, we articulate the need for efficient secure mobile encounters and their requirements, including selective linkability and efficient revocation. We propose a light-weight protocol called SDDR, which provably meets the security requirements under the random oracle model, and enables highly scalable and energy-efficient implementations using Bluetooth. Experimental results show that our protocol outperforms standard Private Set Intersection by four orders of magnitude. Additionally, its energy efficiency exceeds that of SmokeScreen by an order of magnitude, while supporting stronger guarantees. Energy consumption (and the resulting battery life)

remain practical even under worst-case conditions like dense crowds or DoS attacks.

A Formal Security Definitions and Proofs

A.1 Overview

We follow a standard game-based approach for defining security. We describe a game between an adversary and challenger. The adversary controls the communication medium, and is allowed to schedule the actions of legitimate users. For example, the adversary can instruct a legitimate user to run GenBeacon to generate a discovery beacon; or instruct a recipient to receive the beacon(s) and call Recognize to determine the linkability of discovered neighbors. The adversary can also instruct a legitimate user to perform handshake with any member of the compromised coalition. Link identifiers generated during such a handshake (with the adversary) are marked as compromised (i.e., known to the adversary). In addition, the adversary can explicitly compromise an encounter between two legitimate users in which case the secret link identifier and shared key are exposed; or explicitly compromise a user in which case all its internal states, including previous link identifiers, are exposed.

At some point during the game, the adversary will issue a challenge, either an *anonymity challenge* or a *confidentiality challenge*.

An *anonymity challenge* intuitively captures the notion that an adversary cannot break a legitimate user's anonymity, unless the legitimate user has authorized linkability to a party within the adversary's coalition. Note that this part of the definition captures the unlinkability, selective linkability, and revocability requirements (See Section 3.1) simultaneously.

A *confidentiality challenge* intuitively captures the notion that an eavesdropping cannot learn anything about the (online or post-hoc) communication in between two legitimate users. This is guaranteed since for any two users that remain uncompromised at the end of the security, their shared key established for some time epoch t is as good as "random" to the adversary (assuming their encounter in time epoch t also remains uncompromised by the end of the security game).

A.2 Formal Security Definitions

We define the following security game between and an adversary $\mathscr{A}$ and a challenger $\mathscr{C}$. The time epoch t is initialized to 0 at the beginning of the game. The adversary adaptively makes a sequence of queries as below.

Next time epoch. Increments the current time epoch t.

Expose handshake beacons. The adversary specifies an uncompromised user P_i, identifiers of a subset S_i of P_i's previous encounters, and asks the challenger to expose P_i's handshake beacon in the current time step t using the subset of previous encounters S_i.

Handshake - Uncompromised users. The adversary specifies two uncompromised users P_i and P_j, such that P_j can hear P_i in the current time epoch t. After receiving P_i's handshake beacon, P_j calls the Recognize algorithm, and updates its local state accordingly. The adversary does not obtain information from the challenger for this query.

Handshake - Adversary. The adversary sends a handshake beacon to an uncompromised user P_i. P_i calls the Recognize algorithm, and updates its local state. The identifier of this encounter is marked as compromised. The adversary does not obtain any information from the challenger for this query.

Compromise - Encounter. The adversary specifies a reference to an encounter which took place in time $t' \leq t$ between two uncompromised users P_i and P_j, and the challenger reveals to the adversary the corresponding link identifier, encounter key, and any additional information associated with this encounter.

Compromise - User. The adversary specifies an uncompromised user P_i. The adversary learns all P_i's internal state, including the list of all previous link identifiers, encounter keys, received beacons, and any additional information associated with P_i's previous encounters[3]. P_i and all of its link identifiers are marked as compromised.

Challenge. There can only be one challenge query in the entire game, of one of the following types. In both cases, the adversary outputs a guess b' of b selected by the challenger.

- **Anonymity.** Adversary specifies two users P_i and P_j who must remain uncompromised at the end of the game. The adversary specifies S_i and S_j to the challenger, which (respectively) denote a subset of P_i's and P_j's previous encounters that must remain uncompromised at the end of the game. We require that $|S_i| = |S_j|$. Furthermore, at the end of the game, the adversary must not have issued an "expose handshake beacon" query in the current time step for P_i (or P_j) involving any element in the subset S_i (or S_j).

  The challenger flips a random coin b. If $b = 0$, the challenger constructs P_i's handshake beacon for the current time epoch t for the set S_i, and returns it to adversary. If $b = 1$, the challenger constructs P_j's handshake beacon for the set S_j, and returns it to adversary.
- **Confidentiality.** The adversary specifies two users P_i and P_j who must remain uncompromised at the end of the game.

[3] Specific to our construction, the internal states also include the exponents of P_i's own DH beacons in all previous time epochs.

Furthermore, the encounter between P_i and P_j during time epoch t must also remain uncompromised at the end of the game.

The challenger flips a random coin b. If $b = 0$, challenger returns the encounter key sk_{ij} established between P_i and P_j in time epoch t. If $b = 1$, challenger returns a random number (from an appropriate range).

Definition 1 (Anonymity, Selective linkability)**.** *Suppose that the adversary $\mathscr{A}$ makes a single anonymity challenge in the above security game. The advantage of such an adversary $\mathscr{A}$ is defined as $\mathsf{Adv}^{\mathsf{link}}(\mathscr{A}) := |\Pr[b' = b] - \frac{1}{2}|$. We say that our handshake protocol satisfies selective linkability, if the advantage of any polynomially bounded adversary (making an anonymity challenge) in the above game is a negligible function in the security parameter.*

Definition 2 (Confidentiality)**.** *Suppose that the adversary $\mathscr{A}$ makes a single confidentiality challenge in the above security game. The advantage of such an adversary $\mathscr{A}$ is defined as $\mathsf{Adv}(\mathscr{A})^{\mathsf{conf}} := |\Pr[b' = b] - \frac{1}{2}|$. We say that our handshake protocol satisfies confidentiality, if the advantage of any polynomially bounded adversary (making a confidentiality challenge) in the above game is a negligible function in the security parameter.*

A.3 Proofs of Security

Theorem 1 (Anonymity, selective linkability)**.** *Assume that the CDH problem is hard. For any polynomial-time algorithm $\mathscr{A}$, under the random oracle model,*

$$\mathsf{Adv}^{\mathsf{link}}(\mathscr{A}) \leq \mathsf{negl}(\lambda)$$

where λ is the security parameter.

Proof. If there is an adversary that can break the anonymity game with probability ε, we can construct a simulator which breaks CDH assumption with probability $\frac{\varepsilon}{\mathrm{poly}(N,T,q_o)}$, where N denotes the total number of users, T denotes the total number of epochs, and q_o denotes the number of random oracle queries.

Revealing hashes instead of Bloom filter In the challenge stage, the P_{i^*}'s Bloom filter will have m elements. Instead of announcing the Bloom filter, we assume for the proof that users simply broadcast the outcomes of the hash functions used to construct the Bloom filter. This will only reveal more information to the adversary – so as long as we can prove the security when these hashes are revealed, we immediately guarantee security when the Bloom filter instead of the hash values are revealed.

Real-or-random version and sequence of hybrid games Instead of proving the left-or-right version of the game as in the security definition, we prove the real-or-random version. Namely, the adversary specifies one user P_i (instead of two) in the anonymity challenge (who must remain uncompromised at the end of the game), as well as a subset of P_i's previous encounters (which must remain uncompromised at the end of the game). The challenger flips a random coin, and either returns the faithful hash values to the adversary, or returns a list of random values from an appropriate range. The adversary's job is to distinguish which case it is.

We use a sequence of hybrid games. In the k-th game, replace the k-th hash (out of m hashes) in the challenge stage with some random value from an appropriate range.

Simulator construction The simulator obtains a CDH instance g^{α}, g^{β}. The simulator guesses that the k-th encounter in the anonymity challenge took place between users P_{i^*} and $P_{\widehat{i^*}}$ in time step τ. If the guess turns out to be wrong later, the simulator simply aborts. The simulator answers the following queries:

Expose handshake beacons. First, the simulator generates the DH beacons as below: except for users P_{i^*} and $P_{\widehat{i^*}}$ in time step τ, the simulator generates all other DH beacons normally. For P_{i^*} and $P_{\widehat{i^*}}$ in time step τ, their DH beacons will incorporate g^{α} and g^{β} respectively. Notice that the simulator does not know α, β, or the $\mathsf{dhk} := g^{\alpha\beta}$. Except for $g^{\alpha\beta}$, the simulator can compute all other dhks between two uncompromised users (even when one of g^{α} or g^{β} is involved) since the simulator knows the exponent of at least one DH beacon.

In generating the hashes for the Bloom filter, each hash can correspond to an encounter of the following types:

- Case 1: The hash does not involve an encounter in time τ. The simulator can compute the dhk and link identifier normally in this case.
- Case 2: The hash corresponds to an encounter in time τ, but at least one of the parties in the encounter is an uncompromised user (at the time of the challenge query) other than P_{i^*}, $P_{\widehat{i^*}}$. Notice that the simulator can compute the dhk (and hence the link identifier) in this case, since the simulator knows the exponent of the DH beacon of the other party.
- Case 3: The hash corresponds to an encounter in time τ, and between P_{i^*} and $P_{\widehat{i^*}}$. In this case, the simulator does not know the $\mathsf{dhk} = g^{\alpha\beta}$.
- Case 4: The hash corresponds to an encounter in time τ, and between P_{i^*} (or $P_{\widehat{i^*}}$) and the adversary. Suppose in this encounter in question, the adversary sent P_{i^*} the DH beacon g^{γ}. (The case for $P_{\widehat{i^*}}$ is similar and omitted). The simulator does not know the $\mathsf{dhk} = g^{\alpha\gamma}$ in this case.

Regardless of which type of encounter the hash corresponds to, as long as the simulator knows the dhk of this encounter, it can compute the link identifier and Bloom filters. Below, when we explain how to answer queries of the types "Handshake - Uncompromised users" and "Handshake - Adversary", we will explain how the simulator generates and records a link identifier for each of these encounters – even when it may not know the dhk (Cases 3 and 4). In this way, the simulator can answer queries for Cases 3 and 4 as well.

Handshake - Uncompromised users. Except for the encounter between P_{i^*} and $P_{\widehat{i^*}}$ in time epoch τ, for all other encounters, the simulator can compute the resulting dhks for both uncompromised users – even when one of g^{α} or g^{β} is involved. Therefore, the simulator computes and saves the dhk, which may later be used in answering "expose handshake beacon" queries.

For the encounter between P_{i^*} and $P_{\widehat{i^*}}$ in time τ, since the simulator does not know $\mathsf{dhk} := g^{\alpha\beta}$, it simply chooses a random link identifier and saves it internally, which will later be

used in answer "Expose handshake beacon" queries to construct Bloom filters.

Handshake - Adversary. Except when time step τ and user P_{i^*} or $P_{\widehat{i^*}}$ are involved, the simulator can proceed normally, and generate and dhk and other secrets that are derived as hashes of the dhk.

For time step τ, and P_{i^*} or $P_{\widehat{i^*}}$, something special needs to be done. Assume the adversary sends P_{i^*} handshake beacon g^γ (the case for $P_{\widehat{i^*}}$ is similar and omitted). The simulator does not know α or γ, hence it cannot compute the corresponding $\mathsf{dhk} := g^{\alpha\gamma}$. Without loss of generality, assume $g^\alpha < g^\gamma$. The simulator picks a random link identifier L^* – intended to be the link identifier for this encounter with the adversary. The simulator saves L^*, which will later be used in answering "Expose handshake beacon" queries.

The simulator informs the random hash oracle of the tuple $(\mathsf{L}^*, g^\alpha, g^\gamma)$. Later, random oracle may receive multiple queries of the form $H_0(g^\alpha||g^\gamma||Z)$. Suppose there are at most q_o of these queries. With probability $\frac{1}{q_o+1}$, the hash oracle never uses encK^* as the answer. With probability $1-\frac{1}{q_o+1}$, the hash oracle guesses one of these queries at random, and uses L^* as the answer. The simulator guesses correctly with probability at least $\frac{1}{q_o+1}$ where q_o is the number of hash oracle queries.

Compromise - Encounter. The adversary specifies a reference to a previous encounter (i, j, t'), where users P_i and P_j are uncompromised thus far. If i and j are not i^* or $\widehat{i^*}$, or $t' \neq \tau$, the simulator answers the query normally.

If $t' = \tau$, i and j cannot simultaneously be i^* and $\widehat{i^*}$, otherwise the simulator would have aborted. If one of i or j is i^* or $\widehat{i^*}$, the simulator can still answer the query, even without knowing α or β – since the simulator knows the exponent of the other player's DH beacon.

Compromise - User. If the adversary issues this query for user P_{i^*} or $P_{\widehat{i^*}}$, the simulator simply aborts. For all other uses, the query can be answered normally.

Random oracle. Above, we mentioned how the random oracle handles queries of the form $H_0(g^\alpha||g^\gamma||Z)$, where g^γ was a DH beacon from the adversary in a "Handshake - Adversary" query. For all other random oracle queries, the simulator picks random numbers to answer. The simulator records previous random oracle queries, so in case of a duplicate query, the same answer is given. Whenever the simulator needs to evaluate the hash function, it also queries its own random oracle.

Challenge - Anonymity. The Bloom filter hash values requested in the challenge stage must not have been queried in an "Expose handshake beacon" query. In the k-th hybrid game, the simulator outputs random values for the first k hashes. For the rest, the simulator constructs the answers normally – since these encounters happened before time τ, the simulator can compute their link identifiers and compute these hashes normally.

Without loss of generality, assume that $g^\alpha < g^\beta$. In the above simulation, the simulator makes all guesses correctly with probability at least $\frac{1}{\mathrm{poly}(N,T,q_o)}$. Conditioned on the fact that the simulator made all guesses correctly, unless the adversary queried $H_0(g^\alpha||g^\beta||g^{\alpha\beta})$, the $(k-1)$-th and k-th hybrid games are information theoretically indistinguishable from each other to the adversary. Now the adversary cannot have queried at any point $H_0(g^\alpha||g^\beta||g^{\alpha\beta})$ with more than negligible probability, since otherwise we can construct a simulator that outputs $g^{\alpha\beta}$ with non-negligible probability, thus breaking the CDH assumption.

□

Theorem 2 (Confidentiality)**.** *Assume that the CDH problem is hard. For any PPT algorithm $\mathscr{A}$, under the random oracle model,*

$$\mathsf{Adv}^{\mathsf{conf}}(\mathscr{A}) \leq \mathsf{negl}(\lambda)$$

where λ is the security parameter.

Proof. The simulator guesses that the adversary will issue a confidentiality between users P_{i^*} and $P_{\widehat{i^*}}$ in time epoch τ. If the guess turns out to be wrong later, the simulator simply aborts.

Suppose that simulator gets a CDH instance (g^α, g^β). The simulator would then answer all queries exactly as in the proof of Theorem 1, except for the challenge – instead of submitting a anonymity challenge, the adversary now submits a confidentiality challenge:

Challenge - Confidentiality. If i, j, and current time epoch τ does not agree with what the simulator had guessed, the simulator simply aborts. Otherwise, the simulator would have chosen a random link identifier in a "Handshake - Uncompromised users" query for $(i^*, \widehat{i^*}, \tau)$. The encounter key of this session is obtained by making a random oracle query on $H_2(L)$.

The simulator makes all guesses correctly with probability at least $\frac{1}{\mathrm{poly}(N,T,q_o)}$. Conditioned on the fact that all guesses are correct, the encounter key returned in the challenge stage is information theoretically indistinguishable from random, unless the adversary has queried $H_0(g^\alpha||g^\beta||g^{\alpha\beta})$ (assuming $g^\alpha < g^\beta$ without loss of generality). However, if the adversary makes such a random oracle query with non-negligible probability, we can construct a simulation that leverages the adversary to break the CDH assumption.

□

A.4 Co-Linking

Proposition 1. *Any non-interactive handshake protocol must be subject to a co-linking attack.*

Proof. In an non-interactive protocol, a user Alice publishes a message M in a certain time epoch. Suppose Bob and Charles have met Alice before (in encounters with link-ids L and L' respectively), and Alice has granted both of them permission to link her. Bob should be able to derive from his secret state and the message M, the link identifier L linking this encounter to the previous encounter L. Similarly, with his secret state and the message M, Charles should also be able to derive L'. Now trivially, if Bob and Charles collude, they can decide that the message M can be linked to previous encounters L and L'. □

Enforcing Forward-Edge Control-Flow Integrity in GCC & LLVM

Abstract

Constraining dynamic control transfers is a common technique for mitigating software vulnerabilities. This defense has been widely and successfully used to protect return addresses and stack data; hence, current attacks instead typically corrupt vtable and function pointers to subvert a forward edge (an indirect jump or call) in the control-flow graph. Forward edges can be protected using Control-Flow Integrity (CFI) but, to date, CFI implementations have been research prototypes, based on impractical assumptions or ad hoc, heuristic techniques. To be widely adoptable, CFI mechanisms must be integrated into production compilers and be compatible with software-engineering aspects such as incremental compilation and dynamic libraries.

This paper presents implementations of fine-grained, forward-edge CFI enforcement and analysis for GCC and LLVM that meet the above requirements. An analysis and evaluation of the security, performance, and resource consumption of these mechanisms applied to the SPEC CPU2006 benchmarks and common benchmarks for the Chromium web browser show the practicality of our approach: these fine-grained CFI mechanisms have significantly lower overhead than recent academic CFI prototypes. Implementing CFI in industrial compiler frameworks has also led to insights into design tradeoffs and practical challenges, such as dynamic loading.

1 Introduction

The computer security research community has developed several widely-adopted techniques that successfully protect return addresses and other critical stack data [13, 20]. So, in recent years, attackers have changed their focus to non-stack-based exploits. Taking advantage of heap-based memory corruption bugs can allow an attacker to overwrite a function-pointer value, so that arbitrary machine code gets executed when that value is used in an indirect function call [6]. Such exploits are referred to as *forward-edge* attacks, as they change forward edges in the program's control-flow graph (CFG).

To make these attacks more concrete, consider a C++ program that makes virtual calls and has a use-after-free bug involving some object. After the object is freed, an attacker can reallocate the memory formerly occupied by the object, overwriting its vtable pointer. Later virtual calls through this object get the attacker's vtable pointer and jump to a function from the attacker's vtable. Such exploits are becoming commonplace, especially for web browsers where the attacker can partially control executed JavaScript code [14, 23].

Control-Flow Integrity (CFI) [1] guards against these control-flow attacks by verifying that indirect control-flow instructions target only functions in the program's CFG. However, although CFI was first developed over a decade ago, practical CFI enforcement has not yet been adopted by mainstream compilers. Instead, CFI implementations to date are either ad-hoc mechanisms, such as heuristic-driven, custom binary rewriting frameworks, or experimental, academic prototypes based on simplifying assumptions that prevent their use in production compilers [1, 9, 12, 29, 31–34].

In this paper, we present implementations of two mechanisms that provide forward-edge CFI protection, one in LLVM and one in GCC. We also provide a dynamic CFI analysis tool for LLVM which can help find forward-edge control-flow vulnerabilities. These CFI implementations are fully integrated into their respective compilers and were developed in collaboration with their open source communities. They do not restrict compiler optimizations, operation modes, or features, such as Position-Independent Code (PIC) or C++ exceptions. Nor do they restrict the execution environment of their output binaries, such as its use of dynamically-loaded libraries or Address Space Layout Randomization (ASLR).

The main contributions of this paper are:

- We present the first CFI implementations that are fully integrated into production compilers without restrictions or simplifying assumptions.
- We show that our CFI enforcement is practical and highly efficient by applying it to standard benchmarks and the Chromium web browser.
- We identify, discuss, and resolve the main challenges in the development of a real-world CFI implementation that is compatible with common software-engineering practices.

All our mechanisms verify targets of forward-edge in-

direct control transfers but at different levels of precision, depending on the type of target and the analysis applied. For example, C++ indirect-control transfers consist mostly of virtual calls, so one of our approaches focuses entirely on verifying calls through vtables. Our security analyses show that our CFI mechanisms protect from 95% to 99.8% of all indirect function calls. They are also highly efficient, with a performance penalty (after optimizations) ranging from 1% to 8.7%, as measured on the SPEC CPU2006 benchmark suite and on web browser benchmarks.

Most notably, our CFI mechanisms compare favorably to recent CFI research prototypes. The security guarantees of our work differ from these prototypes, but a comparison is nonetheless instructive, since our attack model is realistic, and our defenses give strong guarantees.

MIP [28] and CCFIR [34] state efficiency as their main innovation. In particular, on the SPEC Perl benchmarks (where they both were slowest), CCFIR reports 8.6% overhead, and MIP reports 14.9% to 31.3% overhead. Our mechanisms have a corresponding overhead of less than 2%, as we report in Section 7.2. For C++ benchmarks, which perform indirect calls more frequently, the performance differences can be even greater. Another recent CFI implementation, bin-CFI [35], reports overheads of 12% on the SPEC Perl benchmarks, but 45% for the C++ benchmark omnetpp, while the overhead is between -1% and 6.5% for omnetpp compiled using our mechanisms. Even the most recent CFI implementation, SAFEDISPATCH [19], must sacrifice software-engineering practicality and use profile-driven, whole-program optimization to achieve overheads comparable to ours (roughly 2% for all three of their Chromium benchmarks).

2 Attacks and Compiler-based Defenses

Software is often vulnerable to attacks that aim to subvert program control flow in order to control the software's behavior and assume its privileges. Typically, successful attacks exploit software mistakes or vulnerabilities that allow corruption of low-level state.

To thwart these low-level attacks, modern compilers, operating systems, and runtime libraries protect software integrity using a variety of techniques, ranging from coarse-level memory protection, through address-space layout randomization, to the fine-grained type-safety guarantees of a high-level language. In particular, machine-code memory is commonly write protected, and thread execution stacks are protected by placing them at random, secret locations, and by checking that secret values (a.k.a. canary values) remain unmodified. This guards return addresses and other stack-based control data against unintended overwriting [7, 13].

As a result of such compiler-based defenses becoming widely used, corruption of the execution stack or machine code has become a far less common means of successful attack in well-maintained, carefully-written software such as web browsers [20]. However, there has been a corresponding increase in attacks that corrupt program-control data stored on the heap, such as C++ vtable pointers (inside objects) [14], or function pointers embedded in data structures; these attacks subvert indirect control transfers and are known as "return-to-libc" or return-oriented programming [3, 8, 22, 25–27, 30].

In this paper we present three compiler-based mechanisms for further protecting the integrity of program control data. Focusing on the integrity of control-transfer data stored on the heap, two of our mechanisms enforce forward-edge CFI by restricting the permitted function pointer targets and vtables at indirect call sites to a set that the compiler, linker, and runtime have determined to be possibly valid. The third mechanism is a runtime analysis tool designed to catch CFI violations early in the software development life-cycle. Our mechanisms are efficient and practical and have been implemented as components of the GCC and LLVM production compiler toolchains. While they differ in their details, and in their security — such as in how precisely the program's CFG is enforced — all three of our implementations:

- add new, read-only metadata to compilation modules to represent aspects of the program's static CFG;
- add machine code for fast integrity checks before indirect forward-edge, control-flow instructions;
- optionally divert execution to code that performs slower integrity checks in certain complex cases;
- call out to error handlers in the case of failures; and
- may employ runtime library routines to handle important exceptional events such as dynamic loading.

Like all defenses, we aim to prevent certain threats and not others, according to an attack model. As in the original work on CFI, our model pessimistically assumes that an adversary can arbitrarily perturb most writable program data at any time [1]. The program code, read-only data, and thread register state cannot be modified. While pessimistic, this attack model has stood the test of time, and is both conceptually simple and realistic.

Similar to recent independent CFI work done concurrently with ours [19], and motivated by attackers' increasing focus on heap-based exploits, our mechanisms protect only forward-edge control transfers. Our attack model does not contain many types of stack corruption, since, as stated previously, effective defenses against such corruption are already in common use. Thus, our choice of attack model differs from most earlier work on CFI, except for work on mechanisms like XFI [12], which place the stack outside of pointer-accessible memory.

In our attack model we also depart from most previous CFI work by choosing to trust the compiler toolchain. For the integration of general-purpose defenses in pro-

duction compilers, we find relying only on stand-alone verification of the final, output binaries to be impractical — although well-suited to custom compilers for specific scenarios, such as in Google's Native Client [17, 21]. While eliminating trust in the compiler is a laudable goal [24], doing so increases complexity, reduces portability, and prevents optimizations, while providing only uncertain benefits. In particular, we know of no exploits on previous compiler-based defenses that justify the software engineering costs of eliminating trust in the compiler.

By adopting the above attack model, our mechanisms are practical as well as efficient. While many experimental CFI mechanisms have been constructed and described in the literature, none have been able to efficiently provide strong, precise integrity guarantees with the full support that programmers demand from a production compiler. In particular, incremental compilation and dynamic libraries have remained primary challenges for CFI implementations, as has achieving low performance overheads; these challenges have only recently started to be addressed in experimental prototypes that enforce more coarse-grained CFI policies [28, 34]. However, CFI enforcement that is too coarse grained may provide only limited protection [4, 10, 15, 16] against modern attackers.

In summary, by focusing on forward-edge CFI, and fully integrating into compilers, our mechanisms can enforce fine-grained CFI at a runtime overhead that improves on that of the best previous work.

Related Work. Following the original 2005 work on CFI, later revised as Abadi et al. [1], there have been a number of implementations that have extended or built-upon CFI: XFI by Erlingsson et al. [12], BGI by Castro et al. [5], HyperSafe by Wang and Jiang [31], CFI+Sandboxing by Zeng et al. [32], MoCFI by Davi et al. [9], CCFIR by Zhang et al. [34], Strato by Zeng et al. [33], bin-CFI by Zhang et al. [35], MIP by Niu et al. [28], and SAFEDISPATCH by Jang et al. [19].

These CFI-based mechanisms vary widely in their goals, tradeoffs and implementation details. To achieve low overhead, many enforce only coarse-grained CFI, which may be a weak defense [15].

XFI, Strato, HyperSafe, and BGI use control-flow integrity primarily as a building block for higher-level functionality, such as enforcing software-based fault isolation (SFI), or fine-grained memory-access controls. Some, like XFI, focus on statically verifying untrusted binary modules, to establish that CFI will be correctly enforced during their execution, and thus that they can be used safely within different address spaces, such as the OS kernel.

Many implementations of CFI are based on binary rewriting. XFI and the original work on CFI used the sound, production-quality Windows binary rewriter, Vulcan [11], as well as debug information in PDB files. These implementations construct precise control-flow graphs (CFGs) to ensure that all indirect control transfers are constrained in a sound manner. Other implementations — including MoCFI, CCFIR, and bin-CFI — are based on more ad hoc and fragile mechanisms. For example, MoCFI produces an imprecise CFG for ARM applications running on an iPhone based on runtime code dumping, disassembly, and heuristics. CCFIR relies on relocation tables and recursive disassembly with heuristics to identify code that needs to be protected. The code is then rewritten to use a special randomized springboard section through which all indirect control transfers happen. Bin-CFI also uses heuristic disassembly; however, unlike CCFIR, bin-CFI injects a CFI-protected copy of the text section into the original binary and uses dynamic binary translation to convert pointers between the two code copies at runtime.

Other implementations, including HyperSafe, MIP, CFI+Sandboxing, and SAFEDISPATCH are implemented as modifications to the compiler toolchain and compile source code to binaries with CFI protection. The first three are implemented as rewriting either assembly or the compiler's Intermediate Representation (IR) of machine code — essentially a more precise form of binary rewriting.

Our vtable verification (see Section 3) is most similar to SAFEDISPATCH: work done independently and concurrently with ours that adds passes to LLVM for instrumenting code with runtime CFI checks, and relies on profile-driven, whole-program optimization to reduce enforcement overhead. At a call site, SAFEDISPATCH checks that either (1) the vtable pointer is to a valid vtable, for the call site, or (2) the address in the vtable points to a valid method for the call site. However, SAFEDISPATCH disallows separate compilation, dynamic libraries, etc., and relies on profile-driven, whole-program optimization, which is not very practical.

The overhead of all these various CFI mechanisms ranges from 6% to 200%, with some significant variations. In particular, the recent papers on MIP, CCFIR, and Strato state their low CFI enforcement overhead as a main contribution; Strato also highlights its support for compiler optimizations. However, as mentioned previously, their overheads on comparable benchmarks are several times larger than those of our CFI mechanisms — and they are likely to perform even worse on C++ benchmarks. This is due in part to the different properties our work enforces: we limit our scope to protecting control data that is not already well-protected by other mechanisms.

3 VTV: Virtual-Table Verification

Vtable Verification (VTV) is a CFI transformation implemented in GCC 4.9 for C++ programs. VTV protects only virtual calls and does not attempt to verify other types of

indirect control flow. However, most indirect calls in C++ are virtual calls (e.g., 91.8% in Chrome), making them attractive targets for attackers. VTV is our most precise CFI approach: it guarantees that the vtable used by each protected virtual call is both valid for the program and also correct for the call site.

3.1 Problem Description

Virtual calls are made through objects, which are instances of a particular class, where one class (e.g., `rectangle`) inherits from another class (e.g., `shape`), and both classes can define the same function (e.g., `draw()`), and declare it to be virtual. Any class that has a virtual function is known as a *polymorphic class*. Such a class has an associated virtual function table (*vtable*), which contains pointers to the code for all the virtual functions for the class. During execution, a pointer to an object declared to have the type of a parent class (its *static type*, e.g., `shape`) may actually point to an object of one of the child classes (its *dynamic type*, e.g., `rectangle`). At runtime, the object contains a pointer (the *vtable pointer*) to the appropriate vtable for its dynamic type. When it makes a call to a virtual function, the vtable pointer in the object is dereferenced to find the vtable, then the offset appropriate for the function is used to find the correct function pointer within the vtable, and that pointer is used for the actual indirect call. Though somewhat simplified, this explanation is generally accurate.

The vtables themselves are placed in read-only memory, so they cannot be easily attacked. However, the objects making the calls are allocated on the heap. An attacker can make use of existing errors in the program, such as use-after-free, to overwrite the vtable pointer in the object and make it point to a vtable created by the attacker. The next time a virtual call is made through the object, it uses the attacker's vtable and executes the attacker's code.

3.2 Overview of VTV

To prevent attacks that hijack virtual calls through bogus vtables, VTV verifies the validity, at each call site, of the vtable pointer being used for the virtual call, before allowing the call to execute. In particular, it verifies that the vtable pointer about to be used is correct for the call site, i.e., that it points either to the vtable for the static type of the object, or to a vtable for one of its descendant classes. VTV does this by rewriting the IR code for making the virtual call: a verification call is inserted after getting the vtable pointer value out of the object (ensuring the value cannot be attacked between its verification and its use) and before dereferencing the vtable pointer. The compiler passes to the verifier function the vtable pointer from the object and the set of valid vtable pointers for the call site. If the pointer from the object is in the valid set, then it gets returned and used. Otherwise, the verification function calls a failure function, which normally reports an error and aborts execution immediately.

3.3 More Details

VTV differs from all previous compiler-based CFI implementations in that it allows incremental compilation rather than requiring that all files be recompiled if a single one is changed. VTV also does not forbid or restrict dynamic library loading. Such requirements and restrictions are common in research prototypes but impractical for real world systems.

Because VTV allows incremental compilation and dynamic loading, it must assume that its knowledge of the class hierarchy is incomplete during any particular compilation. Therefore, VTV has two pieces: the main compiler part, and a runtime library (*libvtv*), both of which are part of GCC. In addition to inserting verification calls at each call site, the compiler collects class hierarchy and vtable information during compilation, and uses it to generate function calls into libvtv, which will (at runtime) build the complete sets of valid vtable pointers for each polymorphic class in the program.

To keep track of static types of objects and to find sets of vtable pointers, VTV creates a special set of variables called *vtable-map variables*, one for each polymorphic class. At runtime, a vtable-map variable will point to the set of valid vtable pointers for its associated class. When VTV inserts a verification call, it passes in the appropriate vtable-map variable for the static type of the object, which points to the set to use for verification.

Because our vtable-pointer sets need to be built before any virtual calls execute, VTV creates special constructor init functions and gives them a high priority. The compiler inserts into these special functions the calls for building vtable-pointer sets. These functions run before standard initialization functions, which run before `main`, ensuring the data is in place before any virtual calls are made.

Vtable-map variables and vtable-pointer sets need to be read only to avoid introducing new vectors for attack. However, they must be writable when they are first initialized and whenever a dynamic library is loaded, since the dynamic library may need to add to the vtable-pointer sets. So, we need to be able to find all our data quickly. To keep track of the vtable-pointer sets, we wrote our own memory allocation scheme based on mmap. VTV uses this scheme when creating the sets; this lets it find all such sets in memory.

To find vtable-map variables, VTV writes them into a special named section in the executable, which is page-aligned and padded with a page-sized amount of zeros to prevent any other data from residing on the same pages. Before updating its data, VTV finds all memory pages that contain vtable-map variables and vtable-pointer sets and makes them writable. When it finishes the update, it finds

all appropriate pages and makes them read-only. Thus, the only times these VTV data structures are vulnerable to attack are during program initialization, and possibly during `dlopen` calls. The VTV code that updates our data structures uses pthread mutexes to prevent races between multiple threads.

3.4 Practical Experience with VTV

We encountered some challenges while developing VTV.

Declaring global variables. Originally, VTV declared vtable-map variables as COMDAT and as having global visibility, because incremental compilation can result in multiple compilation units defining the same vtable-map variable, and COMDAT sections can be coalesced by the linker. However, this did not work reliably because there are many ways in which programmers can override the visibility of a symbol: linker version scripts can explicitly declare which symbols have global visibility; the rest of the symbols become hidden by default. Also, if global symbols are not added to the dynamic symbol table, then vtable-map variables might not be global. Finally, calls to `dlopen` with the RTLD_LOCAL flag have similar effects. We found all these techniques at work in Chromium.

When some vtable-map variables do not have global visibility, there can be multiple live instances of a vtable-map variable for a particular class, each pointing to a different vtable-pointer set containing only part of the full vtable-pointer set for the class. If the verification function is passed a variable pointing to the wrong part of the set, execution aborts incorrectly. We call this the *split-set problem*.

We finally concluded that there is no existing mechanism for the compiler to ensure a symbol will always be globally visible. The only way to eliminate the split-set problem was to accept that there would be multiple live versions of some vtable-map variables. To handle the consequences of this new assumption, VTV keeps track of the first instance of a vtable-map variable for each class. When initializing any vtable-map variable, it first checks if it has already seen a version of that variable. If not, then it allocates a vtable-pointer set for the variable, makes the variable point to the vtable-pointer set, and registers the variable in its variable registry. All subsequent vtable-map variables for that class are then initialized to point to the same vtable-pointer set as the first one.

Mixing verified and non-verified code. VTV causes execution to halt for one of three reasons: (1) a vtable pointer has been corrupted; (2) the C++ code contains an incorrect cast between two class types (programmer error); or (3) the set of valid vtable pointers used for verification is incomplete. The split-set problem is an example of the last case. This can also occur if some files that define or extend classes are instrumented with vtable verification, and other files that define or extend part of the class hierarchy are not. A similar effect also can occur with libraries or plugins that pass objects in and out, if one is instrumented and the other is not.

lib.cc

```
#include "lib.h"
struct Derived_Priv : public Base {
  virtual ~Derived_Priv() {}
};

Base *GetPrivate() {
  return new Derived_Priv;
}
void Destroy(Base *pb) {
  delete pb; // virtual call #1
}
```

main.cc

```
#include "lib.h"
struct Derived : public Base {
        virtual ~Derived() {}
};

int main() {
  Derived *d = new Derived;
  Destroy(d);
  Base *pp = GetPrivate();
  delete pp; // virtual call #2
}
```

main.cc w/ VTV	lib.cc w/ VTV	vcall #1 OK	vcall #2 OK	Missing from vtable pointer set
Yes	Yes	Yes	Yes	Nothing
No	No	Yes	Yes	Nothing
Yes	No	Yes	No	`Derived_Priv`
No	Yes	No	Yes	`Derived`

Figure 1: Example of problems resulting from mixing verified and unverified code. If only main.cc is compiled with verification, the vtable pointer for `Derived_Priv` does not get added to the valid set for Base, so virtual call #2 fails to verify. If only lib.cc is compiled with verification, the vtable pointer for `Derived` does not get added to the valid set for Base, so virtual call #1 fails.

Figure 1 shows this problem: a header file, lib.h, declares a base class `Base`. The class `Base` contains one virtual function, its destructor. There are two source files, lib.cc and main.cc, that each includes lib.h and contains classes that inherit from `Base`, as shown in the upper part of Figure 1. The table in the lower part of Figure 1 shows the effects on the two marked virtual calls of compiling lib.cc and main.cc with and without VTV. Note that the only cases where both virtual calls pass verification are when everything is built with VTV or nothing is.

We encountered this problem in ChromeOS with the Chrome browser. There are two third-party libraries which are built without VTV and are distributed to ChromeOS as stripped, obfuscated binaries (these binaries are not part of the open-source Chromium project). To make matters worse, when we built the rest of Chrome

and ChromeOS with VTV and ran tests that exercised those libraries, we encountered verification failures.

To deal with the mixed-code problem in general, VTV was designed and written with a replaceable failure function. This function gets called if the verification function fails to find a vtable pointer in a valid set. To replace the default failure function, a programmer writes a replacement function (using the same signature, provided in a header file in libvtv), compiles it, and links it into the final binary. For Chrome we replaced the default failure function with a whitelist failure function. The whitelist function maintains an array with one record for each whitelisted library. The record contains the memory address range where the readonly data section for the library (which contains all of the library's vtables) is loaded. If a vtable pointer fails normal verification, it gets passed to the whitelist failure function. The function goes through the array, checking to see if the pointer is in any of the address ranges. If so, it assumes the pointer is valid and execution continues (verification succeeded). Otherwise, it reports an error and aborts.

Because the obfuscated libraries are dynamically loaded, the whitelist array records do not initially contain any addresses. If any records are empty when the whitelist failure function is called, then the function checks to see if the corresponding library has been loaded, and if so, it fills in the addresses before verification. For ChromeOS, our whitelist consists of the two third-party libraries mentioned above. This secondary verification, while not as accurate as normal VTV verification, still severely limits what an attacker can do, and with it we were able to execute all our tests on Chrome with no verification failures. Our secondary failure function only gets called in those cases where the main verification function fails. In that case it usually performs at most one alignment check and four pointer comparisons. Therefore, its overall impact on performance is small.

3.5 Alternatives & Enhancements for VTV

Since our performance overhead is reasonably good (ranging from 2.0% to 8.7% in the worst case, as we discuss in Section 7.1), we have not spent much time improving the performance of VTV. However, there are some things that could be done to improve these numbers. For various reasons, Chrome/ChromeOS currently cannot be compiled with devirtualization[1] enabled; we could enable devirtualization in Chrome and tune the devirtualizer to be more aggressive when combined with VTV. Partial inlining of the verification call sequences is another avenue we could explore, since call overhead accounts for a significant portion of our overall performance penalties. We could also implement secure methods for caching and reusing frequently verified values.

When we started implementing VTV, we decided that we did not want to modify any element of the toolchain except the compiler, especially because GCC can be used with a variety of different assemblers and linkers, and we did not want to modify all of them. An alternative approach would have been to have the compiler store the vtable-pointer sets as data in the assembly files. This data would be passed through the assembler to the linker. At link time the linker would see the whole program and could efficiently combine the vtable-pointer sets from the various object files into the appropriate final vtable-pointer sets. The dynamic loader, when loading the program, could load the pointers into our data sets and mark them read-only. This approach would eliminate ordering issues between functions that build vtable-pointer sets and functions that make virtual calls. The dynamic loader would also need to update the data, as appropriate, whenever it loaded a dynamic library that contained additional vtable pointers. A disadvantage of this alternative approach is that instead of requiring modifications only to the compiler, it would modify the entire toolchain: the compiler, the assembler, the linker, and the dynamic loader.

4 IFCC: Indirect Function-Call Checks

Indirect Function-Call Checks (IFCC) is a CFI transformation implemented over LLVM 3.4. It operates on LLVM IR during link-time optimization (LTO). IFCC does not depend on the details of C++ or other high-level languages; instead, it protects indirect calls by generating *jump tables* for indirect-call targets and adding code at indirect-call sites to transform function pointers, ensuring that they point to a jump-table entry. Any function pointer that does not point into the appropriate table is considered a CFI violation and will be forced into the right table by IFCC. IFCC collects function-pointers into jump tables based on function-pointer sets, like VTV's vtable-pointer sets, with one table per set.

IFCC forces all indirect-calls to go through its jump tables. This significantly reduces the set of possible indirect-call targets, and severely limits attacker options, preventing attacks that do not jump to a function entry point of the right type.

Each entry in a jump table consists solely of an aligned jump instruction to a function. The table is written to the read-only text area of the executable and is padded with trap instructions to a power-of-two size so that any aligned jump to the padding will cause the program to crash. Since the size of the table is a power of two, IFCC can compute a mask that can be used at call sites to force

[1] Devirtualization is an optimization that replaces virtual calls with a fast-path/slow-path mechanism: the fast path uses a direct call to the most common target, with a conditional check to make sure this is right; the slow path falls back on the normal virtual call mechanism. Devirtualization reduces the number of indirect calls and verifications and improves the overall performance of VTV.

a function pointer into the right function-pointer set. For example, if each jump-table entry takes up 8 bytes, and the table is 512 bytes in size, then there are 64 entries in the table, and the mask would be 111111000 in binary, which is 504 in decimal.

IFCC rewrites IR for functions that have their address taken; we call these *address-taken* functions. The main transformation replaces the address of each such function with the address of the corresponding entry in a jump table. Additionally, indirect calls are replaced with a sequence of instructions that use a mask and a base address to check the function pointer against the function-pointer set corresponding to the call site. The simplest transformation subtracts the base address from the pointer, masks the result, and adds the masked value back to the base. If the pointer was in the right function-pointer set before this transformation, then it remains unchanged. If not, then a call through the resulting pointer is still guaranteed to transfer control only to addresses in the function-pointer set or to trap instructions. Note that every pointer in a jump table is a valid function pointer (although some of them immediately hit trap instructions when they are called), so they can correctly be passed to external code.

IFCC can support many kinds of function-pointer sets, each with different levels of precision. For example, the most precise version would have one function-pointer set per function type signature. However, real world code does not always respect the type of function pointers, so this can fail for function-pointer casts. We will focus on two simple ways of constructing function-pointer sets: (1) *Single* puts all the functions into a single set; and (2) *Arity* assigns functions to a set according to the number of arguments passed to the indirect call at the call site (ignoring the return value).

Note that although we implemented only two simple types of tables, any disjoint partitioning of the function-pointer types in the program will work, as long as each call site can be uniquely associated with a single table. This is true no matter what analysis is used to generate these tables — be it static, dynamic, or manual. So, for example, the compiler could perform a detailed analysis of escaping pointers and use it to separate these pointers into their own tables.

The following example demonstrates the IFCC technique for a simple program. Consider a function `int f(char a) { return (int)a; }` and a main function that makes an indirect call to `f` through a function-pointer variable `g`. In LLVM IR, the symbol `@f` will refer to function defined above; IFCC adds a `@baseptr` symbol that stores a pointer to the first function pointer in the generated jump table. Before IFCC, the LLVM IR contains an indirect call instruction `%call = call i32 %2(i8 signext 0)` to the function pointer stored in variable `%2`.

IFCC generates a new symbol `@f_JT` and defines it in the IR as an external function. It finds each instance where the program uses the address of `@f` and makes it use the address of `@f_JT` instead. It also creates a jump table of the form:

```
  .align 8
  .globl f_JT
f_JT:
  jmp f
```

This defines the symbol `@f_JT` and satisfies the linker. IFCC instruments the code before the indirect call with instructions that transform the pointer. There are several ways to perform this transformation. We show two techniques, one that requires large alignments, and another for when large alignments are not supported. The requirement for large alignment in one scheme is because the base pointer must be aligned to the size of its table. This makes the base a prefix of each entry in its table.

When the object format and the kernel support large table alignments (e.g., greater than one page), IFCC can use a compact set of instructions to transform a pointer. The following IR assumes integer representations of `@baseptr` in `%1` and `@mask` in `%2`, and a pointer to `@f` in `%3`.

```
%4 = and i64 %2, %3
%5 = add i64 %1, %4
%6 = inttoptr i64 %5 to i32 (i8)*
%7 = call i32 %6(i8 signext 0)
```

In x86-64 assembly, this becomes:

```
and     $mask, %rax
add     $baseptr, %rax
callq   *%rax
```

The ELF format supports arbitrary alignments but the Linux kernel does not (as of version 3.2.5, under ASLR with Position-Independent Executables (PIE)). Under ASLR, the kernel treats the beginning of each ELF segment as an offset and generates a random base to add to the offset. The base is guaranteed to be aligned to a page boundary (2^{12}) but the resulting address is not guaranteed to have larger alignment.

Under these circumstances, IFCC changes the way it operates on function pointers; instead of adding a masked pointer to a base, it computes the difference between the base address and the function pointer, masks this value with the same mask as before, and adds the result to the base. This ends up generating 3 instructions for pointer manipulation in x86-64: a `sub`, then an `and`, then an `add`.

4.1 Practical Experience with IFCC

We modified the Chromium build scripts to build under LTO as much of the code as possible. It built 128 files as x86-64 ELF objects, and 11,012 files as LLVM IR. We

then applied, separately, the Single and Arity versions of IFCC in this configuration.

Like VTV, IFCC suffers from false positives due to external code. In particular, any function that was not defined or declared during link-time optimization will trigger a CFI violation. This can happen for several reasons. First, JIT code (like JavaScript engines) can generate functions dynamically. Second, some external functions (like `dlsym` or `sigaction`) can return external function pointers. Finally, some functions can be passed to external libraries and can be called there with external function pointers; this is common in graphics libraries like `gtk`. The number of false positives varies greatly depending on the external code, ranging from extremely frequent in the case of JIT-generated code to extremely infrequent in the case of signal handlers.

To handle function pointers returned by external code, we added a fixed-size set of special functions to the beginning of each table. These functions perform indirect jumps through function pointers stored in an array. IFCC rewrites all calls to external functions (including `dlsym`) that return function pointers and inserts a function call that takes the pointer and writes it to the array if it is not already present. It returns a pointer to the table entry that corresponds to the array entry used to store the pointer. If the array has no more space, then it halts the program with an error. This converts function pointers from external code into table entries at the expense of adding a small number of writable function pointers to the code. This memory can be protected using the techniques described in Section 3.4, though the prototype in this paper does not perform this protection.

To handle functions passed to external functions, IFCC must find all cases in which functions are passed to external code and must rewrite the functions to not test their function pointers against the jump tables generated by IFCC. We added a flag to the IFCC plugin that takes the name of a function to skip in rewriting. To discover these function pointers, we added a warning mode to the IFCC transformation that prints at run time the names of functions that make indirect calls to functions outside the function-pointer sets. We found 255 such functions in Chromium, mostly associated with graphics libraries.

4.2 Annotations

The version of IFCC described in this section provides automatic methods for discovering and handling false positives. To improve maintainability of software with IFCC, however, we have implemented a different version that uses annotations instead of compile-time flags and uses custom failure functions like VTV. This is the version that we are working on upstreaming into LLVM.

Instead of functions being forced into the appropriate jump table, they are checked using the same code sequences as above, and any pointer that fails the check is passed to a custom failure function. IFCC's default failure function prints out the name of the function in which the failure occurred, and the value of the pointer that failed the check. This version of IFCC adds a comparison, a jump, and function call to the inserted instruction sequence. However, it gives greater flexibility to the resulting code in handling false positives, as discussed for VTV.

This new implementation provides annotations and a simple interprocedural dataflow analysis to help detect and handle these problems automatically. We provide two annotations that programmers can add using attribute notation: `__attribute__((annotate()))`.

- `cfi-maybe-external` is applied to local variables/parameters as well as to pointers in data structures.
- `cfi-no-rewrite` is applied to functions.

The dataflow analysis in IFCC finds external function pointers and traces their flow into indirect calls and into store instructions. It also traces the flow from `cfi-maybe-external`-annotated pointers and other variables into indirect calls and store instructions. It produces compile-time warnings if it finds a store instruction for an external function pointer and the pointer in the store instruction did not come from a location annotated by `cfi-maybe-external`. The annotations then can be used as a kind of whitelist in the CFI failure function, or these indirect calls can be skipped in rewriting.

The annotation `cfi-no-rewrite` means that all indirect calls in the annotated function might use external function pointers. The information from this annotation can be used either to build a whitelist or to skip rewriting. Our implementation currently skips rewriting for these indirect calls.

These annotations are also useful for cases that IFCC cannot detect, like callbacks buried deep inside data structures passed to external code. Calls to these functions will generate CFI violations at run time; these violations are false positives, and the locations of these indirect calls can be annotated with, e.g., `cfi-maybe-external` to indicate this to the CFI failure function.

It might seem like all an adversary has to do is to find one of the locations that has been annotated with `cfi-maybe-external` and overwrite a pointer that flows into it, and this will defeat IFCC. However, these annotations merely convey information to the CFI failure function; this function can perform arbitrarily complex checks make sure that function pointers that violate CFI are still valid. For the purposes of our evaluation, we implemented a simple failure function, as described above.

5 FSan: Indirect-Call-Check Analysis

The more precise the control-flow graph used in a CFI implementation, the harder it becomes for an attacker to exploit a program while staying within CFI-enforced bounds: a more precise CFG leads to fewer choices in targets for indirect control-transfer instructions. However, building a precise CFG is a hard problem, and programming techniques like function-pointer type punning and runtime polymorphism exacerbate this problem. Every time a CFI mechanism faces uncertainty, it is forced to be conservative to preserve correctness. Although this strategy guarantees correctness, it may result in a loss of security. Thus, techniques that reduce uncertainty about the CFG can increase security. We can achieve the best practical results by combining knowledge of programming language constructs (such as vtables), static analysis (such as we do for IFCC), and dynamic analysis. To that end, we designed FSan—an optional indirect call checker—and integrated it into Clang, LLVM's front end.

Clang's undefined behavior sanitizer (UBSan) instruments C and C++ programs with checks to identify instances of undefined behavior. FSan was added to UBSan in LLVM 3.4. FSan detects CFI violations at runtime for indirect function calls.[2] FSan operates during the translation from the Clang AST to LLVM IR, so it has full access to type information, allowing it to make more accurate checks than IFCC, which uses IR alone.

FSan is a developer tool designed to perform optional type checking. In particular, it is not designed to defend against attacks. Instead, it is designed to be used by developers to identify CFI violations that may lead to security issues. As a fully accurate checker (it checks definedness exactly according to the definition in the C++ standard), it can also be used to help guide the development of control-flow integrity techniques by identifying properties of interest to be checked in the field.

FSan prefixes each function emitted by the compiler with 8 (on x86-32) or 12 (on x86-64) bytes of metadata. Table 1 shows the layout of these bytes; they are executable and cost little in performance, since the first two bytes encode a relative branch instruction which skips the rest of the metadata. The next two bytes encode the instructions `rex.RX push %rsp` (on x86-64) or `incl %esi ; pushl %esp` (on x86-32); this sequence of instructions is unlikely to appear at the start of a non-instrumented function body, and we observed no false positives in Chromium due to this choice of prefix.

Each indirect call site first loads the first four bytes from the function pointer, and compares it to the expected signature — the optionality of FSan arises from selecting a signature unlikely but permitted to appear at the start of an uninstrumented function. Because GCC at optimization level -O2 and higher and Clang at any optimization level will align functions to 16 bytes, this initial read succeeds for each function compiled with these compilers, regardless of the length of the function. This assumes GCC-compiled system libraries are compiled with -O2 or higher.

[2]The undefined behavior sanitizer also includes a vtable-pointer checker which is not described here.

Kind	Offset	Data	Interpretation
Signature	0 1	0xeb 0x06/0x0a	`jmp .+0x08/0x0c`
	2 3	0x46 0x54	'F' 'T'
RTTI	4	Pointer to `std::type_info` for the function's type (4/8 bytes)	

Table 1: Function prefix data layout for the optional function type checker.

If the signature matches, then the next 4 or 8 bytes are loaded and compared against the expected function Run-Time Type Information (RTTI) pointer, which is simply the RTTI pointer for the function type of the callee expression used at the call site. If the pointers are unequal, then a runtime function is called to print an appropriate error message. A pointer equality test is sufficient because the function RTTI pointer for a particular function type is normally unique. This is because the linker will normally (but not always) coalesce RTTI objects for the same type, as they have the same mangled name.

The condition for undefined behavior as specified by the C++ standard is that the function types do not match (see C++11 [18, expr.reinterpret.cast], "The effect of calling a function through a pointer to a function type [...] that is not the same as the type used in the definition of the function is undefined"), so FSan is precise (no false positives or false negatives) with respect to this paragraph of the standard when both the caller and callee are compiled with the checker (provided that the linker coalesces RTTI symbols). However, FSan has not been implemented for C, and indeed would not work in its present form, mainly because the C rules relating to the definedness of calls to functions without a prototype are more complex.

Note that the RTTI pointer for a vtable function call is less precise than the vtable-pointer set check in VTV. FSan checks that each function has the correct type but not whether it was in the original program's CFG.

5.1 Practical Experience with FSan

We evaluated FSan by applying it to Chromium: we ran an instrumented version of the main browser executable, and FSan produced a variety of undefined-behavior reports. Two of the main categories of reports we observed were:

- Template functions whose parameters are of a templated pointer type, which are cast to functions whose parameters are of void pointer type so that they can be used as untyped callbacks;

- Functions that take context parameters as typed pointers in the function declaration but void pointers or pointers to a base class at the call site.

The fix for these types of bugs is simple in principle: give the parameters a void pointer type and move the casts into the function body. One instance of each type of problem was found and fixed in the Skia graphics library that Chromium uses. This eliminated much of the low-hanging fruit reported by FSan; most of the remaining problems were more widespread in the codebase and thus will take more effort to deal with. For example, V8 uses callbacks to implement a feature known as "revivable objects" which Blink (née WebKit) relies on heavily; in many cases these callbacks were implemented using the derived types expected by the object implementation, rather than V8's base value type.

6 Security Analysis

In order to evaluate the efficacy of security techniques it is important to apply them to the real-world code they are expected to protect and measure the impact. To this end, we analyzed Chromium compiled with VTV and GCC, and with IFCC and Clang.

One consequence of implementing security mechanisms in the compiler is that it is important to evaluate the final output rather than simply the output of the particular compiler pass. The reasons for this are twofold: (1) later optimization passes may transform the security mechanism in unpredictable ways; and (2) the final linking step adds additional binary code to the final executable that the security pass never sees.

Basic optimizations such as common-subexpression elimination and loop-invariant code motion can eliminate redundant checks or hoist checks out of loops. Although such optimizations are generally acceptable from a correctness point of view, they may be impermissible from a security standpoint. For example, consider two consecutive calls to C++ member functions `obj.foo(); obj.bar();`. A security mechanism that protects virtual function calls, such as VTV, can load a vtable pointer into a callee-saved register, perform the verification, and then perform the two calls:

```
movq    (%r12), %rbx  ; set rbx to the vptr
movq    %rbx, %rdi
callq   verify_vtable ; verify_vtable(vptr)
movq    %r12, %rdi
callq   *16(%rbx)     ; obj.foo()
movq    %r12, %rdi
callq   *24(%rbx)     ; obj.bar()
```

This is perfectly correct behavior since the first function call is guaranteed by the platform ABI to preserve the value of the register. However, if `rbx` is spilled to the stack in `foo()` and is later overwritten, e.g., via a buffer overflow on the stack, then the call to `bar()` will be to an attacker-controlled location. An alternative to using a callee-saved register is to explicitly spill/reload the register to/from the stack, which has similar security concerns.

Since protecting the stack is outside the scope of this work, the compiler has significantly more freedom to eliminate this sort of redundant check.

Although it is difficult to meaningfully quantify the security provided by a mitigation measure, recent work by Zhang and Sekar [35, Definition 1] introduced the Average Indirect-target Reduction (AIR) metric

$$AIR = \frac{1}{n}\sum_{i=1}^{n}\left(1 - \frac{T_i}{S}\right)$$

where n is the number of indirect control-transfer instructions (indirect calls, jumps, and returns), T_i is the number of instructions the ith indirect control transfer instruction could target after applying a CFI technique, and S is the size of the binary.

It's clear that for any reasonable CFI technique and a large binary, $T_i \ll S$ for all indirect control-transfer instructions transformed by the technique. Similarly, $T_i \approx S$ for all other indirect control-transfer instructions. So, AIR reduces to the fraction of indirect control transfer instructions that are protected by the technique.[3]

Since we are focused on protecting forward edges, we consider the related metric forward-edge AIR, or fAIR, which performs the same computation as AIR, but the average is taken only over the forward-edge indirect control transfer instructions: indirect calls and jumps.

To compute the statistics reported in the rest of this section, we modified LLVM's object-file disassembler to perform a hybrid recursive and linear scan through the Chromium binary, reconstructing functions and basic blocks on which we performed our analysis. This process was aided by ensuring that Chromium was compiled with debugging information including symbols (cf. Bao et al. [2]). This disassembler was used as part of a stand-alone tool to find all indirect control transfer instructions. For each such instruction, the tool walks backward through the CFG, looking for the specific protection mechanism. It also attempts to find constants which are inserted into registers used for the call or jump. See Table 2 for a break down of forward-edge indirect control transfer (fICT) instructions in Chromium.

VTV. Compiling a recent version of Chromium using GCC with vtable verification leads to a final binary containing 124,325 indirect calls and 18,453 indirect jumps for a total of 142,778 fICT instructions. Of these, 6,855 are neither constant nor protected by vtable verification, giving $fAIR_{\mathrm{VTV}} = 95.2\%$. The majority of the unprotected

[3] This demonstrates that AIR — and our related fAIR — is at best a weak proxy for measuring security. Unfortunately, an actual metric for the security a CFI technique provides has thus far remained elusive.

fICT	VTV	IFCC
Constant	7,410	5,957
Constant, spilled†	7,334	315
Protected	113,617	154,244
Protected, spilled†	7,562	33,914
Unprotected	6,855	908
Total	142,778	195,338

Table 2: Forward-edge indirect control transfer (fICT) instructions in Chromium. Their arguments may be placed in three classes: (a) a type of constant, (b) an indirect address protected by CFI, and (c) an unprotected address. Constant-argument instructions include indirect jumps in the PLT which target a read-only GOT section and indirect jump instructions implementing switch statements, as well as indirect call instructions with constant targets.
† The targets for these indirect control transfer instructions are either spilled to the stack explicitly or are in callee-saved registers which are potentially spilled by intervening function calls.

fICTs come from C libraries, function-pointer adapter classes, and C-style callbacks.

Although more than 89% of the protected or constant fICTs are used almost immediately after being verified or loaded from read-only memory, in 14,896 instances (about 10%), the indirect target is potentially spilled to the stack. But this is not a flaw in our protection (see below).

IFCC. Compiling the same version of Chromium using Clang with IFCC (Single) produces a different binary containing 175,396 indirect calls and 19,942 indirect jumps for a total of 195,338 fICT instructions. Having more calls and jumps is what we would expect since the link-time optimizer has more inlining opportunities than is the case when optimizing one translation unit at a time.[4]

Since IFCC is designed to protect all fICT instructions, not just C++ virtual member function calls, only 908 fICT instructions are left unprotected. This gives $fAIR_{\text{IFCC}} = 99.5\%$. In fact, this is an over estimate of the number of unprotected fICT instructions. Of the 908 unprotected instructions, 512 correspond to the special functions created for function pointers returned from non-instrumented functions. Discounting those gives the more accurate value of $fAIR_{\text{IFCC}} = 99.8\%$. Most of the remaining unprotected fICT instructions correspond to functions which are explicitly not instrumented. (See Section 4.1 for a discussion of both of these.) The remaining handful come from the C run time statically linked into every binary.

With IFCC, about 18% of the constant or protected fICTs have targets which are potentially spilled to the stack. However this is not a fatal flaw, as discussed immediately below, since we are assuming that the stack is protected by some other means.

Stack spilling implications. For the purpose of our techniques, spilling target values to the stack introduces no additional security risk, since an attacker who can overwrite one value on the stack can easily overwrite a saved return address. This does have serious implications for CFI schemes that attempt to protect backward edges.

Our experience shows the importance of verifying a protection mechanism's intended invariants on the final binary output after all optimizations, including architecture-dependent optimization in the compiler backend, have taken place and the language runtime has been linked in.

Counting ROP gadgets. It is common in CFI papers to count the number of return-oriented programming gadgets that remain after applying the protection mechanism. Since we are explicitly not protecting return instructions, it does not make sense to count gadgets.

7 Performance Measurements and Results

We measured the performance of our approaches both on the C++ tests from the SPEC CPU2006 benchmark suite and on the Chromium browser running Dromaeo, SunSpider, and Octane. Except where otherwise specified, the VTV tests were run all on an HP Z620 Xeon E52690 2.9GHz machine, running Ubuntu Linux 12.04.2, and the IFCC and FSan tests were run on an HP Z620 Xeon E5550 2.67GHz machine, running the same OS. We turned off turbo mode and ASLR on these machines, as doing so significantly reduced the variation in our results.

The Chromium web browser is a large, complex, real-world application, comprising over 15 million lines of C++ code in over 50,000 source files, and containing hundreds of thousands of virtual calls. It links in many third-party libraries and makes extensive use of dynamic library loading. It is also representative of the type of target attackers are interested in. For all these reasons, Chromium makes an excellent test for measuring the effects of our CFI approaches on real-world systems. Both VTV and IFCC were able to successfully build fully-functional, protected versions of Chromium.

7.1 VTV Performance

Since verification adds instructions to the execution, some performance penalty is unavoidable. Initially, we ran SPEC CPU2006 C++ benchmarks with and without VTV to get a baseline. Table 3 shows that omnetpp, astar, and xalancbmk suffer a noticeable performance penalty in this naive implementation, ranging from 2.4% to 19.2%. We improve on this later. The other four benchmarks (povray, namd, soplex, and dealII) showed no significant performance effects. To determine why, we collected statistics on those benchmarks, for both compile-time

[4] There is a corresponding decrease in the number of return instructions for the same reason.

Test	no VTV (seconds)	VTV (seconds)	% slowdown
omnetpp	320.70	346.42	8.0
astar	440.61	450.95	2.4
xalanc.	248.86	296.53	19.2
namd	445.19	445.32	*
dealII	344.89	348.39	*
soplex	235.20	236.46	*
povray	181.18	181.87	*

Table 3: Untuned SPEC run-time numbers, at -O2. The asterisks indicate changes that are too small to be of any significance. These numbers are the minimum out of three runs (standard deviation is very close to zero).

Test	virtual calls (static)	verified calls (dynamic)	run time (secs)	verified calls per second
namd	2	0	445.32	0
dealII	2,118	201,867,094	348.39	579,428
soplex	720	4,846,399	236.46	20,496
povray	159	159,186	181.87	875
omnetpp	1,312	1,029,110,532	346.42	2,970,702
astar	2	2,780,359,179	450.95	6,165,560
xalanc.	15,753	2,629,817,426	296.53	8,868,639
dromaeo	NA	6,705,708,649	2379.34	2,818,303
octane	NA	113,037,194	66.41	1,702,214
sunspi.	NA	27,068,246	16.36	1,654,943

Table 4: Verifications per second when running SPEC CPU2006 C++ benchmarks and Chrome with VTV.

(static) and run-time (dynamic) numbers of verified virtual calls. From this we calculated the number of verified calls per second. As shown at the top of Table 4, those tests do not perform enough calls per second to noticeably affect performance, so we did not include them in any further analyses of VTV.

Next, we looked at reducing VTV's performance penalty. To determine the minimum lower bound penalty, we considered two sources of performance overhead: (1) the cost of making the verification function calls; and (2) the (potential) cost due to the overall increase in code size (code bloat). We measured these by doing two experiments on the three SPEC benchmarks of interest. First, we replaced the bodies of the functions in libvtv with stubs. Second, we inserted an unreachable region of code preceded by an unconditional jump over the region just before each virtual call instruction (the unreachable region represented the code that would be inserted by VTV). Our results can be seen in Table 5. Note that making calls with stubs must increase the number of instructions, just as with the code bloat test. Therefore the stubs penalty automatically includes the code bloat penalty. This shows that

	Code Bloat % Slowdown	VTV Stubs % Slowdown
omnetpp	0.0	2.4
astar	0.2	1.0
xalancbmk	0.8	4.7

Table 5: Results of lower bound experiments for VTV.

even if we could reduce to zero the time spent executing inside the verification function, the minimum lower bound VTV penalty for these tests ranges from 1.0% to 4.7%. Note that the lower bound is test-specific and depends on the number of virtual calls a test executes.

We then tried various options to reduce VTV's performance penalties. The two most effective options were: using profile guided optimizations (PGO) to improve devirtualization, via GCC's -ripa flag, thus reducing the overall number of virtual calls; and statically linking libvtv itself, to reduce the level of indirection at each verification call. We re-ran the SPEC benchmarks using these various options, and the results are shown at the top of Figure 2. The xalancbmk test had the worst performance with VTV, so it is instructive to consider its results under optimization: devirtualization brought the performance penalty from 19.2% down to 10.8%, and static linking reduced it further to 8.7%. The lower bound of VTV is 4.7% for xalancbmk (see Table 5).

Chrome interacts with many system libraries, so to avoid the problems of mixing verified and unverified code with VTV we built and ran a verified version of Chrome in a verified version of ChromeOS on a Chromebook (thus building all the libraries with verification as well). We built ChromeOS version 28 with VTV, and ran the Dromaeo, SunSpider 1.0.2, and Octane 2.0 benchmarks with it. For these tests, we loaded our images onto a Chromebook with an Intel Celeron 867 chip, pinned at 1.3GHz, with ASLR turned off, and we ran the tests there, with and without VTV. The bottom of Figure 2 shows the performance costs. We were not able to build Chrome with PGO and devirtualization, nor with the statically linked libvtv, so for these measurements we only have the naive, untuned VTV numbers. For Octane we saw a 2.6% penalty with VTV. SunSpider had a 1.6% penalty. Dromaeo had a fair amount of variation across the full set of micro-benchmarks, but the overall performance penalty across all of them was 8.4%. We expect that adding devirtualization would significantly improve these numbers. As with the SPEC benchmarks, the performance penalty varies depending on the number of verified calls made at runtime. We measured this for each of these tests (see Table 4). As expected, Dromaeo, which had the largest penalty, makes significantly more verified calls/second than the other two.

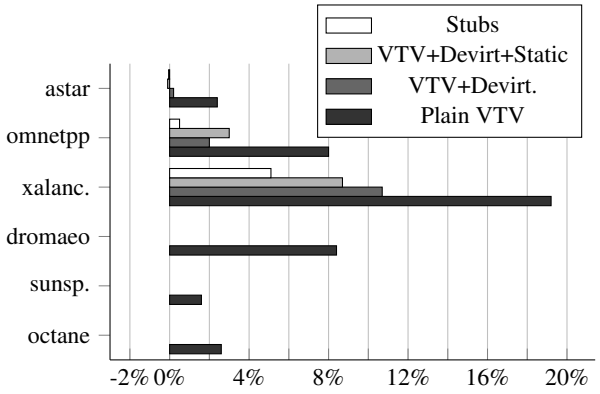

Figure 2: Relative performance overhead of VTV, with various tuning options, for the SPEC 2006 C++ benchmarks and for Chrome browser.

7.2 IFCC and FSan Performance

The performance of code compiled under IFCC depends on how often it makes indirect calls. IFCC adds code to every indirect call site that is not explicitly skipped by a command-line directive. The amount of code it adds depends on the version of IFCC: if tables are small enough to fit in a page in memory, then it can use the transformation that adds only two instructions (comprising 14 bytes) to each site. Otherwise, it uses the subtraction version, which adds 4 instructions (which become 20 bytes). Each indirect call has additional extra overhead from the `jmp` in the indirect call table(s); and jumps through a table might have effects on instruction-cache usage. Finally, when rewritten code receives a pointer from `dlsym` or from a dynamically-linked library, this pointer is wrapped using linear search through a fixed-length array; this is a slow operation but should not happen often.

The exact instructions added by FSan depend on the specific optimization level used, but we found that it usually adds about 12 instructions to each call site.

Figure 3 shows results from running C++ programs from the SPEC benchmark suite under IFCC and FSan and provides relative performance overhead compared to an optimized version compiled using Clang; each running time is the minimum of 10 executions. As expected, LTO outperforms both IFCC transformations in most cases. This is because IFCC adds instructions to the base LTO-compiled binary, and these instructions reduce performance of the executable. The cases in which IFCC outperforms LTO involve only small differences in performance and are likely due to effects similar to the noise discussed by Mytkowicz et al. [24], so we do not analyze them further here.

We ran the Dromaeo benchmark on Chromium 31.0.1650.41 built with Clang LTO, a version built with IFCC Single, and a version built with IFCC Arity. Single got 96.6% of the LTO score, and Arity got 96.1%; higher is better in Dromaeo, so this is about a 4% overhead, as shown in Figure 3a. We also built a version of Chromium and the SPEC CPU2006 benchmarks with the annotation version of IFCC, and we saw similar results.

IFCC had nearly the same performance as LTO for both Single and Arity versions of the SPEC CPU2006 benchmarks, except for xalancbmk. FSan had effects similar to IFCC. The xalancbmk benchmark suffers the most performance degradation from IFCC; this is expected due to it having the most dynamic virtual calls, as shown in Table 4. Similarly, Dromaeo has a large number of virtual calls and has the second highest overhead. So, as with VTV, the performance overhead is directly related to the number of indirect calls.

7.3 Comparison to Prior Work

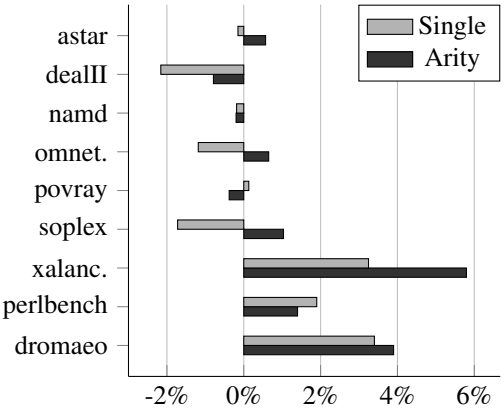
The SPEC Perl benchmark is worth highlighting. As Niu and Tan [28] point out, Perl is, in some sense, a worst case for CFI techniques for C — whereas C++ code can be even worse. Perl operates by translating the source code into bytecode, then sits in a tight loop, interpreting each instruction by making an indirect call. This worst case behavior is apparent in the performance of four recent CFI implementations: CCFIR by Zhang et al. [34], bin-CFI by Zhang and Sekar [35], Strato by Zeng et al. [33], and MIP by Niu and Tan [28]. The overheads reported for CCFIR, bin-CFI, Strato, and MIP are 8.6%, 12%, 15%–25%, and 14.9%–31.3%, respectively.

In contrast, our own work has less than 2% overhead (see Figure 3a). We are able to achieve this significant speed up over prior work by focusing only on forward edges as well as leveraging the compiler to apply optimizations. This gives different security guarantees, but we believe our attack model comports well with reality.

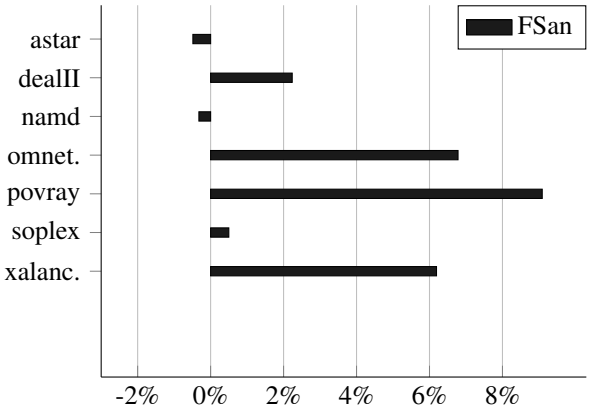
8 Conclusions

This paper advances the techniques of Control-Flow Integrity, moving them from research prototypes to being firmly in the domain of the practical. We have described two different principled, compiler-based CFI solutions for enforcing control-flow integrity for indirect jumps: vtable verification for virtual calls (VTV) guarantees that the vtable being used for a virtual call is not only a valid vtable for the program but is semantically correct for the call site; and indirect function-call checking (IFCC) guarantees that the target of an indirect call is one of the address-taken functions in the program. We also present FSan, an optional indirect call checking tool which verifies at runtime that the target of an indirect call has the correct function signature, based on the call site.

We have demonstrated that each of these approaches is feasible by implementing each one in a production compiler (GCC or LLVM). We have shown via security analysis that VTV and IFCC both maintain a very high level



(a) Relative overhead of IFCC enforcement (baseline LLVM LTO) for SPEC CPU2006 benchmarks and the Dromaeo benchmark.



(b) Relative overhead of the FSan optional indirect-call checking (baseline Clang) for the C++ benchmarks in SPEC CPU2006.

Figure 3: Performance measurements for IFCC and FSan.

of security, with VTV protecting 95.2% of all possible indirect jumps in our test, and IFCC protecting 99.8%. We have also measured the performance of these approaches and shown that while there is some degradation, averaging in the range of 1%–4%, and in the worst case getting up to 8.7% for VTV (the most precise approach), this penalty is fairly low and seems well within the range of what is acceptable, particularly in exchange for increased security.

Due to our relaxed, yet realistic, attack model coupled with compiler optimizations, we achieve significant performance gains over other CFI implementations while defending against real attacks.

ret2dir: Rethinking Kernel Isolation

Vasileios P. Kemerlis Michalis Polychronakis Angelos D. Keromytis
Columbia University
{vpk, mikepo, angelos}@cs.columbia.edu

Abstract

Return-to-user (ret2usr) attacks redirect corrupted kernel pointers to data residing in user space. In response, several kernel-hardening approaches have been proposed to enforce a more strict address space separation, by preventing arbitrary control flow transfers and dereferences from kernel to user space. Intel and ARM also recently introduced hardware support for this purpose in the form of the SMEP, SMAP, and PXN processor features. Unfortunately, although mechanisms like the above prevent the explicit sharing of the virtual address space among user processes and the kernel, conditions of implicit sharing still exist due to fundamental design choices that trade stronger isolation for performance.

In this work, we demonstrate how implicit page frame sharing can be leveraged for the complete circumvention of software and hardware kernel isolation protections. We introduce a new kernel exploitation technique, called *return-to-direct-mapped memory (ret2dir)*, which bypasses *all* existing ret2usr defenses, namely SMEP, SMAP, PXN, KERNEXEC, UDEREF, and kGuard. We also discuss techniques for constructing reliable ret2dir exploits against x86, x86-64, AArch32, and AArch64 Linux targets. Finally, to defend against ret2dir attacks, we present the design and implementation of an exclusive page frame ownership scheme for the Linux kernel that prevents the implicit sharing of physical memory pages with minimal runtime overhead.

1 Introduction

Although the operating system (OS) kernel has always been an appealing target, until recently attackers focused mostly on the exploitation of vulnerabilities in server and client applications—which often run with administrative privileges—as they are (for the most part) less complex to analyze and easier to compromise. During the past few years, however, the kernel has become an equally attractive target. Continuing the increasing trend of the previous years, in 2013 there were 355 reported kernel vulnerabilities according to the National Vulnerability Database, 140 more than in 2012 [73]. Admittedly, the exploitation of user-level software has become much harder, as recent versions of popular OSes come with numerous protections and exploit mitigations. The principle of least privilege is better enforced in user accounts and system services, compilers offer more protections against common software flaws, and highly targeted applications, such as browsers and document viewers, have started to employ sandboxing. On the other hand, the kernel has a huge codebase and an attack surface that keeps increasing due to the constant addition of new features [63]. Indicatively, the size of the Linux kernel in terms of lines of code has more than doubled, from 6.6 MLOC in v2.6.11 to 16.9 MLOC in v3.10 [32].

Naturally, instead of putting significant effort to exploit applications fortified with numerous protections and sandboxes, attackers often turn their attention to the kernel. By compromising the kernel, they can elevate privileges, bypass access control and policy enforcement, and escape isolation and confinement mechanisms. For instance, in recent exploits against Chrome and Adobe Reader, after successfully gaining code execution, the attackers exploited kernel vulnerabilities to break out of the respective sandboxed processes [5, 74].

Opportunities for kernel exploitation are abundant. As an example consider the Linux kernel, which has been plagued by common software flaws, such as stack and heap buffer overflows [14, 23, 26], NULL pointer and pointer arithmetic errors [10, 12], memory disclosure vulnerabilities [13, 19], use-after-free and format string bugs [25, 27], signedness errors [17, 24], integer overflows [10,16], race conditions [11,15], as well as missing authorization checks and poor argument sanitization vulnerabilities [18, 20–22]. The exploitation of these bugs is particularly effective, despite the existence of kernel protection mechanisms, due to the weak separation be-

tween user and kernel space. Although user programs cannot access directly kernel code or data, the opposite is not true, as the kernel is mapped into the address space of each process for performance reasons. This design allows an attacker with non-root access to execute code in privileged mode, or tamper-with critical kernel data structures, by exploiting a kernel vulnerability and redirecting the control or data flow of the kernel to code or data in user space. Attacks of this kind, known as *return-to-user (ret2usr)* [57], affect all major OSes, including Windows and Linux, and are applicable in x86/x86-64, ARM, and other popular architectures.

In response to ret2usr attacks, several protections have been developed to enforce strict address space separation, such as PaX's KERNEXEC and UDEREF [77] and kGuard [57]. Having realized the importance of the problem, Intel introduced Supervisor Mode Execute Protection (SMEP) [46] and Supervisor Mode Access Prevention (SMAP) [54], two processor features that, when enabled, prevent the execution (or access) of *arbitrary* user code (or data) by the kernel. ARM has also introduced Privileged Execute-Never (PXN) [4], a feature equivalent to SMEP. These features offer similar guarantees to software protections with negligible runtime overhead.

Although the above mechanisms prevent the explicit sharing of the virtual address space among user processes and the kernel, conditions of *implicit* data sharing still exist. Fundamental OS components, such as physical memory mappings, I/O buffers, and the page cache, can still allow user processes to influence what data is accessible by the kernel. In this paper, we study the above problem in Linux, and expose design decisions that trade stronger isolation for performance. Specifically, we present a new kernel exploitation technique, called *return-to-direct-mapped memory (ret2dir)*, which relies on inherent properties of the memory management subsystem to bypass existing ret2usr protections. This is achieved by leveraging a kernel region that directly maps part or all of a system's physical memory, enabling attackers to essentially "mirror" user-space data within the kernel address space.

The task of mounting a ret2dir attack is complicated due to the different kernel layouts and memory management characteristics of different architectures, the partial mapping of physical memory in 32-bit systems, and the unknown location of the "mirrored" user-space data within the kernel. We present in detail different techniques for overcoming each of these challenges and constructing reliable ret2dir exploits against hardened x86, x86-64, AArch32, and AArch64 Linux targets.

To mitigate the effects of ret2dir attacks, we present the design and implementation of an exclusive page frame ownership scheme for the Linux kernel, which prevents the implicit sharing of physical memory among user processes and the kernel. The results of our evaluation show that the proposed defense offers effective protection with minimal ($<3\%$) runtime overhead.

The main contributions of this paper are the following:

1. We expose a fundamental design weakness in the memory management subsystem of Linux by introducing the concept of *ret2dir* attacks. Our exploitation technique bypasses all existing ret2usr protections (SMEP, SMAP, PXN, KERNEXEC, UDEREF, kGuard) by taking advantage of the kernel's direct-mapped physical memory region.

2. We introduce a detailed methodology for mounting reliable ret2dir attacks against x86, x86-64, AArch32, and AArch64 Linux systems, along with two techniques for forcing user-space exploit payloads to "emerge" within the kernel's direct-mapped RAM area and accurately pinpointing their location.

3. We experimentally evaluate the effectiveness of ret2dir attacks using a set of nine (eight real-world and one artificial) exploits against different Linux kernel configurations and protection mechanisms. In all cases, our transformed exploits bypass successfully the deployed ret2usr protections.

4. We present the design, implementation, and evaluation of an exclusive page frame ownership scheme for the Linux kernel, which mitigates ret2dir attacks with negligible (in most cases) runtime overhead.

2 Background and Related Work

2.1 Virtual Memory Organization in Linux

Designs for safely combining different protection domains range from putting the kernel and user processes into a single address space and establishing boundaries using software isolation [52], to confining user process and kernel components into separate, hardware-enforced address spaces [2, 50, 66]. Linux and Linux-based OSes (Android [47], Firefox OS [72], Chrome OS [48]) adopt a more coarse-grained variant of the latter approach, by dividing the virtual address space into *kernel* and *user* space. In the x86 and 32-bit ARM (AArch32) architectures, the Linux kernel is typically mapped to the upper 1GB of the virtual address space, a split also known as "3G/1G" [28].[1] In x86-64 and 64-bit ARM (AArch64) the kernel is located in the upper *canonical half* [60, 69].

This design minimizes the overhead of crossing protection domains, and facilitates fast user-kernel interactions. When servicing a system call or handling an ex-

[1] Linux also supports 2G/2G and 1G/3G splits. A patch for a 4G/4G split in x86 [53] exists, but was never included in the mainline kernel for performance reasons, as it requires a TLB flush per system call.

ception, the kernel is running within the *context* of a preempted process. Hence, flushing the TLB is not necessary [53], while the kernel can access user space *directly* to read user data or write the result of a system call.

2.2 Return-to-user (ret2usr) Exploits

Although kernel code and user software have both been plagued by common types of vulnerabilities [9], the execution model imposed by the shared virtual memory layout between the kernel and user processes makes kernel exploitation noticeably different. The shared address space provides a unique vantage point to local attackers, as it allows them to control—both in terms of permissions and contents—part of the address space that is accessible by the kernel [91]. Simply put, attackers can easily execute shellcode with kernel rights by hijacking a privileged execution path and redirecting it to user space.

Attacks of this kind, known as return-to-user (ret2usr), have been the de facto kernel exploitation technique (also in non-Linux OSes [88]) for more than a decade [36]. In a ret2usr attack, kernel data is overwritten with user space addresses, typically after the exploitation of memory corruption bugs in kernel code [81], as illustrated in Figure 1. Attackers primarily aim for control data, such as return addresses [86], dispatch tables [36, 44], and function pointers [40, 42, 43, 45], as they directly facilitate arbitrary code execution [89]. Pointers to critical data structures stored in the kernel's heap [38] or the global data section [44] are also common targets, as they allow attackers to tamper with critical data contained in these structures by mapping fake copies in user space [38, 39, 41]. Note that the targeted data structures typically contain function pointers or data that affect the control flow of the kernel, so as to diverge execution to arbitrary points. The end effect of all ret2usr attacks is that *the control or data flow of the kernel is hijacked and redirected to user space code or data* [57].

Most ret2usr exploits use a multi-stage shellcode, with a first stage that lies in user space and "glues" together kernel functions (i.e., the second stage) for performing privilege escalation or executing a rootshell. Technically, ret2usr expects the kernel to run within the context of a process controlled by the attacker for exploitation to be reliable. However, kernel bugs have also been identified and exploited in interrupt service routines [71]. In such cases, where the kernel is either running in *interrupt context* or in a process context beyond the attacker's control [37, 85], the respective shellcode has to be injected in kernel space or be constructed using code gadgets from the kernel's text in a ROP/JOP fashion [8, 51, 87]. The latter approach is gaining popularity in real-world exploits, due to the increased adoption of kernel hardening techniques [31, 65, 68, 92, 93, 95].

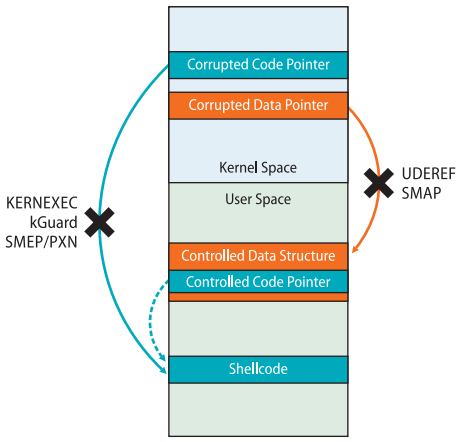

Figure 1: Operation of ret2usr attacks. A kernel code or data pointer is hijacked and redirected to controlled code or data in user space (tampered-with data structures may further contain pointers to code). Various protection mechanisms (KERNEXEC, UDEREF, kGuard, SMEP, SMAP, PXN) prevent arbitrary control flow transfers and dereferences from kernel to user space.

2.3 Protections Against ret2usr Attacks

Return-to-user attacks are yet another incarnation of the confused deputy problem [49]. Given the multi-architecture [42, 83] and multi-OS [88] nature of the problem, several defensive mechanisms exist for it. In the remainder of this section, we discuss the ret2usr defenses available in Linux with the help of Figure 1.

PaX: KERNEXEC and UDEREF are two features of the PaX [77] hardening patch set that prevent control flow transfers and dereferences from kernel to user space. In x86, KERNEXEC and UDEREF rely on memory segmentation [78] to map the kernel space into a 1GB segment that returns a memory fault whenever privileged code tries to dereference pointers to, or fetch instructions from, non-kernel addresses. In x86-64, due to the lack of segmentation support, UDEREF/amd64 [79] remaps user space memory into a different (shadow), non-executable area when execution enters the kernel (and restores it on exit), to prevent user-space dereferences. As the overhead of remapping memory is significant, an alternative for x86-64 systems is to enable KERNEXEC/amd64 [80], which has much lower overhead, but offers protection against only control-flow hijacking attacks. Recently, KERNEXEC and UDEREF were ported to the ARM architecture [90], but the patches added support for AArch32 only and rely on the deprecated MMU domains feature (discussed below).

SMEP/SMAP/PXN: Supervisor Mode Execute Protection (SMEP) [46] and Supervisor Mode Access Prevention (SMAP) [54] are two recent features of Intel

processors that facilitate stronger address space separation (latest kernels support both features [31,95]). SMEP provides analogous protection to KERNEXEC, whereas SMAP operates similarly to UDEREF. Recently, ARM added support for an SMEP-equivalent feature, dubbed Privileged Execute-Never (PXN) [4], but Linux uses it only on AArch64. More importantly, on AArch32, PXN requires the MMU to operate on LPAE mode (the equivalent of Intel's Physical Address Extension (PAE) mode [55]), which disables MMU domains. Therefore, the use of KERNEXEC/UDEREF on AArch32 implies giving up support for PXN and large memory ($>$ 4GB).

kGuard: kGuard [57] is a cross-platform compiler extension that protects the kernel from ret2usr attacks without relying on special hardware features. It enforces lightweight address space segregation by augmenting (at compile time) potentially exploitable control transfers with dynamic control-flow assertions (CFAs) that (at runtime) prevent the unconstrained transition of privileged execution paths to user space. The injected CFAs perform a small runtime check before every computed branch to verify that the target address is always located in kernel space or loaded from kernel-mapped memory. In addition, kGuard incorporates code diversification techniques for thwarting attacks against itself.

3 Attack Overview

Linux follows a design that trades weaker kernel-to-user segregation in favor of faster interactions between user processes and the kernel. The ret2usr protections discussed in the previous section aim to alleviate this design weakness, and fortify the isolation between kernel and user space with minimal overhead. In this work, we seek to assess the security offered by these protections and investigate whether certain performance-oriented design choices can render them ineffective. Our findings indicate that there exist fundamental decisions, deeply rooted into the architecture of the Linux memory management subsystem (`mm`), which can be abused to weaken the isolation between kernel and user space. We introduce a novel kernel exploitation technique, named return-to-direct-mapped memory (ret2dir), which allows an attacker to perform the equivalent of a ret2usr attack on a hardened system.

3.1 Threat Model

We assume a Linux kernel hardened against ret2usr attacks using one (or a combination) of the protection mechanisms discussed in Section 2.3. Moreover, we assume an *unprivileged* attacker with local access, who seeks to elevate privileges by exploiting a kernel-memory corruption vulnerability [10–27] (see Section 2.2). Note that we do not make any assumptions about the type of corrupted data—code and data pointers are both possible targets [36,40,42–45,86]. Overall, the adversarial capabilities we presume are identical to those needed for carrying out a ret2usr attack.

3.2 Attack Strategy

In a kernel hardened against ret2usr attacks, the hijacked control or data flow can no longer be redirected to user space in a direct manner—the respective ret2usr protection scheme(s) will block any such attempt, as shown in Figure 1. However, the implicit physical memory sharing between user processes and the kernel allows an attacker to *deconstruct* the isolation guarantees offered by ret2usr protection mechanisms, and redirect the kernel's control or data flow to user-controlled code or data.

A key facility that enables the implicit sharing of physical memory is *`physmap`*: a large, contiguous virtual memory region inside kernel address space that contains a direct mapping of part or all (depending on the architecture) physical memory. This region plays a crucial role in enabling the kernel to allocate and manage dynamic memory as fast as possible (we discuss the structure of `physmap` in Section 4). We should stress that although in this study we focus on Linux—one of the most widely used OSes—direct-mapped RAM regions exist (in some form) in many OSes, as they are considered standard practice in physical memory management. For instance, Solaris uses the `seg_kpm` mapping facility to provide a direct mapping of the whole RAM in 64-bit architectures [70].

As physical memory is allotted to user processes and the kernel, the existence of `physmap` results in *address aliasing*. Virtual address aliases, or *synonyms* [62], occur when two or more different virtual addresses map to the same physical memory address. Given that `physmap` maps a large part (or all) of physical memory within the kernel, the memory of an attacker-controlled user process is accessible through its kernel-resident synonym.

The first step in mounting a ret2dir attack is to map in user space the exploit *payload*. Depending on whether the exploited vulnerability enables the corruption of a code pointer [36,40,42–45,86] or a data pointer [38,39,41], the payload will consist of either shellcode, or controlled (tampered-with) data structures, as shown in Figure 2. Whenever the `mm` subsystem allocates (dynamic) memory to user space, it actually defers giving page frames until the very last moment. Specifically, physical memory is granted to user processes in a lazy manner, using the *demand paging* and *copy-on-write* methods [7], which both rely on page faults to actually allocate RAM. When the content of the payload is initialized, the MMU generates a page fault, and the kernel allocates a page

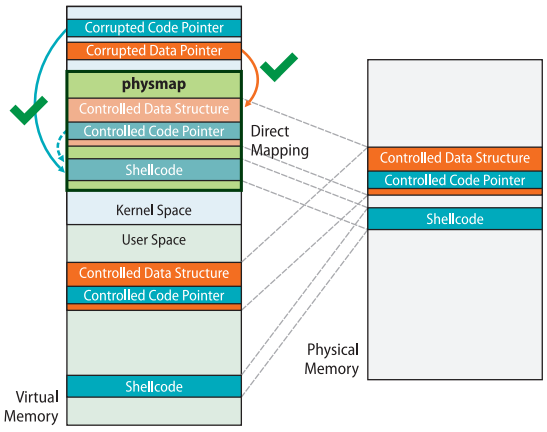

Figure 2: Overall ret2dir operation. The `physmap` (direct-mapped RAM) area enables a hijacked kernel code or data pointer to access user-controlled data, without crossing the user-kernel space boundary.

frame to the attacking process. Page frames are managed by `mm` using a *buddy allocator* [61]. Given the existence of `physmap`, the moment the buddy allocator provides a page frame to be mapped in user space, `mm` effectively creates an alias of the exploit payload in kernel space, as shown in Figure 2. Although the kernel never uses such synonyms directly, `mm` keeps the whole RAM premapped in order to boost page frame reclamation. This allows newly deallocated page frames to be made available to the kernel instantly, without the need to alter page tables (see Section 4.1 for more details).

Overall, ret2dir takes advantage of the implicit data sharing between user and kernel space (due to `physmap`) to redirect a hijacked kernel control or data flow to a set of kernel-resident synonym pages, effectively performing the equivalent of a ret2usr attack without reaching out to user space. It is important to note that the malicious payload "emerges" in kernel space the moment a page frame is given to the attacking process. The attacker does not have to explicitly "push" (copy) the payload to kernel space (e.g., via pipes or message queues), as `physmap` makes it readily available. The use of such methods is also much less flexible, as the system imposes strict limits to the amount of memory that can be allocated for kernel-resident buffers, while the exploit payload will (most likely) have to be encapsulated in certain kernel data objects that can affect its structure.

4 Demystifying `physmap`

A critical first step in understanding the mechanics of ret2dir attacks is to take a look at how the address space of the Linux kernel is organized—we use the x86 platform as a reference. The x86-64 architecture uses 48-bit virtual addresses that are sign-extended to 64 bits (i.e., bits `[48:63]` are copies of bit `[47]`). This scheme natively splits the 64-bit virtual address space in two canonical halves of 128TB each. Kernel space occupies the upper half (`0xFFFF800000000000` – `0xFFFFFFFFFFFFFFFF`), and is further divided into six regions [60]: the `fixmap` area, modules, kernel image, `vmemmap` space, `vmalloc` arena, and `physmap`. In x86, on the other hand, the kernel space can be assigned to the upper 1GB, 2GB, or 3GB part of the address space, with the first option being the default. As kernel virtual address space is limited, it can become a scarce resource, and certain regions collide to prevent its waste (e.g., modules and `vmalloc` arena, kernel image and `physmap`).[2] For the purposes of ret2dir, in the following, we focus only on the direct-mapped region.

4.1 Functionality

The `physmap` area is a mapping of paramount importance to the performance of the kernel, as it facilitates dynamic kernel memory allocation. At a high level, `mm` offers two main methods for requesting memory: `vmalloc` and `kmalloc`. With the `vmalloc` family of routines, memory can only be allocated in multiples of page size and is guaranteed to be virtually contiguous but *not* physically contiguous. In contrast, with the `kmalloc` family of routines, memory can be allocated in byte-level chunks, and is guaranteed to be *both* virtually and physically contiguous.

As it offers memory only in page multiples, `vmalloc` leads to higher internal memory fragmentation and often poor cache performance. More importantly, `vmalloc` needs to alter the kernel's page tables every time memory is (de)allocated to map or unmap the respective page frames to or from the `vmalloc` arena. This not only incurs additional overhead, but results in increased TLB thrashing [67]. For these reasons, the majority of kernel components use `kmalloc`. However, given that `kmalloc` can be invoked from any context, including that of interrupt service routines, which have strict timing constraints, it must satisfy a multitude of different (and contradicting) requirements. In certain contexts, the allocator should never sleep (e.g., when locks are held). In other cases, it should never fail, or it should return memory that is guaranteed to be physically contiguous (e.g., when a device driver reserves memory for DMA).

Given constraints like the above, *`physmap` is a necessity, as the main facilitator of optimal performance.* The `mm` developers opted for a design that lays `kmalloc`

[2] To access the contents of a page frame, the kernel must first map that frame in kernel space. In x86, however, the kernel has only 1GB – 3GB virtual addresses available for managing (up to) 64GB of RAM.

Architecture		PHYS_OFFSET	Size	Prot.
x86	(3G/1G)	0xC0000000	891MB	RW
	(2G/2G)	0x80000000	1915MB	RW
	(1G/3G)	0x40000000	2939MB	RW
AArch32	(3G/1G)	0xC0000000	760MB	RW**X**
	(2G/2G)	0x80000000	1784MB	RW**X**
	(1G/3G)	0x40000000	2808MB	RW**X**
x86-64		0xFFFF880000000000	64TB	RW(**X**)
AArch64		0xFFFFFFC000000000	256GB	RW**X**

Table 1: `physmap` characteristics across different architectures (x86, x86-64, AArch32, AArch64).

over a region[3] that pre-maps the entire RAM (or part of it) for the following reasons [7]. First, `kmalloc` (de)allocates memory without touching the kernel's page table. This not only reduces TLB pressure significantly, but also removes high-latency operations, like page table manipulation and TLB shootdowns [70], from the fast path. Second, the linear mapping of page frames results in virtual memory that is guaranteed, by design, to be always physically contiguous. This leads to increased cache performance, and has the added benefit of allowing drivers to directly assign `kmalloc`'ed regions to DMA devices that can only operate on physically contiguous memory (e.g., when there is no IOMMU support). Finally, page frame accounting is greatly simplified, as address translations (virtual-to-physical and vice versa) can be performed using solely arithmetic operations [64].

4.2 Location and Size

The `physmap` region is an architecture-independent feature (this should come as no surprise given the reasons we outlined above) that exists in all popular Linux platforms. Depending on the memory addressing characteristics of each ISA, the size of `physmap` and its exact location may differ. Nonetheless, in all cases: *(i)* there exists a *direct* mapping of part or all physical memory in kernel space, and *(ii)* the mapping starts at a *fixed*, known location. The latter is true even in the case where kernel-space ASLR (KASLR) [35] is employed.

Table 1 lists `physmap`'s properties of interest for the platforms we consider. In x86-64 systems, the `physmap` maps directly in a 1:1 manner, starting from page frame zero, the entire RAM of the system into a 64TB region. AArch64 systems use a 256GB region for the same purpose [69]. Conversely, in x86 systems, the kernel directly maps only a portion of the available RAM.

The size of `physmap` on 32-bit architectures depends on two factors: *(i)* the user/kernel split used (3G/1G, 2G/2G, or 1G/3G), and *(ii)* the size of the `vmalloc` arena. Under the default setting, in which 1GB is assigned to kernel space and the `vmalloc` arena occupies 120MB, the size of `physmap` is 891MB (1GB - `sizeof(vmalloc + pkmap + fixmap + unused)`) and starts at `0xC0000000`. Likewise, under a 2G/2G (1G/3G) split, `physmap` starts at `0x80000000` (`0x40000000`) and spawns 1915MB (2939MB). The situation in AArch32 is quite similar [59], with the only difference being the default size of the `vmalloc` arena (240MB).

Overall, in 32-bit systems, the amount of directly mapped physical memory depends on the size of RAM and `physmap`. If `sizeof(physmap)` $\geq$ `sizeof(RAM)`, then the entire RAM is direct-mapped—a common case for 32-bit mobile devices with up to 1GB of RAM. Otherwise, only up to `sizeof(physmap)/sizeof(PAGE)` pages are mapped directly, starting from the first page frame.

4.3 Access Rights

A crucial aspect for mounting a ret2dir attack is the memory access rights of `physmap`. To get the protection bits of the kernel pages that correspond to the direct-mapped memory region, we built `kptdump`:[4] a utility in the form of a kernel module that exports page tables through the `debugfs` pseudo-filesystem [29]. The tool traverses the kernel page table, available via the global symbols `swapper_pg_dir` (x86/AArch32/AArch64) and `init_level4_pgt` (x86-64), and dumps the flags (`U/S`, `R/W`, `XD`) of every kernel page that falls within the `physmap` region.

In x86, `physmap` is mapped as "readable and writeable" (`RW`) in all kernel versions we tried (the oldest one was v2.6.32, released on Dec. 2009). In x86-64, however, the permissions of `physmap` are *not* in sane state. Kernels up to v3.8.13 violate the `W^X` property by mapping the entire region as "readable, writeable, and executable" (`RWX`)—only very recent kernels ($\geq$ v3.9) use the more conservative `RW` mapping. Finally, AArch32 and AArch64 map `physmap` with `RWX` permissions in every kernel version we tested (up to v3.12).

[3] `kmalloc` is not directly layered over `physmap`. It is instead implemented as a collection of geometrically distributed (32B–4KB) *slabs*, which are in turn placed over `physmap`. The slab layer is a hierarchical, type-based data structure caching scheme. By taking into account certain factors, such as page and object sizes, cache line information, and memory access times (in NUMA systems), it can perform intelligent allocation choices that minimize memory fragmentation and make the best use of a system's cache hierarchy. Linux adopted the slab allocator of SunOS [6], and as of kernel v3.12, it supports three variants: `SLAB`, `SLUB` (default), and `SLOB`.

[4] `kptdump` resembles the functionality of Arjan van de Ven's patch [94]; unfortunately, we had to resort to a custom solution, as that patch is only available for x86/x86-64 and cannot be used "as-is" in any other architecture.

5 Locating Synonyms

The final piece for mounting a ret2dir exploit is finding a way to reliably pinpoint the location of a synonym address in the physmap area, given its user-space counterpart. For legacy environments, in which physmap maps only part of the system's physical memory, such as a 32-bit system with 8GB of RAM, an additional requirement is to ensure that the synonym of a user-space address of interest exists. We have developed two techniques for achieving both goals. The first relies on page frame information available through the pagemap interface of the /proc filesystem, which is currently accessible by non-privileged users in all Linux distributions that we studied. As the danger of ret2dir attacks will (hopefully) encourage system administrators and Linux distributions to disable access to pagemap, we have developed a second technique that does not rely on any information leakage from the kernel.

5.1 Leaking PFNs (via /proc)

The procfs pseudo-filesystem [58] has a long history of leaking security-sensitive information [56, 76]. Starting with kernel v2.6.25 (Apr. 2008), a set of pseudo-files, including /proc/<pid>/pagemap, were added in /proc to enable the examination of page tables for debugging purposes. To assess the prevalence of this facility, we tested the latest releases of the most popular distributions according to DistroWatch [34] (i.e., Debian, Ubuntu, Fedora, and CentOS). In all cases, pagemap was enabled by default.

For every user-space page, pagemap provides a 64-bit value, indexed by (virtual) page number, which contains information regarding the presence of the page in RAM [1]. If a page is present in RAM, then bit [63] is set and bits [0:54] encode its page frame number (PFN). That being so, the PFN of a given user-space virtual address uaddr, can be located by opening /proc/<pid>/pagemap and reading eight bytes from file offset (uaddr/4096) * sizeof(uint64_t) (assuming 4KB pages).

Armed with the PFN of a given uaddr, denoted as PFN(uaddr), its synonym SYN(uaddr) in physmap can be located using the following formula: SYN(uaddr) = PHYS_OFFSET + 4096 * (PFN(uaddr) − PFN_MIN). PHYS_OFFSET corresponds to the known, fixed starting kernel virtual address of physmap (values for different configurations are shown in Table 1), and PFN_MIN is the first page frame number—in many architectures, including ARM, physical memory starts from a non-zero offset (e.g., 0x60000000 in Versatile Express ARM boards, which corresponds to PFN_MIN = 0x60000). To prevent SYN(uaddr) from being reclaimed (e.g., after swapping out uaddr), the respective user page can be "pinned" to RAM using mlock.

sizeof(RAM) > sizeof(physmap): For systems in which part of RAM is direct-mapped, only a subset of PFNs is accessible through physmap. For instance, in an x86 system with 4GB of RAM, the PFN range is 0x0–0x100000. However, under the default 3G/1G split, the physmap region maps only the first 891MB of RAM (see Table 1 for other setups), which means PFNs from 0x0 up to 0x37B00 (PFN_MAX). If the PFN of a user-space address is greater than PFN_MAX (the PFN of the last direct-mapped page), then physmap does not contain a synonym for that address. Naturally, the question that arises is whether we can *force* the buddy allocator to provide page frames with PFNs less than PFN_MAX.

For compatibility reasons, mm splits physical memory into several *zones*. In particular, DMA processors of older ISA buses can only address the first 16MB of RAM, while some PCI DMA peripherals can access only the first 4GB. To cope with such limitations, mm supports the following zones: ZONE_DMA, ZONE_DMA32, ZONE_NORMAL, and ZONE_HIGHMEM. The latter is available in 32-bit platforms and contains the page frames that cannot be directly addressed by the kernel (i.e., those that are not mapped in physmap). ZONE_NORMAL contains page frames above ZONE_DMA (and ZONE_DMA32, in 64-bit systems) and below ZONE_HIGHMEM. When only part of RAM is direct-mapped, mm orders the zones as follows: ZONE_HIGHMEM > ZONE_NORMAL > ZONE_DMA. Given a page frame request, mm will try to satisfy it starting with the highest zone that complies with the request (e.g., as we have discussed, the direct-mapped memory of ZONE_NORMAL is preferred for kmalloc), moving towards lower zones as long as there are no free page frames available.

From the perspective of an attacker, user processes get their page frames from ZONE_HIGHMEM first, as mm tries to preserve the page frames that are direct-mapped for dynamic memory requests from the kernel. However, when the page frames of ZONE_HIGHMEM are depleted, due to increased memory pressure, *mm inevitably starts providing page frames from ZONE_NORMAL or ZONE_DMA*. Based on this, our strategy is as follows. The attacking process repeatedly uses mmap to request memory. For each page in the requested memory region, the process causes a page fault by accessing a single byte, forcing mm to allocate a page frame (alternatively, the MAP_POPULATE flag in mmap can be used to pre-allocate all the respective page frames). The process then checks the PFN of every allocated page, and the same procedure is repeated until a PFN less than PFN_MAX is

obtained. The synonym of such a page is then guaranteed to be present in physmap, and its exact address can be calculated using the formula presented above. Note that depending on the size of physical memory and the user/kernel split used, we may have to spawn additional processes to completely deplete ZONE_HIGHMEM. For example, on an x86 machine with 8GB of RAM and the default 3G/1G split, up to three processes might be necessary to guarantee that a page frame that falls within physmap will be acquired. Interestingly, the more benign processes are running on the system, the easier it is for an attacker to acquire a page with a synonym in physmap; additional tasks create memory pressure, "pushing" the attacker's allocations to the desired zones.

Contiguous synonyms: Certain exploits may require more than a single page for their payload(s). Pages that are virtually contiguous in user space, however, do not necessarily map to page frames that are physically contiguous, which means that their synonyms will not be contiguous either. Yet, given physmap's linear mapping, two pages with consecutive synonyms have PFNs that are sequential. Therefore, if 0xBEEF000 and 0xFEEB000 have PFNs 0x2E7C2 and 0x2E7C3, respectively, then they are contiguous in physmap despite being ~64MB apart in user space.

To identify consecutive synonyms, we proceed as follows. Using the same methodology as above, we compute the synonym of a random user page. We then repeatedly obtain more synonyms, each time comparing the PFN of the newly acquired synonym with the PFNs of those previously retrieved. The process continues until any two (or more, depending on the exploit) synonyms have sequential PFNs. The exploit payload can then be split appropriately across the user pages that correspond to synonyms with sequential PFNs.

5.2 physmap Spraying

As eliminating access to /proc/<pid>/pagemap is a rather simple task, we also consider the case in which PFN information is not available. In such a setting, given a user page that is present in RAM, there is no direct way of determining the location of its synonym inside physmap. Recall that our goal is to identify a kernel-resident page in the physmap area that "mirrors" a user-resident exploit payload. Although we cannot identify the synonym of a given user address, it is still possible to proceed in the opposite direction: pick an *arbitrary* physmap address, and ensure (to the extent possible) that its corresponding page frame is mapped by a user page that contains the exploit payload.

This can be achieved by exhausting the address space of the attacking process with (aligned) copies of the exploit payload, in a way similar to heap spraying [33]. The base address and length of the physmap area is known in advance (Table 1). The latter corresponds to PFN_MAX − PFN_MIN page frames, shared among all user processes and the kernel. If the attacking process manages to copy the exploit payload into N memory-resident pages (in the physical memory range mapped by physmap), then the probability (P) that an arbitrarily chosen, page-aligned physmap address will point to the exploit payload is: P = N / (PFN_MAX − PFN_MIN). Our goal is to maximize P.

Spraying: Maximizing N is straightforward, and boils down to acquiring as many page frames as possible. The technique we use is similar to the one presented in Section 5.1. The attacking process repeatedly acquires memory using mmap and "sprays" the exploit payload into the returned regions. We prefer using mmap, over ways that involve shmget, brk, and remap_file_pages, due to system limits typically imposed on the latter. MAP_ANONYMOUS allocations are also preferred, as existing file-backed mappings (from competing processes) will be swapped out with higher priority compared to anonymous mappings. The copying of the payload causes page faults that result in page frame allocations by mm (alternatively MAP_POPULATE can be used). If the virtual address space is not enough for depleting the entire RAM, as is the case with certain 32-bit configurations, the attacking process must spawn additional child processes to assist with the allocations.

The procedure continues until mm starts swapping "sprayed" pages to disk. To pinpoint the exact moment that swapping occurs, each attacking process checks periodically whether its sprayed pages are still resident in physical memory, by calling the getrusage system call every few mmap invocations. At the same time, all attacking processes start a set of background threads that repeatedly write-access the already allocated pages, simulating the behavior of mlock, and preventing (to the extent possible) sprayed pages from being swapped out—mm swaps page frames to disk using the LRU policy. Hence, by accessing pages repeatedly, mm is tricked to believe that they correspond to fresh content. When the number of memory-resident pages begins to drop (i.e., the resident-set size (RSS) of the attacking process(es) starts decreasing), the maximum allowable physical memory footprint has been reached. Of course, the size of this footprint also depends on the memory load inflicted by other processes, which compete with the attacking processes for RAM.

Signatures: As far as PFN_MAX − PFN_MIN is concerned, we can reduce the set of potential target pages in the physmap region, by excluding certain pages that correspond to frames that the buddy allocator will never provide to user space. For example, in x86 and x86-64, the BIOS typically stores the hardware configuration de-

tected during POST at page frame zero. Likewise, the physical address range 0xA0000–0xFFFFF is reserved for mapping the internal memory of certain graphics cards. In addition, the ELF sections of the kernel image that correspond to kernel code and global data are loaded at known, fixed locations in RAM (e.g., 0x1000000 in x86). Based on these and other predetermined allocations, we have generated *physmap signatures* of reserved page frame ranges for each configuration we consider. If a signature is not available, then all page frames are potential targets. By combining physmap spraying and signatures, we can maximize the probability that our informed selection of an arbitrary page from physmap will point to the exploit payload. The results of our experimental security evaluation (Section 7) show that, depending on the configuration, the probability of success can be as high as 96%.

6 Putting It All Together

6.1 Bypassing SMAP and UDEREF

We begin with an example of a ret2dir attack against an x86 system hardened with SMAP or UDEREF. We assume an exploit for a kernel vulnerability that allows us to corrupt a kernel *data* pointer, named kdptr, and overwrite it with an arbitrary value [38,39,41]. On a system with an unhardened kernel, an attacker can overwrite kdptr with a user-space address, and force the kernel to dereference it by invoking the appropriate interface (e.g., a buggy system call). However, the presence of SMAP or UDEREF will cause a memory access violation, effectively blocking the exploitation attempt. To overcome this, a ret2dir attack can be mounted as follows.

First, an attacker-controlled user process reserves a single page (4KB), say at address 0xBEEF000. Next, the process moves on to initialize the newly allocated memory with the exploit payload (e.g., a tampered-with data structure). This payload initialization phase will cause a page fault, triggering mm to request a free page frame from the buddy allocator and map it at address 0xBEEF000. Suppose that the buddy system picks page frame 1904 (0x770). In x86, under the default 3G/1G split, physmap starts at 0xC0000000, which means that the page frame has been pre-mapped at address 0xC0000000 + (4096 * 0x770) = 0xC0770000 (according to formula in Section 5.1). At this point, 0xBEEF000 and 0xC0770000 are synonyms; they both map to the physical page that contains the attacker's payload. Consequently, any data in the area 0xBEEF000–0xBEEFFFFF is readily accessible by the kernel through the synonym addresses 0xC0770000–0xC0770FFF. To make matters worse, given that physmap is primarily used for implementing dynamic memory, the kernel cannot distinguish whether the kernel data structure located at address 0xC0770000 is fake or legitimate (i.e., properly allocated using kmalloc). Therefore, by overwriting kdptr with 0xC0770000 (instead of 0xBEEF000), the attacker can bypass SMAP and UDEREF, as both protections consider benign any dereference of memory addresses above 0xC0000000.

6.2 Bypassing SMEP, PXN, KERNEXEC, and kGuard

We use a running example from the x86-64 architecture to demonstrate how a ret2dir attack can bypass KERNEXEC, kGuard, and SMEP (PXN operates almost identically to SMEP). We assume the exploitation of a kernel vulnerability that allows the corruption of a kernel function pointer, namely kfptr, with an arbitrary value [40, 42, 43, 45]. In this setting, the exploit payload is not a set of fake data structures, but machine code (shellcode) to be executed with elevated privilege. In real-world kernel exploits, the payload typically consists of a multi-stage shellcode, the first stage of which stitches together kernel routines (second stage) for performing privilege escalation [89]. In most cases, this boils down to executing something similar to commit_creds(prepare_kernel_cred(0)). These two routines replace the credentials ((e)uid, (e)gid) of a user task with zero, effectively granting root privileges to the attacking process.

The procedure is similar as in the previous example. Suppose that the payload has been copied to user-space address 0xBEEF000, which the buddy allocator assigned to page frame 190402 (0x2E7C2). In x86-64, physmap starts at 0xFFFF880000000000 (see Table 1), and maps the whole RAM using regular pages (4KB). Hence, a synonym of address 0xBEEF000 is located within kernel space at address 0xFFFF880000000000 + (4096 * 0x2E7C2) = 0xFFFF87FF9F080000.

In ret2usr scenarios where attackers control a kernel function pointer, an advantage is that they also control the memory access rights of the user page(s) that contain the exploit payload, making it trivially easy to mark the shellcode as executable. In a hardened system, however, a ret2dir attack allows controling only the *content* of the respective synonym pages within physmap—not their permissions. In other words, although the attacker can set the permissions of the range 0xBEEF000 – 0xBEEFFFF, this will *not* affect the access rights of the corresponding physmap pages.

Unfortunately, as shown in Table 1, the W^X property is not enforced in many platforms, including x86-64. In our example, the content of user ad-

dress 0xBEEF000 is also accessible through kernel address 0xFFFF87FF9F080000 as plain, executable code. Therefore, by simply overwriting kfptr with 0xFFFF87FF9F080000 and triggering the kernel to dereference it, an attacker can directly execute shellcode with kernel privileges. KERNEXEC, kGuard, and SMEP (PXN) cannot distinguish whether kfptr points to malicious code or a legitimate kernel routine, and as long as kfptr $\geq$ 0xFFFF880000000000 and *kfptr is RWX, the dereference is considered benign.

Non-executable physmap: In the above example, we took advantage of the fact that some platforms map part (or all) of the physmap region as executable (X). The question that arises is whether ret2dir can be effective when physmap has sane permissions. As we demonstrate in Section 7, even in this case, ret2dir attacks are possible through the use of return-oriented programming (ROP) [8, 51, 87].

Let's revisit the previous example, this time under the assumption that physmap is not executable. Instead of mapping regular shellcode at 0xBEEF000, an attacker can map an equivalent ROP payload: an implementation of the same functionality consisting solely of a chain of code fragments ending with ret instructions, known as gadgets, which are located in the kernel's (executable) text segment. To trigger the ROP chain, kfptr is overwritten with an address that points to a *stack pivoting* gadget, which is needed to set the stack pointer to the beginning of the ROP payload, so that each gadget can transfer control to the next one. By overwriting kfptr with the address of a pivot sequence, like xchg %rax, %rsp; ret (assuming that %rax points to 0xFFFF87FF9F080000), the synonym of the ROP payload now acts as a kernel-mode stack. Note that Linux allocates a separate kernel stack for every user thread using kmalloc, making it impossible to differentiate between a legitimate stack and a ROP payload "pushed" in kernel space using ret2dir, as both reside in physmap. Finally, the ROP code should also take care of restoring the stack pointer (and possibly other CPU registers) to allow for reliable kernel continuation [3, 81].

7 Security Evaluation

7.1 Effectiveness

We evaluated the effectiveness of ret2dir against kernels hardened with ret2usr protections, using real-world and custom exploits. We obtained a set of eight ret2usr exploits from the Exploit Database (EDB) [75], covering a wide range of kernel versions (v2.6.33.6–v3.8). We ran each exploit on an unhardened kernel to verify that it works, and that it indeed follows a ret2usr exploitation approach. Next, we repeated the same experiment with every kernel hardened against ret2usr attacks, and, as expected, all exploits failed. Finally, we transformed the exploits into ret2dir-equivalents, using the technique(s) presented in Section 5, and used them against the same hardened systems. Overall, our ret2dir versions of the exploits *bypassed all available ret2usr protections*, namely SMEP, SMAP, PXN, KERNEXEC, UDEREF, and kGuard.

Table 2 summarizes our findings. The first two columns (EDB-ID and CVE) correspond to the tested exploit, and the third (Arch.) and fourth (Kernel) denote the architecture and kernel version used. The Payload column indicates the type of payload pushed in kernel space using ret2dir, which can be a ROP payload (ROP), executable instructions (SHELLCODE), tampered-with data structures (STRUCT), or a combination of the above, depending on the exploit. The Protection column lists the deployed protection mechanisms in each case. Empty cells correspond to protections that are not applicable in the given setup, because they may not be *(i)* available for a particular architecture, *(ii)* supported by a given kernel version, or *(iii)* relevant against certain types of exploits. For instance, PXN is available only in ARM architectures, while SMEP and SMAP are Intel processor features. Furthermore, support for SMEP was added in kernel v3.2 and for SMAP in v3.7. Note that depending on the permissions of the physmap area (see Table 1), we had to modify some of the exploits that relied on plain shellcode to use a ROP payload, in order to achieve arbitrary code execution (although in ret2usr exploits attackers can give executable permission to the user-space memory that contains the payload, in ret2dir exploits it is not possible to modify the permissions of physmap).[5] Entries for kGuard marked with $\star$ require access to the (randomized) text section of the respective kernel.

As we mentioned in Section 2.3, KERNEXEC and UDEREF were recently ported to the AArch32 architecture [90]. In addition to providing stronger address space separation, the authors made an effort to fix the permissions of the kernel in AArch32, by enforcing the W^X property for the majority of RWX pages in physmap. However, as the respective patch is currently under development, there still exist regions inside physmap that are mapped as RWX. In kernel v3.8.7, we identified a ~6MB physmap region mapped as RWX that enabled the execution of plain shellcode in our ret2dir exploit.

The most recent kernel version for which we found a publicly-available exploit is v3.8. Thus, to evaluate the latest kernel series (v3.12) we used a custom exploit. We

[5] Exploit 15285 uses ROP code to bypass KERNEXEC/UDEREF and plain shellcode to evade kGuard. Exploit 26131 uses ROP code in x86 (kernel v3.5) to bypass KERNEXEC/UDEREF and SMEP/SMAP, and plain shellcode in x86-64 (kernel v3.8) to bypass kGuard, KERNEXEC, and SMEP.

Figure 4: Example of an x86 ROP payload (kernel v3.8) used in our ret2dir exploits for elevating privilege.

artificially injected two vulnerabilities that allowed us to corrupt a kernel data or function pointer, and overwrite it with a user-controlled value (marked as "Custom" in Table 2). Note that both flaws are similar to those exploited by the publicly-available exploits. Regarding ARM, the most recent PaX-protected AArch32 kernel that we successfully managed to boot was v3.8.7.

We tested every applicable protection for each exploit. In all cases, the ret2dir versions transfered control *solely* to kernel addresses, bypassing all deployed protections. Figure 3 shows the shellcode we used in x86-64 and AArch32 architectures. The shellcode is *position independent*, so the only change needed in each exploit is to to replace `pkcred` and `ccreds` with the addresses of `prepare_kernel_cred` and `commit_creds`, respectively, as discussed in Section 6.2. By copying the shellcode into a user-space page that has a synonym in the `physmap` area, we can directly execute it from kernel mode by overwriting a kernel code pointer with the `physmap`-resident synonym address of the user-space page. We followed this strategy for all cases in which `physmap` was mapped as executable (corresponding to the entries of Table 2 that contain `SHELLCODE` in the Payload column).

For cases in which `physmap` is non-executable, we substituted the shellcode with a ROP payload that achieves the same purpose. In those cases, the corrupted kernel code pointer is overwritten with the address of a stack pivoting gadget, which brings the kernel's stack pointer to the `physmap` page that is a synonym for the user page that contains the ROP payload. Figure 4 shows an example of an x86 ROP payload used in our exploits. The first gadgets preserve

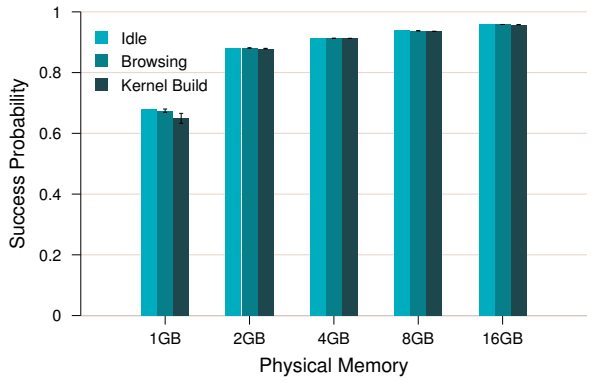

Figure 5: Probability that a selected `physmap` address will point to the exploit payload (successful exploitation) with a single attempt, when using `physmap` spraying, as a function of the available RAM.

the `esp` and `ebp` registers to facilitate reliable continuation (as discussed in Section 6.2). The scratch space can be conveniently located inside the controlled page(s), so the addresses `SCRATCH_SPACE_ADDR1` and `SCRATCH_SPACE_ADDR2` can be easily computed accordingly. The payload then executes essentially the same code as the shellcode to elevate privilege.

7.2 Spraying Performance

In systems without access to `pagemap`, ret2dir attacks have to rely on `physmap` spraying to find a synonym that corresponds to the exploit payload. As discussed in Section 5.2, the probability of randomly selecting a `physmap` address that indeed points to the exploit payload depends on *(i)* the amount of installed RAM, *(ii)* the physical memory load due to competing processes, and *(iii)* the size of the `physmap` area. To assess this probability, we performed a series of experiments under different system configurations and workloads.

Figure 5 shows the probability of successfully selecting a `physmap` address, with a *single* attempt, as a function of the amount of RAM installed in our system; our testbed included a single host armed with two 2.66GHz quad-core Intel Xeon X5500 CPUs and 16GB of RAM, running 64-bit Debian Linux v7. Each bar denotes the average value over 5 repetitions and error bars correspond to 95% confidence intervals. On every repetition we count the percentage of the *maximum* number of `physmap`-resident page frames that we managed to aquire, using the spraying technique (Section 5.2), over the size of `physmap`. We used three different workloads of increasing memory pressure: an idle system, a desktop-like workload with constant browsing activity in multiple tabs (Facebook, Gmail, Twitter, YouTube, and the USENIX website), and a distributed kernel compilation with 16 parallel threads running on 8 CPU cores (`gcc`, `as`, `ld`, `make`). Note that it is necessary to maintain continuous activity in the competing processes so that their working set remains *hot* (worst-case scenario), otherwise the attacking ret2dir processes would easily steal their memory-resident pages.

The probability of success increases with the amount of RAM. For the lowest-memory configuration (1GB), the probability ranges between 65–68%, depending on the workload. This small difference between the idle and the intensive workloads is an indication that despite the continuous activity of the competing processes, the ret2dir processes manage to claim a large amount of memory, as a result of their repeated accesses to all already allocated pages that in essence "lock" them to main memory. For the 2GB configuration the probability jumps to 88%, and reaches 96% for 16GB.

Note that as these experiments were performed on a 64-bit system, `physmap` always mapped all available memory. On 32-bit platforms, in which `physmap` maps only a subset of RAM, the probability of success is even higher. As discussed in Section 5.1, in such cases, the additional memory pressure created by competing processes, which more likely were spawned *before* the ret2dir processes, helps "pushing" ret2dir allocations to the desired zones (`ZONE_NORMAL`, `ZONE_DMA`) that fall within the `physmap` area. Finally, depending on the vulnerability, it is quite common that an unsuccessful attempt will not result in a kernel panic, allowing the attacker to run the exploit multiple times.

8 Defending Against ret2dir Attacks

Restricting access to `/proc/<pid>/pagemap`, or disabling the feature completely (e.g., by compiling the kernel without support for `PROC_PAGE_MONITOR`), is a simple first step that can hinder, but not prevent, ret2dir attacks. In this section, we present an eXclusive Page Frame Ownerwhip (XPFO) scheme for the Linux kernel that provides effective protection with low overhead.

8.1 XPFO Design

XPFO is a thin management layer that enforces *exclusive ownership* of page frames by either the kernel or user-level processes. Specifically, under XPFO, page frames can *never* be assigned to both kernel and user space, unless a kernel component explicitly requests that (e.g., to implement zero-copy buffers [84]).

We opted for a design that does not penalize the performance-critical kernel allocators, at the expense of low additional overhead whenever page frames are allocated to (or reclaimed from) user processes. Recall

that physical memory is allotted to user space using the demand paging and copy-on-write (COW) methods [7], both of which rely on page faults to allocate RAM. Hence, user processes already pay a runtime penalty for executing the page fault handler and performing the necessary bookkeeping. XPFO aligns well with this design philosophy, and increases marginally the management and runtime overhead of user-space page frame allocation. Crucially, the `physmap` area is left untouched, and the slab allocator, as well as kernel components that interface directly with the buddy allocator, continue to get pages that are guaranteed to be physically contiguous and benefit from fast virtual-to-physical address translations, as there are no extra page table walks or modifications.

Whenever a page frame is assigned to a user process, XPFO unmaps its respective synonym from `physmap`, thus breaking unintended aliasing and ensuring that malicious content can no longer be "injected" to kernel space using ret2dir. Likewise, when a user process releases page frames back to the kernel, XPFO maps the corresponding pages back in `physmap` to proactively facilitate dynamic (kernel) memory requests. A key requirement here is to *wipe out* the content of page frames that are returned by (or reclaimed from) user processes, before making them available to the kernel. Otherwise, a non-sanitizing XPFO scheme would be vulnerable to the following attack. A malicious program spawns a child process that uses the techniques presented in Section 5 to map its payload. Since XPFO is in place, the payload is unmapped from `physmap` and cannot be addressed by the kernel. Yet, it will be mapped back once the child process terminates, making it readily available to the malicious program for mounting a ret2dir attack.

8.2 Implementation

We implemented XPFO in the Linux kernel v3.13. Our implementation (~500LOC) keeps the management and runtime overhead to the minimum, by employing a set of optimizations related to TLB handling and page frame cleaning, and handles appropriately *all* cases in which page frames are allocated to (and reclaimed from) user processes. Specifically, XPFO deals with: *(a)* demand paging frames due to previously-requested anonymous and shared memory mappings (`brk`, `mmap`/`mmap2`, `mremap`, `shmat`), *(b)* COW frames (`fork`, `clone`), *(c)* explicitly and implicitly reclaimed frames (`_exit`, `munmap`, `shmdt`), *(d)* swapping (both swapped out and swapped in pages), *(e)* NUMA frame migrations (`migrate_pages`, `move_pages`), and *(f)* huge pages and transparent huge pages.

Handling the above cases is quite challenging. To that end, we first extended the system's page frame data structure (`struct page`) with the following fields: `xpfo_kmcnt` (reference counter), `xpfo_lock` (spinlock) and `xpfo_flags` (32-bit flags field)—`struct page` already contains a flags field, but in 32-bit systems it is quite congested [30]. Notice that although the kernel keeps a `struct page` object for *every* page frame in the system, our change requires only 3MB of additional space per 1GB of RAM (~0.3% overhead). Moreover, out of the 32 bits available in `xpfo_flags`, we only make use of three: "Tainted" (`T`; bit 0), "Zapped" (`Z`; bit 1), and "TLB-shootdown needed" (`S`; bit 2).

Next, we extended the buddy system. Whenever the buddy allocator receives requests for page frames destined to user space (requests with `GFP_USER`, `GFP_HIGHUSER`, or `GFP_HIGHUSER_MOVABLE` set to `gfp_flags`), XPFO unmaps their respective synonyms from `physmap` and asserts `xpfo_flags.T`, indicating that the frames will be allotted to userland and their contents are not trusted anymore. In contrast, for page frames destined to kernel space, XPFO asserts `xpfo_flags.S` (optimization; see below).

Whenever page frames are released to the buddy system, XPFO checks if bit `xpfo_flags.T` was previously asserted. If so, the frame was mapped to user space and needs to be wiped out. After zeroing its contents, XPFO maps it back to `physmap`, resets `xpfo_flags.T`, and asserts `xpfo_flags.Z` (optimization; more on that below). If `xpfo_flags.T` was not asserted, the buddy system reclaimed a frame previously allocated to the kernel itself and no action is necessary (fast-path; no interference with kernel allocations). Note that in 32-bit systems, the above are not performed if the page frame in question comes from `ZONE_HIGHMEM`—this zone contains page frames that are not direct-mapped.

Finally, to achieve complete support of cases *(a)–(f)*, we leverage `kmap`/`kmap_atomic` and `kunmap`/`kunmap_atomic`. These functions are used to temporarily (un)map page frames acquired from `ZONE_HIGHMEM` (see Section 5.1). In 64-bit systems, where the whole RAM is direct-mapped, `kmap`/`kmap_atomic` returns the address of the respective page frame directly from `physmap`, whereas `kunmap`/`kunmap_atomic` is defined as NOP and optimized by the compiler. If XPFO is enabled, all of them are re-defined accordingly.

As user pages are (preferably) allocated from `ZONE_HIGHMEM`, the kernel wraps *all* code related to the cases we consider (e.g., demand paging, COW, swapping) with the above functions. Kernel components that use `kmap` to operate on page frames not related to user processes do exist, and we distinguish these cases using `xpfo_flags.T`. If a page frame is passed to `kmap`/`kmap_atomic` and that bit is asserted, this means that the kernel tries to oper-

ate on a frame assigned to user space via its kernel-resident synonym (e.g., to read its contents for swapping it out), and thus is temporarily mapped back in physmap. Likewise, in kunmap/kunmap_atomic, page frames with xpfo_flags.T asserted are unmapped. Note that in 32-bit systems, the XPFO logic is executed on kmap routines only for direct-mapped page frames (see Table 1). xpfo_lock and xpfo_kmcnt are used for handling recursive or concurrent invocations of kmap/kmap_atomic and kunmap/kunmap_atomic with the same page frame.

Optimizations: The overhead of XPFO stems mainly from two factors: *(i)* sanitizing the content of reclaimed pages, and *(ii)* TLB shootdown and flushing (necessary since we modify the kernel page table). We employ three optimizations to keep that overhead to the minimum. As full TLB flushes result in prohibitive slowdowns [53], in architectures that support single TLB entry invalidation, XPFO selectively evicts only those entries that correspond to synonyms in physmap that are unmapped; in x86/x86-64 this is done with the INVLPG instruction.

In systems with multi-core CPUs, XPFO must take into consideration TLB coherency issues. Specifically, we have to perform a TLB shootdown whenever a page frame previously assigned to the kernel itself is mapped to user space. XPFO extends the buddy system to use xpfo_flags.S for this purpose. If that flag is asserted when a page frame is alloted to user space, XPFO invalidates the TLB entries that correspond to the synonym of that frame in physmap, in *every* CPU core, by sending IPI interrupts to cascade TLB updates. In all other cases (i.e., page frames passed from one process to another, reclaimed page frames from user processes that are later on alloted to the kernel, and page frames allocated to the kernel, reclaimed, and subsequently allocated to the kernel again), XPFO performs only local TLB invalidations.

To alleviate the impact of page sanitization, we exploit the fact that page frames previously mapped to user space, and in turn reclaimed by the buddy system, have xpfo_flags.Z asserted. We extended clear_page to check xpfo_flags.Z and avoid clearing the frame if the bit is asserted. This optimization avoids zeroing a page frame twice, in case it was first reclaimed by a user process and then subsequently allocated to a kernel path that required a clean page—clear_page is invoked by every kernel path that requires a zero-filled page frame.

Limitations: XPFO provides protection against ret2dir attacks, by braking the unintended address space sharing between different security contexts. However, it does not prevent generic forms of data sharing between kernel and user space, such as user-controlled content pushed to kernel space via I/O buffers, the page cache, or through system objects like pipes and message queues.

Table 3: XPFO performance evaluation results using macro-benchmarks (upper part) and micro-benchmarks (lower part) from the Phoronix Test Suite.

8.3 Evaluation

To evaluate the effectiveness of the proposed protection scheme, we used the ret2dir versions of the real-world exploits presented in Section 7.1. We back-ported our XPFO patch to each of the six kernel versions used in our previous evaluation (see Table 2), and tested again our ret2dir exploits when XPFO was enabled. In all cases, XPFO prevented the exploitation attempt.

To assess the performance overhead of XPFO, we used kernel v3.13, and a collection of macro-benchmarks and micro-benchmarks from the Phoronix Test Suite (PTS) [82]. PTS puts together *standard* system tests, like apachebench, pgbench, kernel build, and IOzone, typically used by kernel developers to track performance regressions. Our testbed was the same with the one used in Section 7.2; Table 3 summarizes our findings. Overall, XPFO introduces a minimal (negligible in most cases) overhead, ranging between 0.18–2.91%.

9 Conclusion

We have presented ret2dir, a novel kernel exploitation technique that takes advantage of direct-mapped physical memory regions to bypass existing protections against ret2usr attacks. To improve kernel isolation, we designed and implemented XPFO, an exclusive page frame ownership scheme for the Linux kernel that prevents the implicit sharing of physical memory. The results of our experimental evaluation demonstrate that XPFO offers effective protection with negligible runtime overhead.

Availability

Our prototype implementation of XPFO and all modified ret2dir exploits are available at: http://www.cs.columbia.edu/~vpk/research/ret2dir/

Abstract

Processes retrieve a variety of resources, such as files, from the operating system to function. However, securely accessing resources has proven to be a challenging task, accounting for 10-15% of vulnerabilities reported each year. Current defenses address only a subset of these vulnerabilities in ad-hoc and incomplete ways. In this paper, we provide a comprehensive defense against vulnerabilities during resource access. First, we identify a fundamental reason that resource access vulnerabilities exist – a mismatch between programmer expectations and the actual environment the program runs in. To address such mismatches, we propose JIGSAW, a system that can automatically derive programmer expectations and enforce it on the deployment. JIGSAW constructs programmer expectations as a *name flow graph*, which represents the data flows from the inputs used to construct file pathnames to the retrieval of system resources using those pathnames. We find that whether a program makes any attempt to filter such flows implies expectations about the threats the programmer expects during resource retrieval, the enabling JIGSAW to enforce those expectations. We evaluated JIGSAW on widely-used programs and found that programmers have many implicit expectations. These mismatches led us to discover two previously-unknown vulnerabilities and a default misconfiguration in the Apache webserver. JIGSAW enforces program expectations for approximately 5% overhead for Apache webservers, thus eliminating vulnerabilities due to resource access efficiently and in a principled manner.

1 Introduction

Processes retrieve a variety of *resources* from the operating system to function. A resource is any abstraction that the system call API of an operating system (OS) offers to a process (apart from a process itself). Examples of resources are files (configuration, data, or log files), network ports, or interprocess communication channels (IPCs) such as sockets and shared memory. Such OS abstractions free the programmer from having to know details of the underlying hardware and allow her to write portable code. Conceptually, resource access is a procedure that takes as input the name (e.g., filename) and namespace bindings (e.g., directories or symbolic links), and returns the resource (e.g., file) as output to the process.

Securely accessing resources has proven to be a challenging task because of adversarial control of the inputs to resource access. Adversaries may control the input name or a binding to direct victim processes to unsafe resources. In the well-known *time-of-check to time-of-use* (TOCTTOU) attack [6], an adversary exploits the non-atomicity between check operations (e.g., access) and use operations (e.g., open) to redirect the victim to resources of the adversary's choosing. Other attacks are link following, untrusted search paths, Trojan-horse library loads, and directory traversal. These attacks are collectively referred to as *resource access attacks* [40]. 10-15% of the vulnerabilities reported each year in the CVE database [12] are due to programs not defending themselves against these attacks.

Current defenses against such vulnerabilities in conventional OSes are ad-hoc and fundamentally limited. First, traditional access control is too coarse-grained to prevent resource access vulnerabilities. A process may have legitimate access to both low-integrity adversarial files and high-integrity library files; however, the resource access to load libraries should not access adversary files (and vice versa). Traditional access control does not differentiate between these resource accesses, and thus cannot protect programs. Second, defenses in the research literature require either system or program modifications. System defenses have been mainly limited to TOCTTOU [11, 13, 25–27, 35–38, 44] and link following [10], or require programs to be written to new APIs [19,29,34,42]. However, system defenses are fund-

mentally limited because they do not have sufficient information about programs [8], and new APIs do not protect existing programs.

This paper presents an approach to automatically protect programs that use the current system call API from resource access vulnerabilities. We make the following observations: first, we find that a fundamental cause for resource access vulnerabilities is programmer expectations not being satisfied during the program's system deployment. For example, during a particular resource access, a programmer might expect to fetch a resource that is inaccessible to an adversary (e.g., a log file in `/var/log`) and thus not add defensive code checks, called *filters*, to protect against adversarial control of names and bindings. However, this expectation may not be consistent with the view of the OS distributors (e.g., Red Hat, Ubuntu) who actually frame the access control policy. Thus, if permissions to `/var/log` allow adversary access (e.g., through a world-writable directory), adversaries can compromise the victim program. Our second insight is that we can *automatically* infer if the programmer expected adversarial control at a particular resource access or not, without requiring any annotations or changes to the program. We do this by detecting the presence of name and binding filters that programmers place in the program.

In this paper, we develop JIGSAW, the first system to provide automated protection for programs during resource access without requiring additional programmer effort. JIGSAW infers programmer expectations and enforces these on the deployment[1]. JIGSAW is based on two conceptually simple invariants – that the system deployment's attack surface be a subset of the programmer's expected attack surface, and that resource accesses not result in confused deputy attacks [16]. These invariants, if correctly evaluated and enforced, can theoretically provide complete program protection during resource access. JIGSAW operates in two phases. In the first phase, it mines programmer expectations by detecting the presence of filters in program code. Using these filters, JIGSAW constructs a novel representation, called the *name flow graph*, from which the programmer's expected attack surface is derived. We show that anomalous cases in the name flow graph can be used to detect vulnerabilities to resource access attacks. In the second phase, JIGSAW enforces the invariants by leveraging the open-source Process Firewall of Vijayakumar *et al.* [40], a Linux kernel module that (i) knows about deployment attack surface using the system's adversary accessibility, and (ii) introspects into the program to identify the resource access and to enforce its expectations as determined in the first phase.

[1]Informally, JIGSAW enables "fitting" the programmer's expectations on to its deployment.

We evaluate our technique by hardening widely-used programs against resource access attacks. Our results show that in general, programmers have many implicit expectations during resource access. For example, in the Apache web server, we found 65% of all resource accesses are implicitly expected not to be under adversary control. However, this is not conveyed to OS distributors in any form, and may result in vulnerabilities. JIGSAW can be use to detect such vulnerabilities, and we did find two *previously-unknown* vulnerabilities and a default misconfiguration. However, the key feature of JIGSAW is that it protects program vulnerabilities during resource access whenever there is a discrepancy between the programmers' inferred expectations and the system configuration, without the need to modify the program or the system's access control policies. We also find that the Process Firewall can enforce such protection to block resource access vulnerabilities whilst allowing legitimate functionality for a modest performance overhead of approximately 5%. An automated analysis as presented in this paper can thus enforce efficient protection for programs during resource access at runtime.

In summary, we make the following contributions.

- We precisely define resource access vulnerabilities and show how they occur due to a mismatch in expectations between the programmer, the OS distributor, and the administrator,
- We propose two invariants that, if evaluated and enforced correctly, can theoretically provide complete program protection during resource access,
- We develop JIGSAW, an automated approach that uses the invariants to protect programs during resource access by inferring programmer expectation using the novel abstraction of a name flow graph, and
- We evaluate our approach on widely-used programs, showing how programmers have many implicit expectations, as demonstrated by our discovery of two previously-unknown vulnerabilities and a default misconfiguration in our deployment of the Apache web server. Further, we show that we can produce rules to enforce these implicit assumptions efficiently using the Process Firewall on any program deployment.

2 Problem definition

In this section, we first give a precise definition of when a resource access is vulnerable. This definition classifies vulnerabilities into two broad categories. We then identify the fundamental cause for each of these vulnerability categories – mismatch between programmer expectation and system deployment, and difficulty in writing proper defensive code.

```
01  conf = open("httpd.conf");
02  log_file = read(conf);
03  socket = bind(port 80);
04  open(log_file, O_CREAT);          // File Squat
05  loop {
06    html_page = recv(socket);
07    strip(html_page, "../");        // Directory Traversal
08    stat(html_page not symlink);    // TOCTTOU Race
09    open(html_page, O_RDONLY);      // TOCTTOU Race, Symlink
10    write(client_socket, "200 OK");
11    log("200 OK to client")
12  }
```

Figure 1: Motivating example of resource access vulnerabilities using a typical processing cycle of a web server.

2.1 Resource Access Attacks

A resource access occurs when a program uses a *name* to resolve a *resource* using namespace *bindings*. That is, the inputs to the resource access are the name and the bindings, and the output is the final resource. Figure 1 shows example webserver code that we use throughout the paper: the webserver starts up and accesses its configuration file (line 2), from which it gets the location of its log file. It then binds a socket on port 80 (line 3), opens the log file (line 4), and waits for client requests. When a client connects, it receives the HTTP request (line 6), uses this name to fetch the HTML file (line 9). Finally, it writes the status code to its log file (line 11).

Let us examine some possible resource access vulnerabilities. Consider line 6. Here, the program receives a HTTP request from the client, and serves the page to the client. The client can supply a name such as `../../etc/passwd`, and if the server does not properly sanitize the name (which it attempts to do in line 7), the client is served the password file on the server. This is a *directory traversal* vulnerability. Next, consider the check the server makes in line 8. Here, the server checks that the HTML file is not a symbolic link. The reason for this is that in many deployments (e.g., a university web server serving student web pages), the web page is controlled by an adversary (i.e., student). The server attempts to prevent a symbolic link vulnerability, where a student links her web page to the password file. However, a race condition between the check in line 8 and the use in line 9, leads to a *link following* vulnerability exploiting a *TOCTTOU race condition*.

To see how such vulnerabilities can be broadly classified, we introduce adversary accessibility to resources and adversarial control of resource access. We then define when resource accesses are vulnerable, and use this to derive a classification for vulnerabilities.

Adversary accessible resources. An *adversary-accessible resource* is one that an adversary has permissions to access (read for secrecy attacks, write for integrity attacks) under the system's access control policy. The complement set is the set of *adversary-inaccessible* resources.

Expected/Safe Resource	*Malicious/Unsafe Resource*	*Vulnerability Class*
Adversary-Inaccessible (Hi) Resource	*Adversary-Accessible (Lo) Resource*	**Unexpected Attack Surface** Untrusted Search Path File/IPC Squat PHP File Inclusion
Adversary-Accessible (Lo) Resource	*Adversary-Inaccessible (Hi) Resource*	**Confused Deputy** Link Following Directory Traversal TOCTTOU races

Table 1: Adversaries control resource access to direct victims to adversary-accessible resources when the victim expected an adversary inaccessible resource and vice-versa.

Adversary control of resource access. An adversary controls the resource access by controlling its inputs (the name or a binding). An adversary controls a binding if she uses her write permissions in a directory to create a binding [39]. An adversary controls a name if there is an explicit data flow[2] from an adversary-accessible resource to the name used in resource access. The adversary needs write permissions to these resources to control names.

The directory traversal vulnerability above relies on the adversary's ability to control the name used in resource access. The link following vulnerability relies on the adversary's ability to control the binding (creating a symbolic link).

Resource Access Vulnerability. A resource access is vulnerable, i.e., a resource access attack is successful, when an adversary uses her control of inputs to resource access (the name or a binding) to direct a victim to an adversary-accessible output resource when the victim expected an adversary-inaccessible resource (and vice versa).

On the one hand, the adversary can use control to direct the victim to an adversary-inaccessible resource when the program expects an adversary-accessible resource. The directory traversal and link following vulnerabilities of the classical *confused deputy* [16] (Row 2 in Table 1). On the other hand, the adversary can direct the victim to an adversary-accessible resource when the program expects an adversary-inaccessible resource. Trojan-horse libraries is an example vulnerability of this type. We call these *unexpected attack surface* vulnerabilities (Row 1 in Table 1), as they occur because the programmer is not expecting adversary control at these resource accesses. Table 1 classifies all resource access vulnerabilities into these two types.

2.2 Causes for Resource Access Vulnerabilities

We identify two causes for resource access vulnerabilities – one for each category in Table 1. The first cause is a mismatch in expectations of adversary control of names and bindings between the program and the deployment.

[2] Attacks involving names require the adversary to inject sequences of `../` or unicode characters. Thus, explicit data flow is necessary; just implicit data flow is insufficient.

Consider Figure 2 that describes resource accesses from the web server example in Figure 1. Here, the programmer expects the resource access of the HTML file to be under adversary control, and to combat this, adds a name filter [3] from the TCP socket (stripping `../`) as well as a binding filter (check for a link). The programmer did not expect the log file's resource access to be adversary-controlled, and therefore did not add any filters. However, due to a misconfiguration, this programmer expectation is not satisfied in the deployment configuration, causing a resource access vulnerability.

In general, resource access vulnerabilities are very challenging to eliminate because they involve multiple disconnected parties. First, programmers write code assuming that a certain subset of resource accesses are under adversarial control. Resource access checks cause overhead, so the programmer generally tries to minimize the number of checks, thereby motivating fewer filters. Second, there are OS distributors who define access control policies, thereby determining adversarial control of resource accesses. However, these OS distributors have little or no information about the assumptions the programmer has made about adversarial control, resulting in a set of possible mismatches. Finally, there are administrators who deploy the program on a concrete system. The configuration specifies the location of various resources such as log files. Thus, the administrator's configuration too may not match the programmer's expectation.

The second cause for resource access vulnerabilities is where the programmer does expect adversary-controlled resource access, but the filter may be insufficient to protect the program. Note that when a program encounters an adversary-controlled resource access, the only valid resource is an adversary-accessible resource; otherwise, the program is victim to a confused deputy vulnerability. Thus, the program needs to defend itself by filtering improper requests leading to a confused deputy. However, both name and binding filters are difficult to get right due to difficulty in string parsing [4] and inherent race conditions in the system call API [8] (e.g., lines 8, 9 in Figure 1).

In summary, the two causes of resource access vulnerabilities are: *(a)* unexpected adversarial control of resource access, and *(b)* improper filtering of resource access when adversary control of resource access is expected. These causes correspond to Rows 1 and 2 in Table 1 respectively. With these two causes in mind, we proceed to a model that precisely describes our solution.

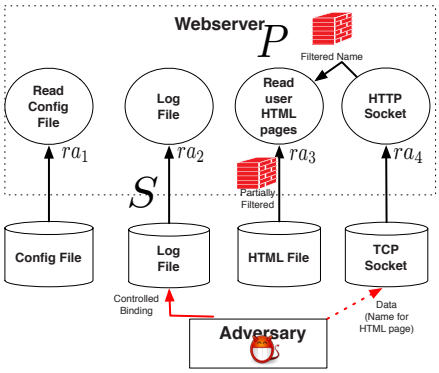

Figure 2: Demonstrating a mismatch between the expected and deployed attack surfaces.

3 Model and Solution Overview

In this section, we provide two invariants that directly address the two causes for resource access vulnerabilities outlined above.

Consider the set of all resource accesses *RA* made by a program[4]. A resource access happens when a system call resolves a resource using a name and namespace bindings. The program has code to filter the names and bindings used during certain resource accesses (e.g., ra_3 in Figure 2). From this knowledge, we show in Section 5 how to derive *P*, the set of resource accesses that a programmer expects to be under adversarial control. This set *P* is the *expected resource access attack surface*, or simply, the expected attack surface.

Now, assume that the program is deployed and run on a system. A subset of the resource accesses made by the program is adversary-controlled in the deployment. Let *Y* be the deployment's access control policy. Let *S* be the set of resource accesses that are adversary-controlled under *Y* (ra_2 in Figure 2). This set *S* defines the *deployment resource access attack surface*, or simply, the deployment attack surface.

Given *Y*, the expected attack surface *P* is *safe* for the deployment *S* if $S \subseteq P$, i.e., if all resource accesses in the deployment attack surface are part of the program's expected attack surface. Intuitively, this means that the program has filters to protect itself whenever a resource access is adversary-controlled. If *r* is the resource access under consideration, then, the invariant stated in propositional logic blocking unexpected adversary is:

$$\textbf{Invariant: Unexpected Adversary Control}(r): (r \in S) \rightarrow (r \in P) \quad (1)$$

If this safety invariant is enforced, resource access vul-

[3] A filter is a check in code that allows only a subset of names, bindings and resources through.

[4] The representation used to identify a resource access is implementation-dependent. In our implementation, we use program stacks at the time of the resource access system call.

nerabilities are eliminated where programs do not expect adversary control. Therefore, vulnerabilities are only possible where programs expect adversary control.

Now that we are dealing with an adversary-controlled resource access ($\in S$) that is also expected ($\in P$), the only valid resource is an adversary-accessible resource; otherwise, the program would be victim to a confused deputy attack. We say that resource accesses in P are protected from a confused deputy vulnerability if, when the resource access is adversary-controlled (i.e., $\in S$), it does not accept adversary-inaccessible resources. Let R be the set of resource accesses that retrieve adversary-accessible resources (as defined under Y). Then, a resource access r is protected from confused deputy vulnerabilities if the following invariant stated in proposition logic holds:

$$\textbf{Invariant: Confused Deputy}(r): \quad (r \in S) \rightarrow (r \in R) \tag{2}$$

Once these two rules are enforced, the only resources that are allowed are adversary-accessible resources where programs expect adversary control. Problems occur if the program does not properly handle this adversary-accessible resource. For example, if it does not filter data read from this resource properly, memory corruption vulnerabilities might result. Such vulnerabilities that occur in spite of fetching the expected resource are not within the scope of this work.

Let us examine how the rules above stop the vulnerability classes in Table 1. Consider vulnerability in Row 2, where the victim expects an adversary inaccessible resource (high integrity or secrecy), but ends up with an adversary-accessible (low integrity or secrecy) resource. The typical case is an untrusted search path where the program expects to load a high-integrity library, but searches for libraries in insecure paths due to programmer oversight or insecure environment variables, and ends up with a Trojan horse low-integrity library. Here, since the programmer does not expect a low-integrity library, she does not place a binding (or name) filter. Thus, we will infer that this resource access is not part of the expected attack surface ($\notin P$), and Invariant 1 above will stop the vulnerability if this resource access is controlled in any way (binding or name) by an adversary ($\in S$). The other vulnerability classes in this category are blocked similarly. Next, consider vulnerabilities in Row 1. Here, the victim expects an adversary-accessible resource (low integrity or secrecy), but ends up with an adversary inaccessible resource (high integrity or secrecy). In a link following vulnerability, the adversary creates a symbolic link to a high-secrecy or high-integrity file, such as the password file. Thus, the adversary uses her control of bindings ($\in S$) to direct the victim to an adversary-inaccessible resource ($\notin R$). In a directory traversal vulnerability, the adversary uses her control of the name to supply sequences of `../` to direct the victim to a high-secrecy or high-integrity file. In both cases, Invariant 2 will block the vulnerability since the adversary controls the resource access ($\in S$) through the name or binding, but the resource is adversary inaccessible ($\notin R$).

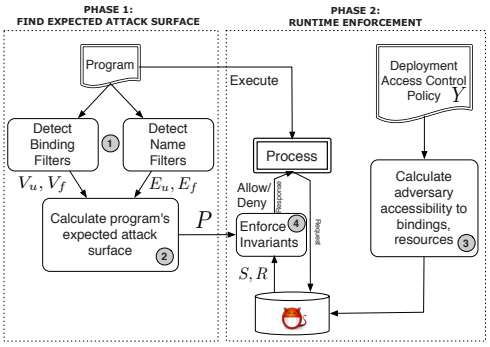

Figure 3: Overview of the design of our system.

4 JIGSAW Approach Overview

Figure 3 shows an outline of the design of JIGSAW. JIGSAW has two phases. In the first phase, JIGSAW calculates P, the expected attack surface. Finding P requires inferring programmer expectations. To infer programmer expectations, we propose an intuitive heuristic – if the programmer expects adversary control at a resource access, she will place filters in code to handle such control. Given the program, we perform a black-box analysis to detect the existence of any binding and name filtering separately (Step 1 in Figure 3), and use this information to calculate the program's expected attack surface (Step 2).

In the second phase, JIGSAW enforces Invariants 1 and 2 above by determining S, the deployment attack surface, and R, the set of adversary-accessible resources. The deployment's access control policy Y determines which resources and bindings are adversary-accessible. We leverage existing techniques to calculate adversary accessibility given Y [10, 17, 41] (Step 3). At runtime, if an adversary-accessible resource is used, that resource access is in R. If the name is read from an adversary-accessible resource or the binding used in resolving that name is adversary accessible, then that resource access is in S. Finally, we need to enforce Invariants 1 and 2 for individual resource accesses (Step 4). Any enforcement mechanism that applies distinct access control rules per individual resource access system call would be suitable. In our prototype implementation we leverage the open-source Process Firewall [40] which enables us to support binary-only programs (i.e., our prototype implementation does not rely on source code access).

5 Phase 1: Find Expected Attack Surfaces

The first step is to determine the expected attack surface P for a program. We do this in two parts. First, we propose a heuristic that implies the expectations of programmers with respect to the adversary control of the inputs to resource access and introduce the abstraction of a *name flow graph* to model these expectations and enable the detection of missing filters (Sections 5.1 to 5.3). Next, we outline how one can use dynamic analysis methods to build name flow graphs by accounting for adversary control of names and bindings (Sections 5.4 and 5.5).

5.1 Resource Access Expectations

Determining P requires knowledge of the programmers' expectations – whether the programmers expected the resource access to be under adversary control or not. The most precise solution to this problem is to ask each programmer to specify her expectation. Unfortunately, such annotations do not exist currently. As an alternative, we use the presence of code filters to infer programmer expectation. We use the following heuristic:

Heuristic. *If a programmer expects adversarial control of a resource access, she will add code filters to protect the program from adversarial control.*

Thus, the way we infer if a programmer expects an adversary-controlled resource access is by detecting if she adds *any* code to filter such adversarial control. An adversary controls a resource access by controlling either the name or a binding used in the resource access. Thus, we need to detect whether a program filters names and bindings separately.

Before presenting exactly how we detect filtering, we will introduce the concept of a *name flow graph* for a program, which we will use to derive the expected attack surface P given knowledge of filtered resource accesses.

5.2 Name Flow Graph

We introduce the abstraction of a name flow graph, which represents the data flow of name values among resource accesses in the program annotated with the knowledge of whether names and/or bindings are filtered each individual resource access. Using this name flow graph, we will show that we can compute resources accesses that are missing filters automatically. A name flow graph $G_n = (V, E)$ is a graph where the resource accesses are nodes and each edge $(a, b) \in E$ represents whether *there exists* a data flow in the program between the data of any of the resources retrieved at the access at node a and any of the name variables used in an access at node b. We refer to these edges as *name flows*.

Further, $V = V_f \cup V_u$ where V_f is the set of resource accesses that filter bindings and V_u the set of vertices that do not. Similarly, $E = E_f \cup E_u$, where E_f is the set of name flows that are filtered, and E_u the set that is not. That is, a name flow graph is a data-flow graph that captures the flow of names and is annotated with information about filters. The meaning of filtering for names and bindings is described in Sections 5.4 and 5.5, respectively.

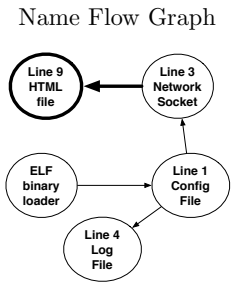

Figure 4: Name flow graph for the example in Figure 1.

The name flow graph for our web server in Figure 1 is shown in Figure 4. Its nodes are resource accesses and edges connect two resource accesses if the data read at the source resource access may affect the name used at the target resource access. The bold nodes are those that filter bindings, whereas the bold edges are those that filter names.

The name flow graph determines P, the expected attack surface. According to our heuristic in Section 5, a resource access is part of the expected attack surface if a programmer places both name and binding filters on the resource access to handle adversarial control. However, not all name flows need be filtered – only name flows originating from other resource accesses also under adversarial control must be. Since this definition is transitive, we need to start with some initial information about resource accesses that are part of the expected attack surface, which we do not have. However, we find that we can easily define which resource accesses should *not* be in P. That is, we can use the *absence* of filters to determine resource accesses that should not be under adversarial control. This complement set of P is $\overline{P}$. We define an approach to calculate $\overline{P}$ below. Any resource access not in $\overline{P}$ is then in P, the expected attack surface.

Formally, a resource access $u \in \overline{P}$ if any of the following conditions are satisfied:

(i) $u \in V_u$: Binding filters do not exist, or
(ii) $u \xrightarrow{e} v \in V_u$: There exists an unfiltered name flow edge originating at u, or
(iii) $(u \xrightarrow{*} v) \wedge (v \in \overline{P})$: There exists a name flow path originating at u to a resource access in $\overline{P}$.

Consider the example in Figure 5. Here, resource accesses a and b filter bindings ($a, b \in V_f$). c does not filter

$a, b, c \in \overline{P}$

Figure 5: Example about determining membership in P

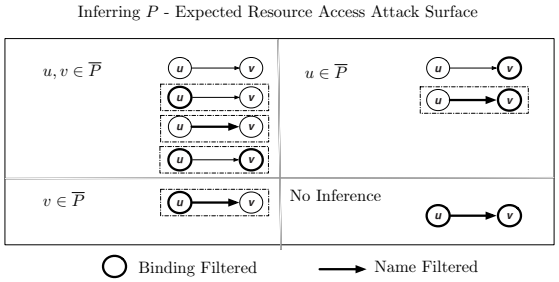

Figure 6: Determining whether a resource access in a resource flow graph should be in $\overline{P}$.

bindings ($c \in V_u$). c's name is determined from input at b, and b's name is determined from input at a. The name flow from a to b is filtered. By *(i)* above, $c \in \overline{P}$ since it does not filter bindings, and the programmer did not expect adversary control by our heuristic. Next, by *(ii)* above, $b \in \overline{P}$, since it is the origin of an unfiltered name flow (which adversaries should not control). Finally, by transitivity using *(iii)* above, $a \in \overline{P}$, because it is the origin of a name flow to a resource access that is in $\overline{P}$, and thus adversaries should not control the name read from resource access at a. All combinations of name and binding filters between a pair of nodes and the inference of node membership in P are presented in Figure 6.

Figure 7 describes the algorithm used to calculate membership in P, given V_f, V_u, E_f, and E_u. It implements *(i)-(iii)* above. It starts by initially assigning any node that does not filter bindings to $\overline{P}$ (*(i)*), and the source of unfiltered name flows to $\overline{P}$ (*(ii)*). It then uses a fixed point iteration to apply the transitive rule *(iii)*, and adds the source of any name flow to a target already in $\overline{P}$ to $\overline{P}$. At the termination of the algorithm, any resource access not in $\overline{P}$ is in P.

5.3 Detecting Missing Filters

Using the name flow graph, we can compute cases where filtering is likely missing. Intuitively, a filter is missing if the program filters *some* adversarial control of resource access but not others. This can happen in two cases: *(a)* if an incoming name flow is filtered but the binding at the resource access is not, or *(b)* a binding is filtered but an outgoing name flow is not. The dotted boxes in Figure 6 show these cases.

Precisely, filters are possibly missing at a resource access r in two cases:

Case 1: $\exists s, e : (s \xrightarrow{e} r \wedge e \in E_f \wedge r \in V_u)$. There exists a filter on an incoming name flow (indicating adversarial control of name) but not a binding filter, or

Input: Set of unfiltered names E_u and bindings V_u
Output: P

```
1:  P ← ∅                          ▷ Resource accesses that can be adversary controlled
2:  for v ∈ V_u do                 ▷ Any node that does not filter bindings
3:      P̄ ← P̄ ∪ v                  ▷ Cannot be adversary controlled
4:  end for
5:  for e ∈ E_u do                 ▷ Any edge that does not filter name
6:      P̄ ← P̄ ∪ e.src              ▷ Mark source as not adversary controlled
7:  end for
8:  c ← True
9:  while c = True do              ▷ Propagate set - fixed point iteration
10:     c ← False
11:     for e ∈ E_u do
12:         if e.tgt ∈ P̄ ∧ e.src ∉ P̄ then
13:             P̄ ← P̄ ∪ e.src
14:             c ← True
15:         end if
16:     end for
17: end while
```

Figure 7: Inferring P from knowledge of filtering

Case 2: $\exists s, e : (r \xrightarrow{e} s \wedge e \in E_u \wedge r \in V_f)$. There exists a filter on a binding (indicating an adversary-accessible resource) but not on all outgoing name flows.

As an example of a missing filter indicating a vulnerability, we found that in the default configuration, the Apache web server filters the name supplied by a client (by stripping `../`), but does not filter the binding used to fetch the HTML file. Therefore, an adversary can create a link of her web page to `/etc/passwd`, which will be served.

Not all possibly missing filters indicate a vulnerability. Some filters perform the same checks as JIGSAW. As an example, we found that `libc` had binding filters when it accessed (some) resources under `/etc` to reject adversary-accessible resources, enforcing Invariant 1 itself. Thus, there is no need to filter names originating from this resource (although *Case 2* indicates a possibly missing filter). We call filters that perform the same checks JIGSAW, redundant.

5.4 Detecting Presence of Binding Filters

We now outline our technique for detecting the filtering of bindings. Our objective in detecting here is to determine resource accesses that perform *any* filtering of bindings. Note that we do *not* aim to prove the correctness of the filtering checks themselves.

To define how we detect binding filters, we discuss how bindings are involved in resource access and how programs filter them. A program accesses many bindings (directories and symbolic links) during a single resource access. In theory, any one of these is controllable by the adversary. Filtering of directories is done by checking its security label, whereas link filtering checks if the binding is a link, and optionally, the security label of the link's

target. Bindings are filtered if, in some cases, the program does not accept a binding based on checks done on any binding used during resource access. An ideal solution would detect the existence of any such check.

Both static and dynamic approaches are possible to detect binding filtering. Static analysis uses the program code to determine if checks exist. However, this is quite challenging as there are a wide variety of ways to perform checks, including, for example, lowering the privilege of the process to that of the adversary [9, 39]. Instead, we opt for a dynamic analysis that detects the effects of filtering.

To detect filters, we have to choose a test that will *definitely fire the filter*, if such a filter is present. Our tests are attacks that attempt to exploit vulnerabilities if filters were absent. Not all attacks corresponding to vulnerability classes in Table 1 are suitable as tests to detect program filters. Consider the subset of attacks corresponding to vulnerability classes in Table 1 where the adversary uses her control of bindings to direct the victim to an adversary-accessible resource (Row 1). If the program accepts the adversary-accessible resource, it is generally not possible to determine if this was due to the program intentionally accepting this resource or due to the program assuming that there would be no adversary control of the resource access. On the other hand, consider the subset of attacks corresponding to vulnerabilities where the adversary uses control of bindings to direct the victim to an adversary-inaccessible resource (e.g., link following). Here, if the programmer were expecting adversary-controlled bindings, she *has* to add checks to block this resource access as this scenario is, by definition, a confused deputy vulnerability. Thus, we can use the results of a link following vulnerability to determine the existence of binding filters, and thus, the programmer's expectation. In Section 8, we describe a dynamic analysis framework that performs these tests.

5.5 Detecting Presence of Name Filtering

The other way for adversaries to control resource access is to control names. We aim to determine if the program makes any attempt to filter names, which would indicate that the programmer expected to receive an adversary-controlled name. Again, note that to determine programmer expectation, we only need to determine if there is *any* filtering at all, not if the filtering is correct.

To determine name filters in programs, we first describe how names originate. Names are either hard-coded in the program or received at runtime. First, hard-coded names are constants defined in the program binary or a dynamic library. For an adversary to have control of hard-coded names, she needs to control the binary or library, in which case trivial code attacks are possible. Therefore, we assume hard-coded names to not be under adversarial control. Second, programs get names from runtime input. In Figure 1, a client is requesting a HTML file by supplying its name. The server reads the name from this request (name source) and accesses the HTML file resource from this client input (name sink). In general, a name can be computed from input using one or more read system calls.

Next, we define the action of filtering names. There are two ways in which programs filter names. First, programs can directly manipulate the name. For example, web servers strip malicious characters (e.g., `..`) from names. Second, it can check that the resource retrieved from this name is indeed accessible to the adversary. For example, the setuid `mount` program accepts a directory to mount from untrusted users who are potential adversaries, but checks that the user indeed has write permissions to the directory before mounting. Thus, a name is filtered between a source and a sink if, in some cases, the name read at a source is changed, or the resource access at the sink is blocked. An ideal solution would detect the existence of any such checks.

Determining name filtering is a two-step process. First, we should determine pairs of resource accesses where the name is read from one resource (source) and used in the other (sink). Next, we determine if the program places any filters between this source-sink pair.

Again, we can use static or dynamic analysis to find pairs and filters. To detect filters, Balzarotti et al. used string analysis [4], whereas techniques such as weakest preconditions [7] or symbolic execution [18] can also be used. However, static analysis techniques are traditionally sound, but may produce false positives. Therefore, we use dynamic analysis to detect evidence of filtering.

To determine both pairs and filtering, we use a runtime analysis inspired by Sekar [33]. Sekar's aim is to detect injection attacks in a black-box manner. The technique is to log all reads and writes by programs, and find a correlation between reads and writes using an approximate string matching algorithm. Thus, given as input a log of the program's read and write buffers, the algorithm returns true if a write buffer matches a read buffer "approximately".

We adapt this technique to find name flows. We log all reads and names during resource access, and find matches between names and read buffers. We first try matching the full name; if no match is found, we try to match the directory path and final resource separately. Often, parts of a name are read from data of different resources. For example, a web server's document root is read from the configuration file, whereas the file to be served is read from the client's input. Both of these are combined to form the name of the resource served. As with the method for finding binding filters, we use the directory traversal attack in Row 2 to trigger filtering.

Since our analysis is a black-box approach, if a possible name flow is found, the read buffer might just coincidentally happen to have the name, but not actually flow to it. Thus, we execute a verification step. We run the test suite again, but this time change the read buffer containing the name to special characters, noting if the name also changes. If it does, we have found a name flow.

6 Phase 2: Enforce Programmer Expectations

Once we find the expected attack surface P, JIGSAW enforces resource access protections using Invariant 1 and Invariant 2 in Section 3 on program deployments. To do this, a reference monitor [1] has to mediate all resource accesses and enforce these rules. To enforce these rules correctly for each resource access, a reference monitor must determine whether this resource access is in P, and identify the system deployment's attack surface S and adversary accessibility to resources R.

6.1 Protecting Accesses in P at Runtime

The first challenge is to determine whether the resource access is in P. There are two ways to do this: (a) the program code can be modified to convey its expectation to the monitor through APIs, or (b) the monitor already knows the program expectation and identifies each resource access. Capability systems use code to convey their expectation during each resource access. Capability systems [21] present capabilities for only the expected resources to the OS during access. For example, decentralized information flow control (DIFC) systems [19,45] require the programmer to choose labels for the authorized resource for each resource access. However, such systems require modifying program code and recompilation, which can be complex to do correctly.

Another option is for the reference monitor to extract information necessary for it to identify the specific resource access, and hence whether it is in P. Researchers have recently made the observation that if they only protect a process, they may introspect into the process (safely) to make protection decisions [40]. They implemented a mechanism called the Process Firewall, a Linux kernel module that introspects into the process to enforce rules to block vulnerabilities per system call invocation. This is similar in concept to a network firewall that protects a host by restricting access per individual firewall rules. We use this option because it does not require program code or system access control policy changes, and was shown to be much faster than corresponding program checks in some cases.

The general invariant that the Process Firewall enforces is as follows:

`pf_invariant(subject,` **entrypoint**`,`**syscall_trace**`,`
`object,` **resource_id**`,`**adversary_access**`, op)` $\mapsto$ `Y|N`

Here, **entrypoint** is the user stack at the time of the system call. Resource accesses in P are identified by their entrypoint. A single system call may access multiple bindings (e.g., directories and links) and a resource. As each binding and resource is accessed at runtime, its adversary access is used in the decision. If a binding is adversary-accessible, then the resource access is in S. If the final resource is adversary-accessible, then the resource access is in R. If a resource access in R is the source of a name, this fact is recorded in **syscall_trace** and the resource access using this name is in S. This general invariant is instantiated to enforce our invariants in Section 3. The invariants are converted into Process Firewall rules using templates (Section 8).

6.2 Finding Adversary Accessibility R

R is the set of resource accesses at runtime that use adversary accessible resources, and is required to enforce Invariant 2 in Section 3. Calculating R requires knowing: *(a)* who an adversary is, and *(b)* whether the adversary has permissions to access resources. We address these questions in turn.

There have been several heuristics to determine who an adversary is. Gokyo [17] uses the system's mandatory access control policy to determine the set of SELinux labels that are trusted for the system – the rest are adversarial. Vijayakumar *et al.* [41] extend this approach to identify per-program adversaries. Chari et al. [10] and Pu et al. [43] use a model based on discretionary access control – a process running with a particular user ID (UID) has as its adversaries any other UID, except for the superuser (`root`). We can use any of these approaches to define an adversary.

Second, we need to determine whether an adversary has permissions to resources. As discussed in Section 2, an adversary-accessible resource is one that the system's access control policy Y allows an adversary permissions to (read for secrecy vulnerabilities, write for integrity vulnerabilities, and execute for both). This can be queried directly from the access control policy Y. Any resource access at runtime that uses adversary-accessible resources is in R.

Some resources become adversary-accessible through indirect means. For example, programs log adversarial requests to log files. Thus, adversaries affect data in log files even if the access control policy does not give adversaries direct write permissions to log files. Such exceptional resources are currently manually added to R.

6.3 Finding Deployment Attack Surface S

The deployment attack surface S is the set of resource accesses a process performs at runtime that are adversary-controlled. An adversary can control resource accesses

by controlling either the name or a binding (or both). An adversary controls a binding if she uses her write permissions in a directory to create a binding. An adversary controls a name if the adversary has write permission to the resource the name is fetched from.

To determine adversary control of names, we need to detect if there is a data flow from adversary-supplied data to a name used in a resource access. Data flow is most often determined by taint tracking [5, 20, 22, 31]. However, taint tracking techniques have overheads ranging from 2× to 50× [28]. Instead, JIGSAW approximates data flow using control flow (**entrypoint**s – process stacks at the time of reading names and using names). Pairs of process stacks during read and resource access system calls are initially associated by detecting explicit data flow between these calls (Section 5.5). During enforcement, if the Process Firewall sees the same stacks, we assume an explicit data flow between the read and resource access system calls, and the resource access is in S.

6.4 Finding Vulnerabilities

We can use the rules generated to also find vulnerabilities. Vulnerabilities are detected whenever a resource access is denied by our rules but is allowed by the program.

We use the same dynamic analysis from test suites that we use to detect the presence of filters in Sections 5.4 and 5.5 to also test the program for vulnerabilities in our particular deployment. Instead of enforcing the rules, we compare denials by Invariant 1 or Invariant 2 in Section 3 with whether the program allows the resource access. If the rule denies resource access whereas the program accepts the resource, we flag a vulnerability. Note that this process locates vulnerabilities in our specific deployment; there might be other vulnerabilities in other deployments that we miss. In any case, our rules, if enforced, will protect these program vulnerabilities in any deployment.

7 Proving Security of Resource Access

In this section, we first argue that if P, S and R are calculated perfectly, then JIGSAW eliminates resource access vulnerabilities. Our argument is oracle-based; that is, we can reason about the correctness of our approach assuming the correctness of certain oracles on which it depends. Our argument is contingent on the correctness of the three oracles that determine: *(i)* program expectation for P, *(ii)* adversary accessibility of resources for R, and *(iii)* adversary control of names and bindings for S. We then discuss the practical limitations JIGSAW faces in realizing these oracles.

7.1 Theoretical Argument

Assuming ideally correct oracles for determining programmer expectation, adversary accessibility of resources and adversary control of names and bindings, we argue that Invariants 1 and 2 in Section 3 protect a program from all resource access vulnerabilities as defined in Section 2.1 without false positives.

According to the definition in Section 2.1, a resource access vulnerability is caused when an adversary controls an input (name or binding) to direct a program to an adversary-accessible resource when the program expects an adversary-inaccessible resource (and vice-versa). Our proof hinges on two observations. First, resource access vulnerabilities are impossible if adversaries do not control the input name or binding. Invariant 1 denies all adversary control of inputs where the programmer expects only adversary-inaccessible resources, thus eliminating all vulnerabilities in these cases. Thus, vulnerabilities are only possible where the programmer expects to adversary control of input name or binding. Second, if indeed the adversary controls the input name or binding, the only authorized output is an adversary-accessible resource; otherwise, a confused deputy vulnerability (Row 2 in Table 1) can result. To block this, Invariant 2 allows retrieval of only adversary-accessible resources when input is under adversary control. Hence, we have shown that our rules deny resource accesses *if and only if* adversary control of input directs the program to unexpected resources, thus blocking resource access vulnerabilities without false positives.

7.2 Practical Limitations

In a practical setting, the determination of program expectations, adversary accessibility to resources, and adversary control of names and bindings is imperfect. This may lead to false positives and false negatives. We will discuss limitations with determining each of these in turn.

The first oracle determines programmer expectation, for which we use the intuitive heuristic in Section 5: if a programmer does not place filters, then she does not expect adversary control of resource access, i.e., she only expects adversary-inaccessible resources. The detection of filters themselves uses runtime analysis. This faces three issues: *(i)* if identified filters are actually present, *(ii)* if actual filters are missed, and *(iii)* incompleteness of runtime analysis. First, if a detected filter is not actually present, this might result in false negatives. However, to detect filters, we mimic an attack and detect if the program blocks the attack. The only way the program could have blocked the attack is if it had a filter. Second, if an actual filter is missed, this might result in

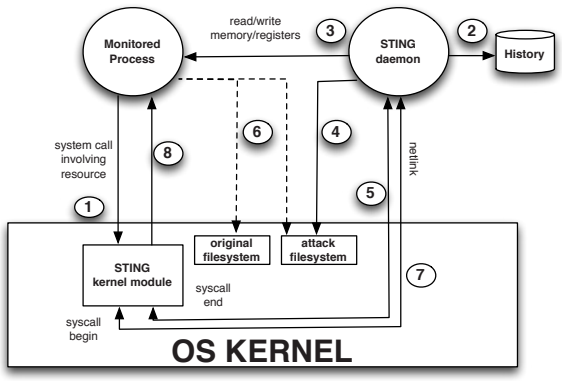

Figure 8: Implementation of JIGSAW's testing framework.

false positives. By the same argument above, if the filter cannot defend against our mimicked attack, then it is not complete enough anyway. Third, runtime analysis is inherently incomplete and may lead to false negatives for those resource accesses not covered. However, even with the limited developer test suites currently available, we were able to generate rules to block many vulnerabilities and find previously-unknown ones even in mature programs.

Next, we have the oracle that determines adversary accessibility to resources. The main challenge here is determining who an adversary is. If we do not have a sufficiently strong adversary model, we may miss adversaries and hence have false negatives. While there is no universally agreed-upon definition of who an adversary is, we use the intuitive DAC model[5] that most programmers assume [10, 43]. However, our framework permits the use of different adversary models. More conservative adversary models [41] will identify more adversary-accessible resources, possibly exposing more vulnerabilities.

The final oracle determines adversary control of names and bindings. The challenge here is to determine if there is a data flow from adversary-supplied data to a name used in a resource access. As described in Section 6.3, JIGSAW approximates data flow using control flow. However, even if control flow is the same across two executions of the program, it does not necessarily imply the data flow is the same, leading to false positives and negatives. While we have not found this to be a problem in our experiments (Section 9.4), more precise data flow tracking techniques [5, 20, 31] will address this challenge.

8 Implementation

There are two parts to our implementation. First, we need to test individual program resource accesses to detect the presence of filters. This is used by the algorithm in Figure 7 to generate P. Second, we need to enforce invariants in Section 3 using the Process Firewall. This involves determining R and S; this is done as discussed in Section 6.2 and Section 6.3 respectively.

8.1 Testing Programs

To test programs, we develop a framework that can intercept system calls and pass control to a user-space component that performs the tests. The kernel component is a small module that intercepts system calls and returns, and forwards them to a user-space daemon through netlink sockets. The flow of operations is as shown in Figure 8. When a monitored program makes a system call, it is intercepted by the framework's kernel module, and forwarded to the user-space daemon. There are two resource namespaces available per program – a "test" namespace that is modified for hypothetical tests and the original namespace (similar in principle to [39]). This daemon introspects into the monitored process to identify its resource access (using the user-space stack), and checks its history to see if filters have already been detected. If not, it then proceeds to modify the test filesystem (for binding filter detection). It then returns to the kernel module. Control passes to the process in kernel mode, which accesses the original or test filesystem (depending on whether binding filters are being tested). The system call end is also intercepted, and similarly forwarded to the user-space daemon to test for name filters (as the read buffer is now available and can be modified).

We use test suites provided with program source code to drive the programs. We repeatedly run these suites until all resource accesses have been tested for filters.

8.2 Enforcing Invariants

As noted, JIGSAW uses the open-source Process Firewall [40] to perform enforcement. The Process Firewall is a kernel module that uses the Linux Security Modules to mediate resource accesses. In addition, it can perform a user stack backtrace to identify the particular resource access being made. Given P and the edges in the name flow graph, we have two rule templates to instantiate invariants into rules to be enforced by the Process Firewall. Figure 9 shows the templates. Note that the rules for confused deputy are stateful. Adversary control of name or binding is recorded by the first rule, the adversary's identity is recorded by the second rule, and the third rule uses

[5] A process with uid X has as its adversaries any uid $Y \neq X$ (except superuser `root`)

Rule Templates

Unexpected Adversary Control: $(r \in S) \wedge (r \in \overline{P}) \implies Deny$
For each $r \in \overline{P}$:
```
pftables -i r.ept -d LOW -o DIR_SEARCH -j DROP
```

Confused Deputy: $(r \in P) \wedge (r \in S) \wedge (r \in \overline{R}) \implies Deny$
Name:
For each $r_1 \in P$ such that $E(r_1, r_2)$:
```
pftables -i r1.ept -d LOW -j STATE --set --key
<random_value> --value 1
pftables -i r1.ept -d LOW -j STATE --set --key "adv"
--value ADV_ID
pftables -i r2.ept -d HIGH -m STATE --key
<random_value> --cmp 1 --equal -m PERM -s --key
"adv" --deny -j DROP
```
Binding:
```
pftables -d LOW -o DIR_SEARCH -j STATE --set --key
<r1.ept> --value 1
pftables -d LOW -o DIR_SEARCH -j STATE --set --key
"adv" --value ADV_ID
pftables -d HIGH -m STATE --key <random_value> --cmp
1 --equal -m PERM -s --key "adv" --deny -j DROP
```

Figure 9: Process Firewall rule templates.

this state to block access to an adversary-inaccessible resource. Thus, R is adversary-specific; in addition to protecting programs against all its adversaries, it also prevents one adversary from using the program as a confused deputy against another adversary.

9 Evaluation

In this section, we evaluate our technique on several widely-used programs. We chose these programs because: *(i)* resource accesses are central to their operation, and *(ii)* they offer a study in contrast – OpenSSH and Postfix were explicitly architected for security [30], whereas the others were not. To derive expectations, we used developer test suites that came with the program or created our own. We answer: (a) how common are implicit programmer expectations during resource access, (b) whether the resulting expected attack surface was safe for our deployment and vulnerabilities where not, and (c) security effectiveness of hardened programs from resource access vulnerabilities. We find that in all programs except OpenSSH, more than 55% of all resource accesses are implicitly expected to be free from adversarial control. Moreover, we discovered two previously-unknown vulnerabilities and one default misconfiguration in the Apache webserver. Finally, we find that protection can be enforced with an overhead of $<$6% on a variety of programs and few false positives.

9.1 Implicit Programmer Expectations

Table 2 shows a summary of the results obtained by JIGSAW. We first note the percentage of resource accesses

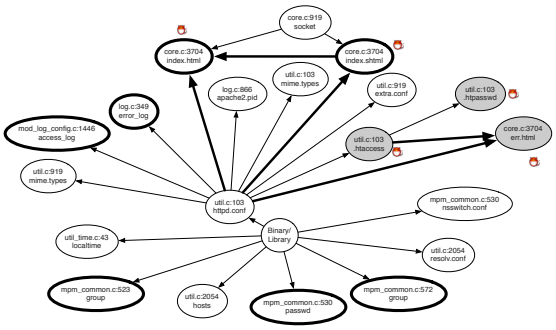

Figure 10: Resource Flow Graph for Apache. Nodes that have the icon of adversaries beside them are those where we found adversarial control of resource access in our deployment.

that are implicitly expected to *not* be in P, due to the absence of name or binding filters. For all programs except OpenSSH, the programmer placed no filters for more than 55% of resource accesses. If any of these resource accesses somehow come under adversarial control, the program can be compromised. It is very easy for OS distributor policies or administrator configurations to not match with these programmer assumptions. By explicitly identifying such resource accesses, we are able to protect them from any adversarial access in *any* deployment. OpenSSH makes fewer assumptions during resource access (17.6%). However, OpenSSH was re-architected after several years of experience with previous vulnerabilities. Using our technique, we can protect all resource accesses.

9.2 Case Study: Apache

In total, we found 20 resource accesses for Apache. Of these, Apache code filtered bindings for 7 accesses, and the name for 5 accesses. This led to 13 out of 20 resource accesses (65%) *not* being in P (using the algorithm in Figure 7). We found three resource accesses in $S-P$ for the Apache web server in our deployment, violating the first rule in Section 3. These corresponded to two previously unknown vulnerabilities in the Apache web server and one default misconfiguration. That such problems occur in even a mature program like Apache shows the importance of principled reasoning of resource access. While we found these vulnerabilities in our deployment, other deployments may have different vulnerabilities, but all will be blocked using our enforcement (Section 9.3).

Figure 10 shows the resource flow graph for Apache. Apache's expected attack surface is centered around resource accesses during the interaction with a client to serve a web page. It assumes that the location of the main configuration file and resources specified in it are not adversary controlled. Apache's resource flow graph is relatively complex due to long chains of resource flows, and it is difficult to reason about safety without the help of automated tools like ours. Resource accesses that had vul-

Program	*Dev Tests?*	$\|V\|$	$\|E\|$	$\|V_f\|$	$\|E_f\|$	$\in P$	$\notin P$	*Impl. Exp. %*	*Missing*	*Redundant*	*Vulns.*	*Inv. 1s*	*Inv. 2s*

Table 2: Statistics of program-wide resource accesses. *Dev Tests* show whether we used developer test suites or created our own. *Impl. Exp.* is the percentage of resource accesses ($|\overline{P}|/|V|$) that are implicitly expected to be adversary-inaccessible. The last two columns show the number of instantiations of Invariant 1 and Invariant 2 in Section 3 for resource accesses in the program. *- We augmented the Apache test suite with additional tests.

nerabilities in our deployment are shaded in the graph.

The first vulnerability we found was during resource access of a user-defined `.htpasswd` file. Apache allows each user the option of enabling HTTP authentication for parts of their website. This includes the ability to specify a password file of their choice. However, the resource access that fetches this password file is not filtered. Thus, users can specify any password file – even one that they do not have access to. One example exploit is to direct this password file to be the system-wide `/etc/passwd`. Traditionally, it is difficult to brute-force the system-wide password file since prompts are rate-limited. However, since HTTP authentication is not rate-limited, this may make such brute-force attacks realistic. Such a scenario, though obvious after discovery, is very difficult to reason about manually due to Apache's complex resource accesses. Thus, it has remained hidden all these years.

The second vulnerability is a default misconfiguration. When serving web pages, Apache controls whether symbolic links can be followed from user web pages by the option `FollowSymLinks`, which is turned on by default in Ubuntu and Fedora packages. Turning this option on implicitly assumes trust in the user to link to only her own web pages. Interestingly, the name for this resource access is filtered – only the bindings are not. One way we were able to take advantage of this misconfiguration was through the error document on specific errors, such as HTTP 404, that is specifiable in the user-defined configuration `.htaccess` file. This allows an adversary to access any resource the Apache web server itself can read, for example, the password file and SSL private keys. We found that our department web server also had this option turned on. By simply making an error document linked to `/etc/passwd`, we were able to view the contents of the password file on the server. This demonstrates another typical cause of resource access attacks – administrators misconfiguring the program and violating safety of the expected attack surface.

The third vulnerability is a link following attack on `.htaccess`. Apache allows `.htaccess` to be any file on the filesystem it has access to. This may be exploited to leak configuration information about the webserver.

Finally, we note that test suites that come with programs are traditionally focussed towards testing functionality and not necessarily resource access. For example, the stock test suite for Apache only uncovered 7 resource accesses in total, and after we augmented it, there were 20 in total. Better test suites for resource access would help test more resource accesses.

9.3 Process Firewall Enforcement

Process Firewall rules enforce the safety of the expected attack surface under the deployment attack surface. Given the program's expected attack surface, Process Firewall rules enforce that any adversary-controlled resource access at runtime (i.e., part of the deployment attack surface) is allowed only if the resource access is also part of the program's expected attack surface. In addition, for those resource accesses allowed, they also protect the program against confused-deputy link and directory traversal vulnerabilities. The last two columns in Table 2 shows the number of Process Firewall rules we obtained (separately due to Invariants 1 and 2).

We evaluated the ability of rules to block vulnerabilities. First, we verified the ability of these rules to block the three discovered vulnerabilities in Apache. Second, we tried previously-known, representative resource access vulnerabilities against Apache and Samba. We tested an untrusted library load (CVE-2006-1564) against Apache. Here, a bug in the package manager forced Apache to search for modules in untrusted directories. Our tool deduced that the resource access that loaded libraries did not have any filtering, and thus, was not in P, blocking this vulnerability due to Invariant 1 in Section 3. In addition, we tested a directory traversal vulnerability in Samba (CVE-2010-0926). This is a confused deputy vulnerability involving a sequence of `../` in a symbolic link. This vulnerability was blocked due to Invariant 2.

9.4 False Positives

As discussed in Section 7.2, false positives are caused by improper determination of: *(i)* programmer expectation and *(ii)* adversary control of names.

First, false positives are caused by a failure of our heuristic in Section 3 that determines program expectation. In some cases, we found that a program had no filters at a resource access, but still expected adversary-controlled resource access. We found that this case occurs in certain small "helper" programs that perform a requested task on a resource without any resource access filters. For example, consider that the administrator (`root`) runs the `cat` utility on a file in an adversarial user's home directory. Because `cat` does not filter the input bindings, the user can always launch a link following attack by linking the file to the password file, for example. However, if there is no attempted attack, then our rule will block `cat` from accessing the user's file, because the resource access has no filters and is thus not part of the expected attack surface (by our heuristic). However, we may want to allow such access, because `cat` has filters to protect itself from the input data to prevent vulnerabilities such as buffer overflows.

To address such false positives, we propose enforcing protection for such helper programs specially. Our intuition is that when these programs perform adversary-controlled resource access, they can be considered adversarial themselves. All subsequent resources to which data is output by these programs are then considered adversary-accessible. Other programs reading these resources should protect themselves from input (e.g., names) as if they were dealing with an adversary-accessible resource.

To enforce this approach, we implemented two changes. First, we enforce only Invariant 2 (confused deputy) in Section 3 for these programs. Second, whenever Invariant 1 would have disallowed access, we instead allow access, but "taint" all subsequent output resources by marking them with the adversary's label (using filesystem extended attributes).

We evaluated the effect of this approach during the bootup sequence of our Ubuntu 10.04 LTS system. We manually identified 15 helper programs. During boot, various startup scripts invoked these helper programs a total of 36 times. In our deployment, 9 of these invocations accessed an adversary-accessible resource. Note that our original approach would have blocked these 9 resource accesses, disrupting the boot sequence, whereas our modification allows these resource accesses. These invocations subsequently tainted 4 output resources – two log files and two files storing runtime state. We found two programs reading from these tainted files – `ufw` (a simplified firewall), and the `wpa_supplicant` daemon (used to manage wireless connections). These programs will find the tainted resources adversary-accessible, and will have to protect themselves from such input.

Second, false positives are caused during enforcement by our implementation's approximation of adversarial data flow using control flow. Such false positives are due to implementation limitations and not any fundamental shortcoming of our approach. To evaluate this, we used two separate test suites for Apache – one to build the name flow graph and generate Process Firewall rules, and the other to test the produced rules. We used our enhanced test suite to generate rules and ApacheBench to test the generated rules. ApacheBench ran without any false positives. However, different configurations or variable values might result in different data flows even if the stacks remain the same. As mentioned in Section 7.2, accurate data flow tracking can solve this problem.

9.5 Performance

A detailed study of the Process Firewall is in [40]. In summary, system call microbenchmarks showed overheads of up to 10.6%, whereas macrobenchmarks had overheads of up to 4%. The main cause for overhead is unrolling the process stack to identify the system call. To confirm these results, we evaluated the performance overhead of a hardened Apache webserver (v2.2.22) that had the 25 rules from Table 2. Using ApacheBench to request the default Apache static webpage, we found an overhead of 4.33% and 5.28% for 1 and 100 concurrent clients respectively. However, we can compensate for such overhead by compiling Apache without resource access filters, since filters are now redundant given our enforced rules. Vijayakumar *et al.* [40] showed that removing code filters causes a throughput increase of up to 8% in Apache.

10 Related Work

10.1 Inferring Expectations

Determining programmer expectations from code has previously been done in a variety of contexts. Engler [14] et al. infer programmer *beliefs* from code. For example, if a pointer `p` is dereferenced, the inferred belief is that `p != NULL`. They use this to find bugs in the Linux kernel. Closely related are techniques to infer invariants from dynamic traces [3, 15, 32]. Daikon [15] uses dynamic traces to infer hypothesis such as that a particular variable is less than another. Baliga *et al.* [3] use Linux kernel traces to propose invariants on data structures. While we deal with a different class of attacks, our approach is in the same spirit as the above works.

10.2 Defenses During Resource Access

Current defenses against resource access attacks in OSes are ad-hoc and fundamentally limited. Defenses can be classified into those that require changes to either the *(i)* system (e.g., OS, libraries), or *(ii)* program code.

The simplest system defense is to change the access control policy to allow a process access to only the set of expected resources. Unfortunately, this defense is both complicated and does not entirely stop resource access attacks. First, fixing access control policies is a complicated task. For example, even the minimal (targeted) SELinux MAC policy on the widely-used Fedora Linux distribution has 95,600 rules. Understanding and changing such rules requires domain specific expertise that not all administrators have. Second, access control alone is insufficient to stop resource access attacks because it treats processes as a black-box and does not differentiate between different resource access system calls. In our example in Figure 1, the web server opens both a log file and user HTML pages. Thus, it needs permissions to both resources. However, it should not access the log file when it is serving a user HTML page, and vice versa. Traditional access control does not make this difference. Other system defenses have mainly focused on TOCTTOU attacks [11, 13, 25–27, 35–38, 44] and link following [10]. However, system defenses are prone to cause false positives because they do not know what programs expect [8], e.g., which pairs of system calls expect to access the same resource.

The simplest program defense is to use program code filters that accept only the expected resources. However, there are a number of challenges to writing correct code checks. First, such checks are *inefficient* and cause performance overhead. For example, the Apache web server documentation [2] recommends switching off resource access checks during web page file retrieval to improve performance. Second, checks are *complicated*. The system-call API that programs use for resource access is not atomic, leading to TOCTTOU races. There is no known race-free method to perform an `access-open` check in the current system call API [8]. Chari *et al.* [10] show that to defend link following attacks, programmers must perform at least four additional system calls per path component for each resource access. Going back to the example in Figure 1, the checks on lines 7 and 8 are not enough – the correct sequence to use is `lstat-open-fstat-lstat` [10]. Thirdly, program checks are *incomplete*, because adversary accessibility to resources is not sufficiently exposed to programs by the system-call API. Currently, programs can query adversary accessibility only for UNIX discretionary access control (DAC) policies (e.g., using the `access` system call), but many UNIX systems now also enforce mandatory access control (MAC) policies (e.g., SELinux [24] and AppArmor [23]) that allow different adversary accessibility. While custom APIs have been proposed [19, 29, 34, 42] to address such limitations, these require additional programmer effort and do not protect current programs.

11 Conclusion

In this paper, we presented JIGSAW, an automated approach to protect programs from resource access attacks. We first precisely defined resource access attacks, and then noted the fundamental cause for them – a mismatch between programmer expectations and the actual deployment the program runs in. We defined two invariants that, if evaluated and enforced correctly, can theoretically offer complete protection against resource access attacks. We proposed a novel technique to evaluate programmer expectations based on the presence of filters, and showed how the invariants could practically be enforced by the Process Firewall.

We applied this technique to harden widely-used programs, and discovered that programmers make a lot of implicit assumptions. In this process, we discovered two previously-unknown exploitable vulnerabilities as well as a default misconfiguration in Apache, the world's most widely used web server. This shows that even mature programs only reason about resource access in an ad-hoc manner. The analysis as presented in this paper can thus efficiently and automatically protect programs against resource attacks at runtime.

Abstract

Web applications evolved in the last decades from simple scripts to multi-functional applications. Such complex web applications are prone to different types of security vulnerabilities that lead to data leakage or a compromise of the underlying web server. So called *second-order vulnerabilities* occur when an attack payload is first stored by the application on the web server and then later on used in a security-critical operation.

In this paper, we introduce the first automated static code analysis approach to detect second-order vulnerabilities and related multi-step exploits in web applications. By analyzing reads and writes to memory locations of the web server, we are able to identify unsanitized data flows by connecting input and output points of data in *persistent data stores* such as databases or session data. As a result, we identified 159 second-order vulnerabilities in six popular web applications such as the conference management systems *HotCRP* and *OpenConf*. Moreover, the analysis of web applications evaluated in related work revealed that we are able to detect several critical vulnerabilities previously missed.

1 Introduction

Web applications are the driving force behind the modern Web since they enable all the services with which users interact. Often, such applications handle large amounts of (potentially sensitive) data such as text messages, information about users, or login credentials that need to be stored persistently on the underlying web server. Further, *sessions* are used to temporarily store data about a user interacting with the web application during multi-step processes. All of this data can potentially be abused by an attacker to cause harm. Many different kinds of attacks against web applications such as *Cross-Site Scripting* (XSS) or *SQL injection* (SQLi) attacks are known and common injection flaws are well understood. Such attacks can be prevented by sanitizing user input and many approaches to address this problem were presented in the last few years (e.g., [2, 8, 15, 21, 22, 24, 27, 29]).

One common assumption underlying many detection and prevention approaches is that data that is already stored on the server is safe. However, an adversary might be able to bypass the defenses via so called *second-order vulnerabilities* if she manages to first abuse the web application to store the attack payload on the web server, and then later on use this payload in a security-critical operation. Such vulnerabilities are often overlooked, but they can have a severe impact in practice. For example, XSS attacks that target the application's users are worse if the payload is stored in a shared resource and distributed to all users. Furthermore, within *multi-step exploits* a vulnerability can be escalated to a more severe vulnerability. Thus, detecting second-order vulnerabilities is crucial to improve the security of web applications.

Detecting Second-Order Vulnerabilities To prevent such attacks, the source code of a given web application is assessed before it is deployed on a web server. This can be done either via dynamic or static analysis. There are several dynamic approaches to detect second-order XSS attacks via fuzzing [14, 19]. Generally speaking, such approaches try to inject random strings to all possible POST request parameters in a black-box approach. In a second step, the analysis tools determine if the random string is printed by the application again without another submission, indicating that it was stored on the web server. However, the detection accuracy for second-order vulnerabilities is either unsatisfying or such vulnerabilities are missed completely [4, 7, 13, 23]. Artzi et. al. [1] presented a dynamic code analysis tool that considers persistent data in sessions, but their approach misses other frequently used data stores such as databases or files. Furthermore, one general drawback of dynamic approaches is the typically low code coverage.

Static code analysis is a commonly used technique to find security weaknesses in source code. Taint analysis and similar code analysis techniques are used to study the data flow of untrusted (also called *tainted*) data into critical operations of the application. However, web applications can also store untrusted data to external resources and later on access and reuse it, a problem that is over-

looked in existing approaches. Since the data flow is deferred and can be split among different files and functions of the application, second-order vulnerabilities are difficult to detect when analyzing the source code statically. Furthermore, static code analysis has no access to the external resources used by the application and does not know the data that is stored in these.

We are not aware of any plain *static* code analysis implementation handling second-order vulnerabilities. The main problem is to decide whether data fetched from persistent stores is tainted or not. Assuming all data to be tainted would lead to a high number of false positives, while a conservative analysis might miss vulnerabilities.

Our Approach In this paper, we introduce a refined type of taint analysis. During our data flow analysis, we collect all locations in persistent stores that are written to and can be controlled (tainted) by an adversary. If data is read from a persistent data store, the decision if the data is tainted or not is delayed to the end of the analysis. Eventually, when all taintable writings to persistent stores are known, the delayed decisions are made to detect second-order vulnerabilities. The intricacies of identifying the exact location within the persistent store the data is written to is approached with string analysis. Furthermore, sanitization through database lookups or checks for existing file names are recognized.

We implemented our approach in a prototype for static PHP code analysis since PHP is the most popular server-side scripting language on the Web with an increasing market share of 81.8% [28]. Note that our approach can be generalized to static code analysis of other languages by applying the techniques introduced in this paper to the data flow analysis of another language. We evaluated our approach by analyzing six popular real-world applications, including *OpenConf*, *HotCRP*, and *osCommerce*. Overall, we detected and reported 159 previously unknown second-order vulnerabilities such as *remote command execution* vulnerabilities in *osCommerce* and *OpenConf*. We also analyzed three web applications that were used during the evaluation of prior work in this area and found that previous work missed several second-order vulnerabilities, indicating that existing approaches do not handle such vulnerabilities correctly.

In summary, we make the following three contributions:

- We are the first to propose an automated approach to statically analyze second-order data flows through databases, file names, and session variables using string analysis. This enables us to detect second-order and multi-step exploitation vulnerabilities in web applications.
- We study the problem of second-order sanitization, a crucial step to lower the number of potential false positives and negatives.
- We built a prototype of the proposed approach and evaluate second-order data flows of six real-world web applications. As a result, we detect 159 previously unknown vulnerabilities ranging from XSS to *remote code execution* attacks.

2 Technical Background

In this section, we introduce the nature of second-order vulnerabilities and multi-step exploits. First, we examine data flow through persistent data stores and the difficulties of analyzing such flows statically. We then present two second-order vulnerabilities as motivating examples.

2.1 Persistent Data Stores

We define *persistent data stores* (PDS) as memory locations that are used by an application to store data. This data is available after the incoming request was parsed and can be accessed later on by the same application to reuse the data. The term *persistent* refers to the fact that data is stored on the web server's hard drive, although it can be frequently deleted or updated. Note that this definition also includes session data since information about a user's session is stored on the server and can be reused by an adversary. We now introduce three commonly used PDS by web applications.

2.1.1 Databases

Databases are the most popular form of PDS found in today's web applications. A database server typically maintains several databases that consist of multiple tables. A table is structured in columns that have a specific data type and length associated with them. Stored data is accessed via SQL queries that allow to filter, sort, or intersect data on retrieval. In PHP, an API for database interaction is bundled as a PHP extension that provides several built-in functions for the database connection, and the query and access of data.

In contrast to other PDS, *writing* and *reading* to a memory location is performed via the same built-in query function. SQL has different syntactical forms of writing data to a table. Listing 1 shows three different ways to perform the same query.

```
1 // specified write
2 INSERT INTO users (id,name,pass) VALUES (1,'admin','foo')
3 INSERT INTO users SET id = 1, name = 'admin', pass = 'foo'
4 // unspecified write
5 INSERT INTO users VALUES (1,'admin','foo')
```

Listing 1: Writing to the database table *users* in SQL.

While the first two queries explicitly define the column names, the third query does not. We refer to the first type as *specified write* and to the second type as *unspecified write*. Both types convey a difficulty for static

analysis of the query: a *specified write* reveals the column names where data is written to, but does not reveal if there are any other columns in the table that are filled with default values. This hinders the reconstruction of table structures when analyzing SQL queries of an application statically. An *unspecified write* tells us exactly how many columns exist, but does not reveal its names. When the columns are accessed later on by name, it is unclear which column was filled with which value. The same applies for read operations. A *specified read* reveals the accessed column names in a field list, whereas an *unspecified read*, indicated by an *asterisk* character, selects all available columns without naming them.

In PHP, the queried data is stored as a result resource. There are different ways to fetch the data from the result resource with built-in functions, as shown in Listing 2.

```
1 // numeric fetch
2 $row = mysql_fetch_row($res);      echo $row[1];
3 // associative fetch
4 $row = mysql_fetch_assoc($res);    echo $row["name"];
5 $row = mysql_fetch_object($res);   echo $row->name;
```

Listing 2: Fetching data from a database result resource.

Basically, *numeric* and *associative fetch* operations exist. The first method stores the data in a numerically indexed array where the index refers to the order of the selected columns. The *associative fetch* stores the data in an array indexed by column name. It is also possible to store the data in an object where the property names equals the column names. The key difference is that the *associative fetch* reveals the accessed column names while the *numeric fetch* does not.

All different combinations of writing, reading, and accessing data can occur within a web application. In certain combinations, it is not clear which columns are accessed without knowledge about the database schema. For example, when data is written *unspecified* and fetched associatively. In practice, however, we are often able to reconstruct the database schema from the source code (see Section 3.4.1 for details).

2.1.2 Session Data

A common way of dealing with the state-less HTTP protocol are *sessions*. In PHP, the `$_SESSION` array provides an abstract way of handling session data that is stored within files (default) or databases. A session value is associated with an alphanumerical key that represents the memory location. Note that the `$_SESSION` array needs to be treated like any other superglobal array in PHP and it can be accessed in any context of the application. As any other array, it can be accessed and modified dynamically, inter-procedurally, and it can have multiple key names. Besides the `$_SESSION` array and the deprecated `$HTTP_SESSION_VARS` array, the built-in functions `session_register()` and `session_decode()` can be used to set session data.

2.1.3 File Names

A common source for vulnerabilities is an unsanitized file name. Developers often overlook that the file name of an uploaded file can contain malicious characters and thus can be used as a PDS for an attack payload. For example, Unix file systems allow any special characters in file names, except for the slash and the null byte [12]. NTFS allows characters such as the single quote that can be used for exploitation [20]. For detecting second-order vulnerabilities, we need to determine paths where files with arbitrary names are located. The analysis of a file upload reveals to which path a file is written to and if the file is named as specified by the user. In PHP, a file that is submitted via a multi-part POST request is stored in a temporary directory with a temporary file name. The temporary and original file name is accessible in the superglobal `$_FILES` array. Furthermore, built-in functions such as `rename()` and `copy()` can be used by an application to rename a file on the server. Note that also directory names can be used as PDS, for example when created with the built-in function `mkdir()`.

2.1.4 Excluded PDS

There are less popular PDS that we do not include in our analysis. For example, data can be retrieved from a CGI environment variable, a configuration file, or from an external resource such as an FTP or SMTP server [5]. However, these PDS are used rarely in practice and decisions can only be made with preconfigured whitelists. We only consider PDS that are tainted by the application itself and not through a different channel. Analyzing the data flow through file content will be an interesting addition in the future. Here, the challenge is to determine to what part of a given file data is written to and from what part of the file data is read from because the structure of the data within the file is unknown.

Note that data stored via PHP's built-in functions `ini_set()` or `putenv()` only exists for the duration of the current request. At the end of the request, the environment is restored to its original state. Thus, they do not hold to our definition of a PDS.

2.2 Second-Order Vulnerabilities

A taint-style vulnerability occurs if data controlled by an attacker is used in a security-critical operation. In the data flow model, this corresponds to tainted data literally flowing into a sensitive sink within one possible data flow of the application. We classify a second-order vulnerability as a taint-style vulnerability where the data flows through one or more PDS. Here, the attack payload is first stored in a PDS and later retrieved and used in a sensitive sink. Thus, *two* distinct data flows require analysis: (i) source to PDS and (ii) PDS to sink.

In the following, we introduce two motivating examples with a payload stored in a PDS. In general, every combination of a source, sensitive sink, and a PDS is possible. Depending on the application's design, the flow of malicious data occurs within a single or multiple attack requests (e.g., when different requests for writing and reading are necessary). Finally, we introduce multi-step exploits as a subclass of second-order vulnerabilities.

2.2.1 Persistent Cross-Site Scripting

Cross-Site Scripting (XSS) [16] is the most common security vulnerability in web applications [22]. It occurs when user input is reflected to the HTML result of the application in an unsanitized way. It is then possible to inject arbitrary HTML markup into the response page that is rendered by the client's browser. An attacker can abuse this behavior by embedding malicious code into the response that for example locally defaces the web site or steals cookie information.

We speak of *Persistent Cross-Site Scripting* if the attacker's payload is stored in a PDS first, read by the application again, and printed to the response page. In contrast to *non-persistent* (*reflected*) XSS, the attacker does not have to craft a suspicious link and send it to a victim. Instead, all users of the application that visit the affected page are attacked automatically, making the vulnerability more severe. Furthermore, a *persistent XSS* vulnerability can be abused to spread an XSS worm [18, 26].

Listing 3 depicts an example of a *persistent XSS* vulnerability. The simplified code allows to submit a new comment which is stored in the table `comments` together with the name of the author. If no new comment is submitted, it lists all previously submitted comments that are fetched from the database. While the comment itself is sanitized in line 7 by the built-in function `htmlentities()` that encodes HTML control characters, the author's name is not sanitized in line 6 and thus affected by XSS. Note that if the source code is analyzed top-down, it is unknown at the point of the `SELECT` query if malicious data can be inserted into the table `comments` by an adversary.

```
1  if(empty($_POST['submit'])) {
2     // list comments
3     $res = mysql_query("SELECT author,text FROM comments");
4     foreach(mysql_fetch_row($res) as $row) {
5        $comment = mysql_fetch_array($row);
6        echo $comment['author'] . ': ' .
7        htmlentities($comment['text']) . "<br />";
8     }
9  }
10 else {
11    // add comment
12    $author = addslashes($_POST['name']);
13    $text = addslashes($_POST['comment']);
14    mysql_query("INSERT INTO comments (author, text)
15                 VALUES ('$author', '$text')");
16 }
```

Listing 3: Example for *second-order XSS* vulnerability.

2.2.2 Second-Order SQL Injection

A *SQL injection* (SQLi) [9] vulnerability occurs when a web application dynamically generates a SQL query with unsanitized user input. Here, an attacker can potentially inject her own SQL syntax to arbitrarily modify the query. Depending on the environment, the attacker can potentially extract sensitive data from the database, modify data, or compromise the web server.

In Listing 4, user supplied credentials are checked in line 6. If the credentials are valid, the session key `loggedin` is set to *true* and the user-supplied user name is saved into the session key `user`. In case the user-supplied data is invalid, the failed login attempt is logged to the database with the help of the user-defined `log()` function. Here, a *second-order SQLi* occurs: if an attacker registers with a malicious user name, this name is written to the session key `user` and on a second failed login attempt used in the logging SQL query.

```
1  function log($error) {
2     $user = $_SESSION['user'];
3     mysql_query("INSERT INTO logs (error, user)
4                  VALUES ('$error', '$user')");
5  }
6  if(validAuth($_POST['user'], $_POST['pass']) {
7     $_SESSION['loggedIn'] = true;
8     $_SESSION['user']     = $_POST['user'];
9  }
10 else {
11    log('Failed login attempt');
12 }
```

Listing 4: Example for *second-order SQLi* vulnerability.

2.2.3 Multi-Step Exploitation

Within a second-order vulnerability, the first order (e. g., safe writing of user input into the database or a file path) is not a vulnerability by itself. However, *unsafe* writing can lead to other vulnerabilities. We define a multi-step exploit as the exploitation of a vulnerability in the second order that requires the exploitation of an unsafe writing in the first order. Thus, a multi-step exploit is a subclass of a second-order vulnerability and it can drastically raise the severity of the first vulnerability.

Since we only consider databases, sessions, and file names as PDS in our analysis, the following vulnerabilities are relevant:

- *SQLi*: A SQLi in an `INSERT` or `UPDATE` statement leads to a full compromise of all columns in the specified table. Furthermore, a SQLi in a `SELECT` query allows arbitrary data to be returned.
- *Path traversal*: A *path traversal* vulnerability allows to change the current directory of a file operation to another location. Arbitrary file names can be created in arbitrary locations if a *path traversal* vulnerability affects the renaming or creation of files.
- *Arbitrary file write*: An *arbitrary file write* vulnerability can modify or create a new session file, leading to the compromise of all session values.

3 Detecting Second-Order Vulnerabilities

In the following, we describe our approach to automatically detect second-order vulnerabilities via static code analysis. For this purpose, we extended our prototype *RIPS* [6] that uses *block summaries* [30]. In this section, we first briefly review the used data flow and taint analysis approach of RIPS (Sections 3.1 and 3.2). Afterwards, we explain our novel additions for detecting second-order vulnerabilities and multi-step exploits (Sections 3.3–3.5).

3.1 Data Flow Analysis

RIPS leverages a context-sensitive, intra- and interprocedural data flow analysis. We use basic block, function, and file *summaries* [30] for efficient, backwards-directed data flow analysis [6]. First, for each PHP file's code, a *control flow graph* (CFG) consisting of connected basic blocks is generated. Definitions of functions, classes, and methods within the code are extracted. Then, every CFG is analyzed top-down by simulating the connected basic blocks one by one. A block edge that links two connected basic blocks is simulated as well to identify data sanitization.

During the simulation of one basic block, all assigned data is transformed into *data symbols* that we will introduce later. The flow of the data is inferred from these symbols and summarized in a *block summary* [30] that maps data locations to assigned data. The return results and side-effects (e.g., data assignment or sanitization) of called built-in functions are determined by a precise simulation of over 900 unique functions.

If a user-defined function is called within a basic block, its CFG is generated and all basic blocks are simulated. Based on these block's summaries, the data flow within the function is determined by analyzing `return` statements in a similar way to taint analysis (see Section 3.2). The results are stored in a *function summary*. This summary is used for each call of the user-defined function, while return values, global variables, and parameters are adjusted to the callee's arguments and environment context-sensitively. When all basic blocks of a file's CFG are simulated, a *file summary* is generated in a similar way to functions that is used during file inclusion.

Data and its access within the application's code is modeled by so called *data symbols* [6]:

- `Value` represents a static `"string"`, integer, float, or a resolved `CONSTANT`'s value. Defined constant values are stored in the environment.
- `Variable` represents a `$variable` by its name.
- `ArrayDimFetch` represents the access of an array (`$array[k]`) and extends the `Variable` symbol with a *dimension* (`k`). The dimension lists the fetched array keys in form of data symbols.
- `ArrayDimTree` represents a newly declared array or the assignment of data to one array key (`$array[k] = $data`). It is organized in a tree structure. The array keys are represented by array edges that point to the assigned data symbol. The `ArrayDimTree` symbol provides methods to add or fetch symbols by a *dimension* that is compared to the tree's edges.
- `ValueConcat` represents the concatenation of two or more data symbols (`$a.$b`). Two consecutive `Value` symbols are merged to one `Value` symbol.
- `Multiple` is a container for several data symbols. It is used, for example, when a function returns different values depending on the control flow or PHP's *ternary* operator is used (`$c ? $a : $b`).

During data flow analysis, one or more *sanitization tags* can be added to a data symbol, for example if sanitization is applied by built-in functions such as `addslashes()` or `htmlentities()`. Each sanitization tag represents one context, for example, a *single-quoted SQL value* or a *double-quoted HTML attribute*. A symbol can be sanitized against one context, but be vulnerable to another. The tags are removed again when built-in functions such as `stripslashes()` or `html_entity_decode()` are called. Furthermore, information about encoding is added to every data symbol.

3.2 Context-Sensitive Taint Analysis

The goal is to create a vulnerability report, whenever a tainted data symbol δ flows into a sensitive sink. Our implementation is performed with 355 sensitive built-in functions of PHP. If a call to a sink is encountered during block simulation, its relevant arguments are analyzed. First, the argument is transformed into a data symbol. If the symbol was defined within the same basic block, it is inferred from the block summary. Then, the symbol is looked up in the block summary of every previous basic block that is linked with a block edge to the current basic block. If the lookup in the block summary succeeds, the inferred symbol is fetched. The dimension of an `ArrayDimFetch` symbol is carried until a mapping `ArrayDimTree` symbol is found. The backwards-directed symbol lookup continues for each linked basic block and stops if a symbol of type `Value` is inferred or the beginning of the CFG is reached. At this point, all resolved symbols are converted to strings in order to perform context-sensitive string analysis [6]. The symbols `Value` and `Boolean` are converted to their representative string values. Data symbols of sources are mapped to a *Taint ID* (TID) that is used as string representation.

Next, each string is analyzed. The location of the TIDs within the markup is determined to precisely detect the context. For complex markup languages such as HTML

or SQL, a markup parser is used. With the help of the *sanitization tags* and encoding information of the linked data symbol, we check if the symbol is sanitized correctly according to its context. If a TID is found that belongs to an unsanitized source regarding the current context, a vulnerability report is generated. Unsanitized parameters or global variables are added to the function's summary as *sensitive parameter* or *global*. These are analyzed in the context of each function call.

3.3 Array Handling

By manually analyzing the code of the most popular PHP applications [28], we empirically found that a common way to write data into a database is by using arrays. An example is shown in Listing 5. In line 9 and 10, the array's *key* defines the table's column and the array's *value* stores the data to write. The separated array values are joined to a string again by using the built-in function `implode()` (lines 2/3). Based on this observation, we redesigned the handling of arrays by adding new data symbols. As a side effect, the handling of fetched database results in form of an array and the handling of the superglobal `$_SESSION` array is significantly improved.

```
1  function insert($table, $array) {
2     $fields = implode(",", array_keys($array));
3     $values = implode("','", $array);
4     mysql_query("INSERT INTO {$table}
5                  (".$fields.") VALUES ('".$values."')");
6  }
7
8  $new_user = array(
9     "name" => addslashes($_POST['name']),
10    "pass" => md5($_POST['pass']),
11 );
12 insert("users", $new_user);
13 // INSERT INTO users (name,pass) VALUES ('X', '123abc...')
```

Listing 5: Using arrays to write data to a database.

We model the popular built-in function `implode()` by adding the data symbol `ArrayJoin`. With the help of this symbol, it is possible to keep track of the *delimiter* that is used to join strings. If the symbol is inferred to an `ArrayDimTree` symbol, a `ValueConcat` symbol is created that joins all symbols of the `ArrayDimTree` symbol with the stored delimiter symbol.

Furthermore, we introduce the new symbol `ArrayKey`. It is used when the *key* of an array is explicitly accessed, such as in the loop `foreach($array as $key => $value)`. It is handled similar to the `Variable` symbol and is associated with the array's name. If the `ArrayKey` symbol is inferred into an `ArrayDimTree` symbol during data flow or taint analysis, a `Multiple` symbol containing all edges' symbols is returned. Built-in functions, such as `array_keys()` and `array_search()`, return all or parts of the available keys in an array and can be modeled more precisely with the `ArrayKey` symbol.

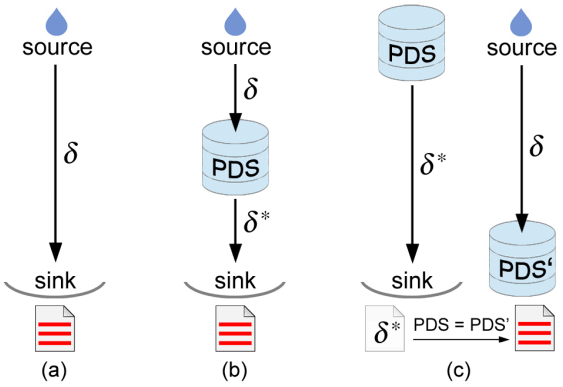

Figure 1: Data flow model of a conventional (a) and a second-order (b, c) vulnerability.

3.4 PDS-centric Taint Analysis

We now introduce our novel approach to detect second-order vulnerabilities. The data flow is illustrated in Figure 1 (b). Contrarily to a conventional taint-style vulnerability as shown in Figure 1 (a), a source flows into a PDS before it flows from the PDS into a sensitive sink. We model the data that is read from a PDS by new data symbols δ^* that hold information about their origin.

During code analysis, *taintable* PDS are identified. They are stored together with the minimum set of applied sanitization and encoding tags of the tainting data symbol δ. If one of the new data symbols δ^* is encountered unsanitized during the taint analysis of a sensitive sink, a vulnerability report is created if its originating PDS was identified as taintable.

If the PDS is not known as taintable, a *temporary* vulnerability report is created, as shown in Figure 1 (c). The report is connected to the data symbol δ^*. At the end of the code analysis, we decide if the data symbol originates from a taintable PDS by comparing its origin to all collected taintable PDS.

In the following, we introduce the analysis of writings to different PDS. Furthermore, our new data symbols δ^* are introduced that model the reading and access of data that is stored in PDS.

3.4.1 Databases

Modeling the data flow through databases is a complex task, mainly due to the large API that is available for databases and the usage of a query language. First, our prototype tries to obtain as much knowledge of the SQL schema as possible. Then we try to reconstruct all SQL queries during SQL injection analysis of 110 built-in query functions. Finally, the type of operation is determined, as well as the targeted table and column names. The access of data is modeled by new data symbols.

Preparation During the initialization of our tool, we collect all files with a *.sql* extension. All available `CREATE TABLE` instructions within these files are parsed so that we can reconstruct the database schema, including all table and column names as well as column types and length. If no schema file is found, each PHP file in the project is searched via regular expression. The knowledge of the database schema improves precision when data is read in an *unspecified* way, or when data is sanitized by the column type or length.

Writing A write operation to a database is detected if the SQL parser identifies an `INSERT`, `UPDATE`, or `REPLACE` statement. By tokenizing the SQL query, we determine the targeted table's name, all specified column names, and their corresponding input values. In case of an *unspecified write*, the parser makes use of the database schema. If an input value of a column contains a TID (see Section 3.2), the affected column and table name is marked as *taintable* together with the linked source symbol and its sanitization tags.

Reading If the SQL parser encounters a `SELECT` statement, we try to determine all selected column and table names. Multiple table names can occur if tables are *joined* or *unioned*. Alias names within the query are mapped and resolved. In case of uncertainty, the parser makes use of the database schema. Finally, a new `ResourceDB` symbol is mapped to the analyzed query function as return value. This symbol holds information about all selected column names in a numerical hash map and its corresponding table names.

Access In PHP, database result resources are transformed into arrays by built-in fetch functions (refer to Listing 2). We ignore the mode of access and let 89 configured fetch functions return a `Variable` symbol with the name of the resource. When an `ArrayDimFetch` symbol accesses the result of these fetch functions, it is inferred to the corresponding `ResourceDB` symbol. In this case, the carried dimension of the `ArrayDimFetch` symbol is evaluated against the available column names in the `ResourceDB` symbol. If the *asterisk* character is contained in the column list and the dimension is numerical, the database schema is used to find the correct column name. Otherwise, if the dimension equals a column name in the field list, a new `DataDB` symbol is returned that states which column of which table is accessed.

Sanitization Certain implicit sanitization is considered when dealing with SQL. If a column is compared to a static value within a `WHERE` clause in a `SELECT` statement, the return value for this column is sanitized. In this case, the static value is saved within the `ResourceDB` symbol and mapped to the column as return value. Furthermore, a sanitization tag for the used quote type is removed when data is updated or inserted to the database because one level of escaping is lost during writing.

3.4.2 Session Keys

The analysis of session variables does not require a complex markup parser or new data symbol. Instead, session data is handled similar to other global arrays. Taintable session keys are stored during the analysis phase.

Writing If data is assigned to a `Variable` or `ArrayDimFetch` symbol during block simulation and the symbol's name is `$_SESSION`, the assigned data is analyzed via taint analysis. If the assigned data is tainted, its resolved source symbol is stored into an `ArrayDimTree` symbol in the environment, together with the dimension of the `$_SESSION` symbol. This way, an `ArrayDimTree` is built with all taintable dimensions of the session array that link to the tainted source symbols and their corresponding sanitization tags.

Reading The access to session data is modeled by `ArrayDimFetch` symbols with the name `$_SESSION` and requires no modification. During taint analysis inside a user-defined function, session variables are handled as global variables. They are added to the function summary and they are inspected for each function call in a context-sensitive way. This avoids premature decisions about the taint status inside a function if the session key is overwritten before the function is called. Just as for a `DataDB` symbol, a *temporary* vulnerability report is created if a `$_SESSION` variable taints a sensitive sink.

3.4.3 File Names

To detect taintable file names, we collect file paths a user can write to. For this purpose, new data symbols model directory resources and their accesses. Whenever a path is reconstructed only partially, we use the same approach as in file inclusion analysis. Here, a regular expression is created and mapped to all available paths that were detected when loading the application files.

Writing To detect a file name manipulation with user input, we analyze 27 built-in functions such as `copy()`, `rename()`, and `file_put_contents()`. Additionally, file uploads with `move_uploaded_file()` are analyzed. Note that at the same time these built-in functions are sensitive sinks and generate vulnerability reports such as an *arbitrary file upload* vulnerability. The path argument is analyzed by conventional context-sensitive string analysis. If the path is tainted, we store it with its prefix as taintable. When no prefix is present, the file path of the currently analyzed file is taken. Additionally, if the source is not sanitized against *path traversal* attacks, all paths are assumed as taintable and a flag is set during analysis accordingly.

Reading We handle three different ways of opening a directory with PHP's built-in functions. First, we model the built-in function `scandir()` that returns an array, listing all files and directories within a specified path.

Second, we model the built-in function `glob()` that also returns an array that lists all files and directories specified by a pattern. We transform the pattern into a regular expression by substituting the pattern characters `*` and `?` into regular expression equivalents. Third, we model the built-in function `opendir()` which returns a *directory handle*. For all mentioned built-in functions, we reconstruct the opened path by string analysis and return a `ResourceDir` symbol that stores the path's name.

Access The returned result of `scandir()` and `glob()` is accessed by an array key. Since we do not know neither the amount nor the order of files in a directory, we return a `DataPath` symbol whenever a `ResourceDir` symbol is inferred from an `ArrayDimFetch` symbol, regardless of its dimension. For this purpose, we let the built-in function `readdir()` that is supposed to read an entry of a *directory handle* return an `ArrayDimFetch` symbol with an arbitrary dimension and the name of the directory handle. It is inferred to a `DataPath` symbol when the trace of the `ArrayDimFetch` symbol results in a `ResourceDir` symbol.

Sanitization In order to model sanitization that checks if a given string is a valid file name, 11 built-in functions such as `file_exists` and `is_file()` are simulated. We modified the sanitization check in a way that these functions only sanitize if there is no taintable file path found. For this purpose, a flag is set during taint analysis if sanitization of a source by file name is detected. The flag issues only a temporary vulnerability report that is revised at the end of the analysis regarding the ability to taint a file path.

3.4.4 Multi-Step Exploits

In order to detect multi-step exploits, we store all table names of all writing SQL queries that are affected by SQLi. Furthermore, we set a flag during the analysis process if an *arbitrary file write* or *arbitrary file rename* vulnerability is detected. At the end of the analysis, when the taint decision is made for data that comes from a PDS, multi-step exploit reports are added to the initial vulnerability. This is done for all vulnerabilities that rely on a `DataDB` symbol that is not tainted through second-order but which table name is affected by SQLi. Also, a multi-step exploit is reported if a `DataDir` symbol occurs and the flag for a *file rename* vulnerability was set. All session data is treated as tainted if an *arbitrary file write* vulnerability was detected. Additionally, any *local file inclusion* vulnerability is extended to a *remote code execution* if a file write or upload feature is detected.

Moreover, a SQLi vulnerability within a `SELECT` query returns a `DataDB` symbol with a *taint* flag. This flag indicates that all accessed columns are taintable by modifying the `SELECT` query during an attack. Thus, all columns of the `DataDB` symbol are taintable.

3.5 Inter-procedural PDS Analysis

We optimized the inter-procedural analysis to refine our string analysis results. Function summaries offer a high performance but they are also inflexible for functions with dynamic behavior. Thus, they can weaken the static reconstruction of dynamically created strings.

3.5.1 Multiple Parameter Trace

As we illustrated in Listing 5, modern applications often define wrapper functions for PDS access where more than one parameter is used within one sensitive sink. In this case, the approach of storing each parameter together with its prefixed and postfixed markup, and the corresponding vulnerability type as *sensitive parameter* in the function summary, is error-prone. When a call to this function occurs, the approach swaps the parameter symbol with the argument of the function call and traces it for user input. While this approach works fine for vulnerability detection, it leads to imprecision when it comes to string reconstruction. Because each argument is traced separately but both are used in the same sink, the result of one trace is missing in the result of the other trace. In Listing 5, for example, the table name is missing in the reconstructed query while the data is reconstructed from the `$new_user` array.

To circumvent this problem, we refined this approach for sinks that execute SQL queries or open file paths within a user-defined function. If multiple parameters or global variables are involved, all symbols are combined to one `ValueConcat` symbol. Then this symbol is stored in the function summary and analyzed for each function call. This way, each parameter is traced within one analysis and all results are present at the same time.

3.5.2 Mapping Returned Resources

Working with function summaries is very efficient when it comes to performance because each function only requires a single analysis on the first call. For every other call, the function summary is reused. However, a user-defined function might return a resource that has different properties for each call. For example, a `SELECT` query that embeds the parameter of an user-defined function as the table name returns a different `ResourceDB` symbol for every call, depending on the function's argument. If the resource is returned by the user-defined function, its symbol's properties change for every different function call.

As a solution, we add empty `ResourceDB` symbols to the function summary's set of return values for user-defined functions with dynamic SQL queries. Once the sensitive parameters are analyzed and the queries are reconstructed, a copy of these symbols is updated with the table and column information and used as returned data.

4 Evaluation

For evaluating our approach, we selected six real-world web applications. We chose the conference management systems *OpenConf 5.30* and *HotCRP 2.61* for their popularity in the academic field and *osCommerce 2.3.3.4* for its large size. Furthermore, we evaluated the follow-up versions of the most prominent software used in related work [3, 11, 30, 31]: *NewsPro 1.1.5*, *MyBloggie 2.1.4*, and *Scarf 2007-02-27*.

A second-order vulnerability consists of two data flows: tainting the PDS and tainting the sensitive sink. We evaluated our prototype for both steps and present the *true positives* (TP) and *false positives* (FP) in this section. In addition, we discuss the root cause for *false negatives* (FN) and outline the limitations of our approach.

4.1 PDS Usage and Coverage

To obtain an overview of the usage of PDS in web applications, we manually evaluated the total amount of different memory locations. Note that these numbers do not reflect how often one memory location is used at runtime. Then, we evaluated the ability to taint these memory locations by an application's user and compared it to the detection rate of our prototype. A PDS is defined as *taintable* if it can contain at least one of the following characters submitted by an application user: `\<>'"`. In total, we manually identified 841 PDS of which 23% are taintable. Our prototype successfully detected 71% of the taintable PDS with a false discovery rate of 6%.

4.1.1 Databases

Our implementation successfully recovered the database schema for all tested applications during the initialization phase. For evaluation, we categorized all available columns in the application's database schema by declared data type. Only columns with a *string* type, such as `VARCHAR` or `TEXT`, are of interest because they can store tainted data. As shown in Table 1, we found that on average about half of the columns are not taintable due to numeric data types such as `INT` and `DATE`.

Table 1: Column types in selected applications.

Software	Tables	Columns	Num	String
osCommerce	50	331	193	138
HotCRP	29	217	142	75
OpenConf	18	129	48	81
NewsPro	8	43	18	25
Scarf	7	37	22	15
MyBloggie	4	24	10	14
Total	116	781	55%	45%

We then carefully fuzzed a local instance of each application manually with common attack payloads in order to determine which columns of type *string* are taintable. Furthermore, we observed which columns were reported by our prototype implementation as taintable when the schema is available and when not. The results are compared in Table 2. Among the columns with a string type, 53% are taintable. As a result, only 24% of all available columns are not sanitized by the application or the columns' data type.

Table 2: Taintable columns in selected applications.

		Schema		No schema	
Software	Taintable	TP	FP	TP	FP
osCommerce	63	55	4	55	37
HotCRP	43	27	1	27	3
OpenConf	47	16	1	16	4
NewsPro	12	12	0	12	0
Scarf	10	10	1	10	3
MyBloggie	9	9	0	9	0
Total	184	70%	5%	70%	27%

For the rather old and simple applications, all taintable columns were detected by our prototype. The modern and large applications often use loops to construct dynamic SQL queries where reconstruction is error-prone. Overall, we detected 70% of all taintable columns. When the database schema is known, 5% of our reports are FP. The root cause is path-sensitive sanitization of data that is written to the database—a sanitization that our current prototype is not able to detect yet. The false discovery rate is higher if the database schema of an application is not found. In this case, a static analysis tool cannot reason about data types within the database and may flag columns of numeric data type as taintable.

4.1.2 Sessions

To obtain a ground truth for our evaluation, we again manually assessed the applications' code for all accessed keys of the superglobal `$_SESSION` array. Dynamic keys were reconstructed and keys in multi-dimensional arrays were counted multiple times. Then, we manually examined which session keys are taintable by the application's user and compared this to the analysis result generated by our prototype implementation. As shown in Table 3, we found that only 12% of the 52 identified session keys are taintable within our selected applications.

Our prototype correctly detected all taintable session keys. One FP occurred because the sanitized email address of a user is written to the session after it is fetched from the database. This FP is based on the previously introduced FP in identifying taintable columns. A custom session management in *osCommerce* led to exclusion from our evaluation.

Table 3: Taintable session keys in selected applications.

Software	Keys	Taintable	TP	FP
HotCRP	29	2	2	0
OpenConf	14	2	1	0
NewsPro	2	1	1	0
Scarf	4	0	0	1
MyBloggie	3	1	1	0
Total	52	12%	83%	16%

4.1.3 File Names

To evaluate the features that allow an application's user to alter a file name, we again manually assessed each application for file upload, file creation, and file rename features and counted the different target paths to obtain a ground truth. Next, we counted the collected taintable path names reported by our prototype. The results are shown in Table 4.

Table 4: Taintable paths in selected applications.

Software	Paths	Taintable	TP	FP
osCommerce	2	2	2	0
HotCRP	1	0	0	0
OpenConf	1	0	0	1
NewsPro	1	0	0	0
Scarf	1	1	1	0
MyBloggie	2	2	2	0
Total	8	63%	100%	16%

We found at least one feature in each of the application's source code to create a new file. However, half of the applications sanitize the name of the file before creating it. Our prototype detected all taintable path names. One FP occurred for *OpenConf*, where uploaded files are sanitized in a path-sensitive way.

Interestingly, a file upload in *Scarf* is based on a second-order data flow. The name of the uploaded file is specified separately and stored as a configuration value in the database before it is read from the database again and the file is copied. Because no sanitization is applied, an administrator is able to copy any file to any location of the server's file system which leads to *remote code execution*. This critical vulnerability was missed in previous work that also used this application for evaluating their approach [3, 31].

4.2 Second-Order Vulnerabilities

We evaluated the ability of our prototype to detect second-order vulnerabilities. Reports of first-order vulnerabilities are ignored for now. Our prototype reported a total of 159 valid second-order vulnerabilities with a false discovery rate of 21% (see Table 5 for details). In summary, 97% of the valid reports are *persistent XSS* vulnerabilities where the payload is stored in the database. Five *persistent XSS* vulnerabilities are caused by session data or file names. This is closely related to the fact that 94% of all taintable PDS we identified are columns in database tables (see Section 4.1) and sensitive sinks such as `echo` are one of PHP's most prominent built-in features [10].

Table 5: Evaluation results for selected applications.

Software	Files	LOC	TP	FP	FN
osCommerce	570	66 381	97	29	6
HotCRP	74	40 339	1	1	0
OpenConf	121	20 404	16	4	0
NewsPro	23	5 077	7	1	0
Scarf	19	1 686	37	8	3
MyBloggie	58	9 485	1	0	0
Total	865	143 372	159	43	9
Average	144	23 895	79%	21%	

Our evaluation revealed that second-order vulnerabilities are highly critical. Next to *persistent XSS* and file vulnerabilities, we detected various *remote code execution* vulnerabilities in *osCommerce*, *OpenConf*, and *NewsPro*. In the following, we introduce two selected vulnerabilities to illustrate the complexity and severity of real-world second-order vulnerabilities. It is evident that these vulnerabilities could only be detected with our novel approach of analyzing second-order data flows.

4.2.1 Second-Order LFI to RCE in OpenConf

OpenConf is a well-known conference management software used by many (academic) conferences. Our prototype found a *second-order local file inclusion* vulnerability in the user-defined `printHeader` function that leads to *remote command execution*. The relevant parts of the affected file *include.php* is shown in Listing 6.

```
1  function printHeader($what, $function="0") {
2     require_once $GLOBALS['pfx'] .
3        $GLOBALS['OC_configAR']['OC_headerFile'];
4  }
5
6  $r = mysql_query("SELECT `setting`, `value`, `parse`
7                    FROM `" . OCC_TABLE_CONFIG . "`");
8  while ($l = mysql_fetch_assoc($r)) {
9     $OC_configAR[$l['setting']] = $l['value'];
10 }
11 printHeader();
```

Listing 6: Simplified *include.php* of *OpenConf*.

When looking at the code, it does not reveal any vulnerability. Whenever the code is included, settings are loaded from the database and the user-defined function `printHeader()` is called. This function includes a configured header file and prints some HTML.

```
1  function updateConfigSetting($setting, $value) {
2     $q = "UPDATE `" . OCC_TABLE_CONFIG . "`
3           SET `value`='" . safeSQLstr(trim($value)) . "'
4           WHERE `setting`='" . safeSQLstr($setting) . "'";
5     return(ocsql_query($q));
6  }
7
8  foreach (array_keys($_POST) as $p) {
9     if (preg_match("/^OC_[\w-]+$/", $p)) {
10       updateConfigSetting($p, $_POST[$p]);
11    }
12 }
```

Listing 7: Simplified code to change settings in *OpenConf*.

However, as shown in Listing 7, it is possible for a privileged chair user to change any configuration setting. The configuration page does not specify an input field to change the *headerFile* setting. Nonetheless, by adding the key *OC_headerFile* to a manipulated HTTP POST request, the setting is changed. The loop over the submitted keys of the `$_POST` array in Listing 7, line 8, as well as the loop over the `$OC_configAR` in Listing 6, line 9, shows once again how important it is to track the taint status of PHP's array keys precisely.

A chair member can now include any local file of the system to the output. Additionally, because the software allows to upload PDF files to the server, our prototype added a multi-step exploit report. Indeed, if a PDF file containing PHP code is uploaded to the server and the *headerFile* setting is pointed to that PDF, arbitrary PHP code is executed. Moreover, our tool reported a SQL injection vulnerability that is accessible to unprivileged users. This allows any visitor to extract the chair's password hash (salted SHA1) from the database.

4.2.2 Second-Order RCE in NewsPro

Utopia NewsPro is a blogging software and was used in previous work for evaluation [29–31]. Our prototype reported a *second-order code execution* vulnerability in the administrator interface. Here, a user is able to alter the template files of the blog. The simplified code is shown in Listing 8.

```
1 $tempid = (int)$_POST['tempid'];
2 $template = mysql_real_escape_string($_POST['template']);
3 $updateTemplate = mysql_query("UPDATE `unp_template`
4         SET template='$template' WHERE id='$tempid'");
```

Listing 8: Simplified code to change the template in *NewsPro*.

The template code is read from the database in various places of the source code with help of the user-defined function `unp_printTemplate()` (see Listing 9). First, this function writes the template's code to a cache array (line 6) and then returns it from this array again. The example demonstrates the importance of inter-procedural analysis and array handling.

```
1  function unp_printTemplate($template) {
2     global $templatecache, $DB;
3     $getTemplate = mysql_query("SELECT name,template
4       FROM `unp_template` WHERE name='$template' LIMIT 1");
5     while ($temp = mysql_fetch_array($getTemplate)) {
6        $templatecache[$template] = $temp['template'];
7     }
8     return addslashes($templatecache[$template]);
9  }
10 eval('$headlines_displaybit = "' .
11        unp_printTemplate('headlines_displaybit').'";');
```

Listing 9: Simplified *Remote Code Execution* vulnerability in *NewsPro*.

At the call-site, the fetched template is evaluated with PHP's `eval` operator that executes PHP code (line 10). The template's code is escaped (line 8), however, the double-quoted value of the evaluated variable `$headlines_displaybit` allows to execute arbitrary PHP code using curly syntax. By adding the code {${system(id)}} to a template, the system command *id* is executed. Note that related work missed to detect this vulnerability, which is also present in prior versions.

4.3 Multi-Step Exploits

Our prototype reported two *arbitrary file upload* vulnerabilities and 14 SQL injection vulnerabilities. Because these vulnerabilities affect a storage operation, the stored data can be manipulated during multi-step exploitation. Our prototype found 14 valid multi-step exploits and a single FP as shown in Table 6.

Table 6: Reported multi-step exploits in selected applications.

Software	File TP	SQLi TP	SQLi FP	Multi-Step TP	Multi-Step FP
osCommerce	1	3	0	3	0
HotCRP	0	1	7	0	1
OpenConf	0	4	1	1	0
NewsPro	0	6	0	9	0
Scarf	1	1	0	1	0
MyBloggie	0	5	0	0	0
Total	2	20	8	14	1
Average	100%	71%	29%	93%	7%

All detected multi-step exploits consist of two steps and no *third-order* vulnerabilities were detected within our selected applications. In the following, we examine two multi-step exploits in *osCommerce* that lead to *remote command execution* to illustrate that these vulnerabilities can only be detected with our novel approach of analyzing multi-step exploits.

4.3.1 Multi-Step RCE in osCommerce

OsCommerce is a popular e-commerce software. For one of three reported SQLi vulnerabilities in *osCommerce*, our prototype additionally reported a *multi-step remote code execution* exploit. The SQLi is located in the backup tool of the administrator interface and shown in Listing 10. Here, a SQL file is uploaded to restore a database backup. Since the name of the uploaded file is later used unsanitized in a SQL query, an attacker is able to insert any data into the `configuration` table by uploading a SQL file with a crafted name. This enables another, more severe vulnerability: the table `configuration` stores a `configuration_value` and a `configuration_title` for each setting. Furthermore, a `use_function` can be specified optionally to deploy the configuration's value.

```
1 $sql_file = new upload('sql_file');
2 $read_from = $sql_file->filename;
3 tep_db_query("insert into " . TABLE_CONFIGURATION .
4    " values (null, 'Last Database Restore', 'DB_RESTORE',
5    '" . $read_from . "', 'Last database restore file',
6    '6', '0', null, now(), '', '')");
```

Listing 10: Simplified code of the *backup.php* file in *osCommerce* shows a SQLi through a file name.

When the list of configuration values is loaded from the database, the function name specified in the `use_function` column is called with the `configuration_value` as argument (see Listing 11, line 5). An attacker can abuse the SQLi to insert an arbitrary PHP function's name, such as `system`, to the column `use_function` and insert an arbitrary argument, such as *id*, to the column `configuration_value`. When loading the configuration list, the specified function is fetched and called with the specified argument that executes the system command *id*.

```
1 $conf_query = tep_db_query("select configuration_id,
      configuration_title, configuration_value,
      use_function from " . TABLE_CONFIGURATION . " where
      configuration_group_id = '" . (int)$gID . "'");
2 while ($configuration = tep_db_fetch_array($conf_query)) {
3    if (tep_not_null($configuration['use_function'])) {
4       $use_function = $configuration['use_function'];
5       $cfgValue = call_user_func($use_function,
6                   $configuration['configuration_value']);
```

Listing 11: Simplified code of the *configuration.php* file in *osCommerce* demonstrates a *multi-step RCE*.

4.3.2 Sanitization Bypass in osCommerce

Another *multi-step RCE* exploit was reported in *osCommerce* that involves a sanitization bypass. The previously mentioned backup tool of the administrator interface allows to specify a local ZIP file that is unpacked via the system command *unzip*. Here, the target file name is specified as an argument in the command line if the specified file name exists on the file system. The simplified code is shown in Listing 12.

```
1 if (file_exists(DIR_FS_BACKUP . $HTTP_GET_VARS['file'])) {
2    $restore_file = DIR_FS_BACKUP . $HTTP_GET_VARS['file'];
3    exec(LOCAL_EXE_UNZIP . ' ' . $restore_file . ' -d ' .
         DIR_FS_BACKUP);
4 }
```

Listing 12: A dynamically constructed system command in *osCommerce* includes the name of an existing file.

An attacker can bypass this check by abusing one of the file upload functionalities in *osCommerce*. By uploading a file with the name *;id;.zip* and afterwards specifying this file as backup file, the command *id* is executed. The semicolons within the file name terminate the previous *unzip* command and introduce a new command.

4.4 False Positives

Our prototype generated 43 false second-order vulnerability reports, leading to a false discovery rate of 21% for our selected applications. All false positives are based on the fact that our prototype is not able to detect path-sensitive sanitization. Thus, *persistent XSS* was reported in *Scarf* and *HotCRP* that are based on email addresses stored in the database. Our prototype erroneously identified these columns as taintable (see Section 4.1.1). The same error applies to a paper format in *OpenConf* which leads to four false positives. A user-defined sanitization function using path-sensitive sanitization based on its argument lead to 29 false *persistent XSS* reports in *osCommerce*. A false multi-step exploit was reported in *HotCRP* caused by a false SQLi report. By performing a path-sensitive sanitization analysis, these false positives can be addressed in the future.

4.5 False Negatives

Evaluating false negatives is an error-prone task because the actual number of vulnerabilities is unknown. Furthermore, no CVE entries are public regarding second-order vulnerabilities in our selected applications. However, it is possible to test for false negatives that stem from insufficient detection of taintable PDS. By pre-configuring our implementation with the taintable PDS we identified manually, we can compare the amount of detected second-order vulnerabilities with the number of reports when PDS are analyzed automatically.

As a result, only six previously missed *persistent XSS* in *osCommerce* were reported. Additionally, another taintable session key in *OpenConf* was reported, although the key does not lead to a vulnerability. Furthermore, we manually inspected the source code of the applications and observed that our SQL parser needs improvement. Three false negatives occurred in *Scarf* because our parser does not handle SQL string functions such as `concat()`. More complex SQL instructions might lead to further false negatives but are used rarely.

4.6 Performance

We evaluated our prototype with the implementation of our approach to detect second-order vulnerabilities (+SO) and without it (-SO). Our testing environment was equipped with an Intel i7-2600 CPU with 3.4 GHz and 16 GB of memory. The amount of memory consumption (M, in megabytes), scan time (T, in seconds), and second-order vulnerability reports (R) for our selected applications are given in Table 7.

Table 7: Performance results for selected applications.

	-SO Analysis		+SO Analysis		
Software	M[mb]	T[s]	M[mb]	T[s]	R
osCommerce	834	134	846	213	129
HotCRP	752	186	775	345	3
OpenConf	528	33	523	47	21
NewsPro	50	1	50	3	17
Scarf	39	1	40	14	46
MyBloggie	87	7	87	11	1
Total	2290	362	2321	633	217
Average	382	60	387	106	36

While the memory consumption does not increase significantly by adding second-order analysis, the average scan time increases by 40%. Note, however, that this includes 217 processed vulnerability reports the prototype would have missed without the additional second-order analysis. Furthermore, we believe that a total scan time of less than 11 minutes for our selected applications is still reasonable.

5 Related Work

Web applications are widely used in the modern Web and as a result, security analysis of such applications has attracted a considerable amount of research. We now review related work in this area and discuss how our approach differs from previous approaches.

Dynamic Analysis There are many different dynamic approaches to perform a security analysis of a given web application. For example, Apollo [1] leverages symbolic and concrete execution techniques in combination with explicit-state model checking to perform persistent state analysis for session variables in PHP. Sekar proposes syntax- and taint-aware policies that can accurately detect and/or block most injection attacks [23]. However, such approaches are typically limited to simple types of taint-style vulnerabilities.

There are also dynamic approaches to detect second-order vulnerabilities. For example, McAllister et al. present a blackbox scanner capable of detecting *persistent XSS* [19]. Ardilla [14] aims at detecting both SQL injection and XSS vulnerabilities by generating sample inputs, symbolically tracking taint information through execution (including through database accesses), and automatically generating concrete exploits. The typical drawbacks of such dynamic approaches are the limited test coverage and the missing ability to crawl a given site "deep" enough. This insight is confirmed by Doupé et al., who tested eleven black-box dynamic vulnerability scanners and found that whole classes of vulnerabilities are not well-understood and cannot be detected by the state-of-the-art scanners [7].

Static Analysis We perform static analysis of PHP code and use the concept of *block summaries* as proposed by Xie and Aiken [30] and later on refined by Dahse and Holz [6]. Our analysis tool extends these ideas and we improved the modeling of the language. More precisely, we introduce more data symbols (e.g., to analyze array accesses in a more precise way) and enhance the analysis of built-in functions such that we can perform a taint analysis for persistent data stores. Furthermore, we optimized the inter-procedural analysis to refine our string analysis results. This enables us to analyze the *two* distinct data flows that lead to second-order vulnerabilities: (i) source to PDS and (ii) PDS to sink. As a result, we are able to detect vulnerabilities missed by these approaches. Pixy [11] and Saner [2] are other static code analysis tools for web applications, but both do not recognize second-order vulnerabilities.

There are static analysis approaches that target other classes of security vulnerabilities. For example, SaferPHP [25] attempts to find *semantic attacks* (e.g., denial of service attacks due to infinite loops caused by malicious inputs, or unauthorized database operations due to missing security checks) within web applications. RoleCast [24] identifies security-critical variables and applies role-specific variable consistency analysis to identify missing security checks, while Phantm [17] detects type errors in PHP code. Such kinds of software defects are out of scope for our analysis.

Static Second-Order Analysis The work closest related to our approach is MiMoSA [3]. It is an extension of Pixy [11] to detect multi-module data flow and work flow vulnerabilities. The data flow through databases is modeled, however, it uses a dynamic approach for the reconstruction of SQL queries. Moreover, it focuses on the detection of the work flow of an application and does not handle neither other types of PDS nor multi-step exploits. In comparison, only three data flow vulnerabilities were detected in *Scarf*, whereas our approach detected 37 second-order vulnerabilities and one multi-step exploit.

Zheng and Zhang proposed an approach to detect *atomicity violations* in web applications regarding external resources [31], which can be seen as being closely related to second-order vulnerabilities since such concurrency errors are a pre-condition for second-order exploits. They perform a context- and path-sensitive interprocedural static analysis to automatically detect atomicity violations on shared external resources. The tools *NewsPro* and *Scarf* are included into their evaluation, but the authors did not find any of the second-order vulnerabilities detected by our approach. As such, our approach outperformed prior work on static detection of second-order vulnerabilities.

6 Conclusion and Future Work

In this paper, we demonstrated that it is possible to statically model the data flow through persistent data stores by collecting all storage writings and readings. At the end of the analysis, we can determine if data read from a persistent store can be controlled by an attacker and if this leads to a security vulnerability. Our prototype implementation demonstrated that this is an overlooked problem in practice: we identified more than 150 vulnerabilities in six popular web applications and showed that prior work in this area did not detect these software defects. From a broader perspective, our approach can be broken down to the problem of statically reconstructing all strings that can be generated at runtime by the application and thus, is limited by the halting problem.

Future work includes modeling the data flow when prepared statements are used, supporting more SQL features, and analyzing data flow through file content. Also, path-sensitive sanitization and aliasing should be analyzed more precisely [32].

Abstract

Android, iOS, and Windows 8 are changing the application architecture of consumer operating systems. These new architectures required OS designers to rethink security and access control. While the new security architectures improve on traditional desktop and server OS designs, they lack sufficient protection semantics for different classes of OS customers (e.g., consumer, enterprise, and government). The Android OS in particular has seen over a dozen research proposals for security enhancements. This paper seeks to promote OS security extensibility in the Android OS. We propose the Android Security Modules (ASM) framework, which provides a *programmable interface* for defining new reference monitors for Android. We drive the ASM design by studying the authorization hook requirements of recent security enhancement proposals and identify that new OSes such as Android require new types of authorization hooks (e.g., replacing data). We describe the design and implementation of ASM and demonstrate its utility by developing reference monitors called *ASM apps*. Finally, ASM is not only beneficial for security researchers. If adopted by Google, we envision ASM enabling in-the-field security enhancement of Android devices without requiring root access, a significant limitation of existing bring-your-own-device solutions.

1 Introduction

Consumer operating systems are changing. Android, iOS, and Windows 8 place a high priority on the user-application experience. They provide new abstractions for developing user-applications: applications fill the screen; they have complex lifecycles that respond to user and system events; and they use semantically rich OS provided application programming interfaces (APIs) such as "get location," "take picture," and "search address book." The availability of these semantically rich OS APIs vastly simplifies application development, and has led to an explosive growth in the number and diversity of available applications.

These functional changes caused OS designers to rethink security. The new application abstractions both enable and necessitate assigning each user application to a unique protection domain, rather than executing all user applications with the user's ambient authority (the norm in traditional OSes such as Windows and UNIX). By default, each application's protection domain is small, often containing only the OS APIs deemed not to be security sensitive and the files it creates. The application must be granted capabilities to access the full set of semantically rich OS APIs. This security model provides a better approximation of least privilege, which limits both the impact of an exploited application, as well as the authority granted to a Trojan. However, how and when to grant these privileges has been the topic of much debate [16].

For the last several years, the security research community has contributed significant discourse on the right security architecture for these new operating systems. Android has been the focus of this discourse, mostly due to its open source foundation, widespread popularity for mobile devices, and the emergence of malware targeting it. In the relatively short period of time since the Android platform's initial release in 2008, there have been more than a dozen proposals for new Android security architectures [15, 24, 14, 23, 10, 7, 8, 37, 6, 19, 18, 12, 9, 22, 29]. As we discuss in this paper, while these security architecture proposals have very diverse motivations, their implementations often share hook placements and enforcement mechanisms.

The primary goal of this paper is to promote OS security extensibility [33] in the Android platform. History has shown that simply providing type enforcement, information flow control, or capabilities does not meet the demands of all potential OS customers (e.g., consumers,

*These authors contributed equally to this work.

enterprise, government). Therefore, an extensible OS security interface must be *programmable* [33]. In short, we seek to accomplish for Android what the LSM [34] and TrustedBSD [32] frameworks have provided for Linux and BSD, respectively. What makes this task interesting and meaningful to the research community is the process of determining the correct semantics of authorization hooks for this new OS architecture.

In this paper, we propose the *Android Security Modules* (ASM) framework, which provides a set of authorization hooks to build reference monitors for Android security. We survey over a dozen recent Android security architecture proposals to identify the hook semantics required of ASM. Of particular note, we identify the need to (1) replace data values in OS APIs, and (2) allow third-party applications to define new ASM hooks. We design and implement an open source version of ASM within Android version 4.4 and empirically demonstrate negligible overhead when no security module is loaded. ASM fulfills a strong need in the research community. It provides researchers a standardized interface for security architectures and will potentially lead to field enhancement of devices without modifying the system firmware (e.g., BYOD), if adopted by Google.

This paper makes the following contributions:

- *We identify the authorization hook semantics required for new operating systems such as Android.* The Android OS is responsible for enforcing more than just UNIX system calls. Android includes semantically rich OS APIs and new application lifecycle abstractions that must be included in OS access control. We also identify the need for authorization hooks to replace data values and for third-party applications to introduce new authorization hooks.

- *We design and implement the extensible Android Security Modules (ASM) framework.* ASM brings OS security extensibility to Android. It allows multiple simultaneous *ASM apps* to enforce security requirements while minimizing performance overhead based on the required authorization hooks.

- *We implement two example ASM apps to demonstrate the utility of the ASM framework.* ASM allowed the fast development of useful example ASM apps with functionalities similar to MockDroid [6] and password protected apps.

Finally, we envision multiple ways in which ASM can benefit the security community. ASM currently provides great value to researchers with the ability to modify the source code of a device. It provides a modular interface to define callbacks for a set of authorization hooks that provide mediation of important protection events. As the Android OS changes, only the ASM hook placements need to change, eliminating the need to port each research project to new versions. ASM can provide even greater benefit if it is adopted into the Android Open Source Project (AOSP): ASM apps can be added without source code modification. Ultimately, *we envision an interface that allows enterprise IT and researchers to load ASM apps on production phones without root access.*

The remainder of this paper proceeds as follows. Section 2 provides a short background on Android. Section 3 defines high level goals that underlie the ASM design. Section 4 surveys recent work enhancing Android security and identifies a common set of authorization hook semantics. Section 5 describes the ASM design. Section 6 evaluates the utility and performance of ASM. Section 7 highlights related work on OS security extensibility. Section 8 concludes.

2 Background

The Android OS is based on a Linux kernel, but provides a substantially different application abstraction than found in traditional Linux desktop and server distributions. Android applications are written in Java and compiled into a special DEX bytecode that executes in Android's Dalvik virtual machine. Applications may optionally contain native code components. Application functionality is divided into components. Android defines four types of components: *activity*, *service*, *broadcast receiver*, and *content provider*. The application's user interface is composed of a set of activity components. Service components act as daemons, providing background processing. Broadcast receiver components handle asynchronous messages. Content provider components are per-application data servers that are queried by other applications.

Application components communicate with one another using Binder interprocess communication (IPC). Binder provides message passing (called *parcels*) and thread management. In addition to data values, parcels can pass references to other binder objects as well as file descriptors. When an application holds a reference to a service component binder object, it can execute remote procedure calls (RPCs) for any methods defined by that service. Most of Android's semantically rich OS APIs are implemented as RPCs to OS defined service components. The OS also defines several content provider components (e.g., address book) that are queried using special RPC methods. It should be noted that while developers are encouraged to use Binder IPC, Android also supports standard Linux IPC mechanisms, for example domain sockets or pipes.

Applications often interface with Binder indirectly using *intent messages*. The intent message abstraction is used for communication between activity and broadcast

receiver components, as well as starting service components. Intent messages can be addressed to implicit *action strings* that are resolved by the Activity Manager Service (AMS). Intent messages and action strings allow end users and OEMs to customize the applications used to perform tasks. The AMS resolves the desired target application and component, starting a new process or thread if necessary.

Android enforces component security requirements using *permissions* (i.e., text strings that represent capabilities). Android defines a set of core permissions for protecting OS resources and applications, but third-party application developers can define new permissions that are enforced using the same mechanisms as OS permissions. Permissions are granted to applications on install and stored in the Package Manager Service (PMS). Android places authorization hooks (implemented as a family of *checkPermission()* methods) in the AMS as well as OS service component RPC methods. *checkPermission()* is called along with the process identifier (PID) of the caller and the appropriate permission string. Calling *checkPermission()* invokes an RPC in the PMS, which returns *granted* if the caller's PID belongs to an application that is granted the permission, and throws a security exception if it is denied. However, not all permissions are enforced using *checkPermission()*. Permissions that control access to low-level capabilities are mapped to Linux group identifiers (GIDs). Such capabilities include opening network sockets and accessing the SDcard storage. For these permissions, corresponding GIDs are assigned to applications at installation time, and the kernel provides enforcement.

3 Design Goals

A secure operating system requires a *reference monitor* [2]. Ideally, a reference monitor provides three guarantees: complete mediation, tamperpoofness, and verifiability. We seek to provide a foundation for building reference monitors in Android. As with LSM [34], the ASM only provides the reference monitor interface hooks upon which authorization modules are built. Furthermore, similar to the initial design of LSM, our ASM design manually places hooks throughout Android.

We seek to design a programmable interface for building new security enhancements to the Android platform. Our design is guided by the following goals.

G1 *Generic authorization expressibility.* We seek to provide the reference monitor interface hooks necessary to develop both prior and future security enhancements for Android. Not all authorization modules will use all hooks, and hooks may need to be placed at different levels to obtain sufficient enforcement semantics.

G2 *Ensure existing security guarantees.* Android provides sandboxing guarantees to application providers. Allowing third-parties to extend Android's security framework potentially breaks those guarantees. Therefore, ASM's reference monitor interface hooks should only make enforcement more restrictive (e.g., fewer permissions or less file system access). Note that by only allowing more restrictive enforcement, we lose expressibility (e.g., for capability models).

G3 *Protect kernel integrity.* As an explicit extension to Goal **G2**, we must maintain kernel integrity. Some authorization modules will require hooks within the Linux kernel. We cannot provide the LSM interface to third-parties without some controls. We explore several methods of exposing this functionality in Section 5.4.5.

G4 *Multiple authorization modules.* While there have been proposals for supporting multiple LSMs [27], official support for multiple authorization modules in Linux has not been adopted at the time of writing. We see benefit in allowing multiple ASM modules (e.g., personal and enterprise) and seek to design support for multiple authorization modules into the design of ASM. Achieving multiple authorization modules requires carefully designing the architecture to address potential conflicts.

G5 *Minimize resource overhead.* When no authorization module is loaded, ASM should have negligible impact on system resources (e.g., CPU performance, energy consumption). Furthermore, given the wide variety of authorization hook semantics, we recognize that not all authorization modules will require all hooks. Since some hooks have more overhead than others, we seek to design ASM such that different hooks can be enabled and disabled to minimize overhead.

Threat Model: ASM assumes that the base Android OS and services are trusted. That is, our trusted computing base (TCB) includes the Linux kernel, the AMS, the PMS, and all OS service and content provider components. We assume that third-party applications have complete control over their process address spaces. That is, any authorization hooks placed in framework code that executes within the third-party application's process is untrusted. Finally, since third-party applications can include their own authorization hooks, they must be trusted to mediate the protection events they define.

4 Authorization Hook Semantics

The underlying motivation of ASM is to provide a programmable interface to extend Android security. Re-

Table 1: Classification of authorization hook semantics required by Android security enhancements

System	Android ICC	Package Manager	Sensors / Phone Info	Fake Data	System Content Providers	File Access	Network Access	Third Party Extension

SEAndroid [29]	✓	✓				✓	✓	
TISSA [37]			✓	✓	✓			

cently, Google adopted the UNIX-level portion of the SEAndroid [29] project into AOSP. However, Android security is significantly more complex than simply mediating UNIX system calls. Nearly all application communication occurs through Binder IPC, which from a UNIX perspective is an *ioctl* to `/dev/binder`. Mediating the higher level application communication has been the focus of most Android security research. The goal of this section is to explore these different proposals to identify a common set of authorization hooks semantics. That is, we seek to satisfy Goal **G1** by surveying existing proposals to enhance Android security.

Academic and industry researchers have proposed many different security enhancements to the Android OS. These enhancements have a wide range of motivations. For example, Kirin [15] places constraints on permissions of applications being installed. Frameworks such as Saint [24], XManDroid [7] and TrustDroid [8] focus on mediating communication between components in different applications. FlaskDroid [9] and the aforementioned SEAndroid [29] project also mediate component interaction as a part of their enforcement. Aquifer [22] enforces information flow control policies that follow the user's UI workflow. IPC Inspection [18] and Quire [12] track Android intent messages through a chain of applications to prevent privilege escalation attacks. TaintDroid [14] and AppFence [19] dynamically track privacy sensitive information as it is used within an application. APEX [23] and CRePE [10] provide fine-grained permissions. TISSA [37], MockDroid [6], and AppFence [19] allow fine-grained policies as well as allow the substitution of fake information into Android APIs. While these proposals have diverse motivations, many share authorization hook semantics.

Table 1 classifies this prior work by authorization hook semantics. Nearly all of the proposals modify Android's Activity Manager Service (AMS) to provide additional constraints on Inter-Component Communication (ICC). The Package Manager Service (PMS) is also frequently modified to customize application permissions. Permissions are also occasionally customized by modifying the interfaces to device sensors and system content providers containing privacy sensitive information (e.g., address book). Several proposals also require authorization hooks for file and network access, which are enforced in the Linux kernel.

The table also denotes two areas that are nonstandard for OS reference monitors. The first hook semantics is the use of fake data. That is, instead of simply allowing or denying a protected operation, the hook must modify the value that is returned. This third option is often essential to protecting user privacy while maintaining usability. For example, the geographic coordinates of the north pole, or maybe a coarse city coordinates can be substituted for the devices actual location. Replacing unique identifiers (e.g. IMEI or IMSI) to combat advertising tracking is a further example. The second interesting hook semantics is the inclusion of third-party hooks. That is, a third-party application wishes the OS reference monitor to help enforce its security goals.

Finally, TaintDroid [14] and AppFence [19] use fine-grained taint tracking. They modify Android's Dalvik environment to track information within a process. However, dynamic taint tracking has false negatives, which may lead to access control circumvention. It also incurs more performance overhead than may be tolerable for some environments. In this work, we only consider mediation at the process level. Therefore, TaintDroid and AppFence cannot be built on top of ASM. However, this does not preclude researchers from combining TaintDroid with ASM.

5 ASM Design

The authorization hooks identified in the previous section describe semantically what to mediate, but not how to mediate it. Existing Android security enhancements

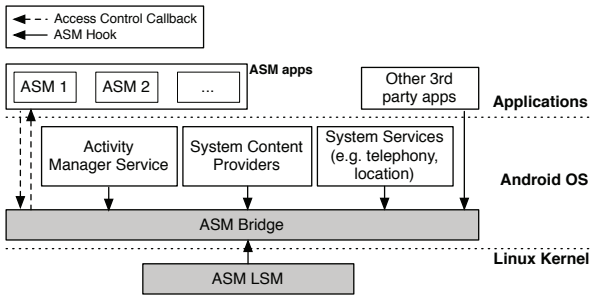

Figure 1: ASM framework architecture

define hooks in different ways, not all of which provide correct or complete mediation. ASM provides a reference monitor interface for building new reference monitors. By doing so, ASM allows reference monitor developers to focus on their novel security enhancements and not on placing hooks correctly. It also allows separate scrutiny of authorization hook placement that benefits all reference monitors built on top of ASM.

Figure 1 shows the ASM framework architecture. Reference monitors are implemented as *ASM apps*. Each ASM app registers for a unique set of authorization hooks, specifying a callback for each. When a protected operation occurs, ASM automatically invokes the callback in the ASM app. The ASM reference monitor interface is contained within the *ASM Bridge*. In addition to managing ASM apps, the ASM Bridge receives protection events from authorization hooks placed throughout the Android OS. Since Android places functionality in multiple userspace processes, authorization hooks only notify the ASM Bridge if the hook is explicitly enabled. ASM also supports authorization hooks within the Linux kernel. To achieve kernel authorization, a special ASM LSM performs upcalls to the ASM Bridge, again only doing so for hooks explicitly enabled.

This section details the design of the ASM framework. We use the following terminology. A *protection event* is an OS event requiring access control. *Authorization hooks* are placed throughout the Android OS, which invoke a callback in the ASM Bridge. The ASM Bridge defines *reference monitor interface hooks*, for which ASM apps register *hook callbacks*. Finally, we frequently refer to the ASM framework as a whole simply as *ASM*.

5.1 ASM Apps

Reference monitors are built as ASM apps. They are developed using the same conventions as other Android applications. The core part of an ASM app is a service component that implements the reference monitor hook interface provided by ASM. There are three main functionalities that must be provided within this service. Finally, the registration interface itself is protected by Android permissions.

ASM App Registration: An ASM app must register itself with the ASM Bridge after it is installed. The time of registration depends on logic in the specific ASM app. For example, the ASM app could register itself automatically after install, or it could provide a user interface to enable and disable it. When the ASM Bridge receives the registration, it updates its persistent configuration. To activate the ASM app, the device must reboot. We require a reboot to ensure ASM apps receive all protection events since boot, which may impact their protection state.

Hook Registration: The ASM app service component is started by ASM during the boot process. At this time, the ASM app registers for reference monitor interface hooks for which it wishes to receive callbacks. Different hooks incur different overheads. ASM only enables a reference monitor hook if it is registered by an ASM app. Therefore, ASM app developers should only register for the hooks required for complete mediation. Finally, if the ASM registers for hooks defined by a third-party application (Section 5.4.4), the application developer and the ASM app developer must agree on naming conventions.

Handling Hook Callbacks: Once an ASM app registers for a reference monitor interface hook, it will receive a callback whenever the corresponding protection event occurs. The information provided in the callback is hook-specific. The ASM app returns the access control decision to the ASM Bridge. As discussed in Section 5.3, some hooks allow the callback to replace data values. Finally, similar to registration for third-party hooks, the ASM app developer must coordinate with the application developer for information passed to the callback.

Registration Protection: Reference monitors are highly privileged. While ASM does not allow an ASM app to override existing Android security protections (Goal **G2**), ASM must still protect the ability to receive callbacks. ASM protects callbacks using Android's existing permission model. It defines two permissions: `REGISTER_ASM` and `REGISTER_ASM_MODIFY`. The ASM Bridge ensures that an ASM app has the `REGISTER_ASM` permission during both ASM app registration and hook registration. Finally, since replacing data values in an access control callback has greater security implications, the ASM Bridge ensures the ASM app has the `REGISTER_ASM_MODIFY` permission if it registers for a hook that allows data modification. This allows easy ASM app inspection to identify its abilities.

ASM App Deployment: How the ASM permissions are granted has a significant impact on the practical security of devices. Previous studies [17] have demonstrated that end users frequently do not read or understand Android's install time permissions. Therefore, malware may attempt to exploit user comprehension of permissions and gain ASM app privileges. To some extent, this threat is

mitigated by our goal to ensure existing security guarantees (Goal **G2**). Different ASM app deployment models can also mitigate malware. In the use case where researchers change AOSP source code, these permissions can be bound to the firmware signing key, thereby only allowing the researchers' ASM apps to be granted access. In the case where ASM is deployed on production devices, ASM could follow the security model used by device administration API. That is, a secure setting that is only modifiable by users would enable whether ASM apps can be used. An alternative is to use a model similar to Android's "Unknown sources" setting for installing applications. That is, unless a secure user setting is selected, only Google certified ASM apps can be installed.

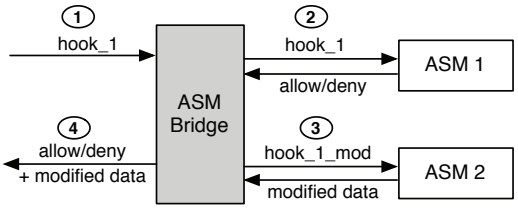
5.2 ASM Bridge

The ASM Bridge 1) provides the reference monitor interface, and 2) coordinates protection events that occur in authorization hooks placed throughout the Android OS, as well as third-party applications. As discussed in Section 5.1, ASM apps notify the ASM Bridge of their existence via an ASM app registration followed by individual hook registrations. We now discuss several reference monitor interface considerations.

Per-Hook Activation: All reference monitor interface hooks are deactivated by default. Each authorization hook maintains an activation state variable that determines whether or not the ASM Bridge is notified of protection events. This approach eliminates unnecessary IPC and therefore improves performance (Goal **G5**) when no ASM app requires a specific hook. Likewise, this approach allows ASM to achieve negligible overheard when no ASM apps are loaded (see Section 6.2).

When an ASM app registers a callback for a deactivated hook, the ASM Bridge activates the hook by notifying the corresponding authorization hook implementation. ASM maintains a list of active hooks in each OS component (e.g., OS service component, OS content provider component). When a protection event occurs, the OS component creates an access control bundle that is sent to the ASM Bridge. When the ASM Bridge receives the access control bundle for a hook, it is forwarded to each ASM app that registered for the hook. Similarly, the ASM LSM in the kernel (Section 5.4.5) maintains a separate activation state variable per hook and performs an upcall for each protection event.

Callback Timeouts: The ASM Bridge is notified of protection events via synchronous communication. Authorization hooks in userspace communicate with the ASM Bridge using Binder IPC, and the ASM LSM uses synchronous upcalls, as described in Section 5.4.5. The ASM Bridge then uses synchronous Binder IPC to invoke all ASM app callbacks for the hook corresponding



1. ASM Bridge receives a callback.
2. The normal hook is invoked.
3. The modified data hook (i.e. mod) is invoked.
4. ASM Bridge returns the result for the initial callback.

Figure 2: ASM Hook Invocation

to the protection event. If the ASM app callback implementation is buggy, the authorization hook may stall execution. Therefore, ASM has the ability to set timeouts on callback execution. If a timeout occurs, the ASM Bridge conservatively assumes access is denied.

Master Policy: ASM supports multiple simultaneous ASM apps (Goal **G4**). This goal is motivated by multi-stakeholder scenarios, e.g. users, administrators, and device manufacturers installing ASM apps on a device. When more than one ASM app is active, a reconciliation strategy is required to handle potential conflicts between access control decisions. The correct conflict resolution strategy is highly use-case specific. Therefore, providing a general solution is infeasible [9].

ASM addresses this problem using a master policy that defines policy conflict reconciliation. For our implementation and evaluation, we use a consensus strategy. That is, all active ASM apps must grant an access control decision for the action to be allowed. Similar to FlaskDroid [9], the master policy can be easily modified to support other conflict resolution strategies [26, 21]. For example, a priority-based resolution policy hierarchically orders ASM apps, and a voting policy allows an action if a specified threshold of ASM apps grant it.

5.3 Callbacks Modifying Data

Before discussing the reference monitor interface hooks provided by ASM, we must describe one last concept. While most ASM apps require a simple allow/deny access control interface, some may benefit from the ability to modify data values. For example, MockDroid [6] modifies values (e.g., IMEI, location) returned by OS APIs before they are sent to applications. ASM supports data modifications by providing a special hook type.

Each reference monitor interface hook that potentially requires data replacement is split into two variants: 1) *normal*, which allows the corresponding callback to simply allow or deny the event, and 2) *modify*, which allows the corresponding callback to modify the value returned by the OS API or content provider, in addition to specifying allow or deny. As mentioned in Section 5.1, modifying data has a greater security sensitivity,

```
1 // Callback received by the ASM Bridge:
2 int start_act(inout Intent intent, in String
   resolvedType, in ActivityInfo activity, int
   requestCode, int callingPid, int callingUid);
3 // Callback to individual ASMs (No modify data):
4 int start_act(in Intent intent, in String
   resolvedType, in ActivityInfo activity, int
   requestCode, int callingPid, int callingUid);
5 // Callback to individual ASMs (Modify data):
6 int start_act_mod(in Intent intent, inout Bundle
   extras, in String resolvedType, in ActivityInfo
   activity, int requestCode, int callingPid, int
   callingUid);
```

Listing 1: Example Callback Prototypes Modifying Data

and therefore registration of a *modify* callback requires the `REGISTER_ASM_MODIFY` permission.

Figure 2 shows how the ASM Bridge manages normal and modify hooks. To reduce the overhead of handling authorization hooks, the ASM Bridge is only notified once per protection event. The ASM Bridge then manages the normal and modify versions, returning the access control decision and modified data value (if needed) to the authorization hook. Additionally, the ASM Bridge invokes all of the normal callbacks before the modify versions. This approach allows a performance improvement if a consensus master policy is used (Section 5.2). In this case, if a normal hook denies access, the modify callbacks do not need to be called.

Example 1: Listing 1 explains this distinction further via example. The listing shows the callback prototypes for the `start_activity` protection event. The first prototype shown, `start_act()`, is the ASM Bridge callback used by the authorization hook in the Activity Stack subsystem of Android's AMS. This hook is invoked after intent resolution but before the chosen activity component is started. The hook includes 1) the intent message from the caller, 2) information about the activity to be started, 3) the caller's identity, and 4) additional information for the current event. By marking *intent* as *inout* (a directive defined in the *Android Interface Definition Language*), the ASM Bridge can modify it.

The ASM Bridge splits `start_act()` into the normal and modify versions. To ensure restrictive enforcement, ASM apps can modify only the *extras* field supplied by the caller. It cannot modify information that has been reviewed by the user or the OS, such as the action string or the target activity. To ensure this restriction, the ASM Bridge makes the intent immutable, but supplies a mutable *Bundle* of extras extracted from the intent to the ASMs registered for the modify data hook. The modified extras received by the ASM Bridge are then set back to the intent before the initial callback from the Activity Stack to the ASM Bridge returns.

```
1 // Callback received by the ASM Bridge:
2 int resolveActivity_mod(inout List<ResolveInfo>
   resolvedList, in String resolvedtype, int userId,
   inout Intent intent, int callingPid, int callingUid);
3 // Callback to individual ASM apps (Modify data):
4 int resolveActivity_mod(inout List<ResolveInfo>
   resolvedList, in String resolvedtype, int userId, in
   Intent intent, int callingPid, int callingUid, inout
   Bundle extras);
```

Listing 2: Resolve Activity Hook

5.4 Hook Types

ASM provides a reference monitor interface for authorization hooks placed throughout the Android OS. We now describe five general categories of hooks: 1) lifecycle hooks, 2) OS service hooks, 3) OS content provider hooks, 4) third-party app hooks, and 5) LSM hooks.

5.4.1 Lifecycle Hooks

ASM provides reference monitor hooks for component lifecycle events in the Activity Manager Service, the AMS subsystems, and the Package Manager Service. Hooks in this category include: resolving intents, starting activities and services, binding to services, dynamic registration of broadcast receivers, and receiving broadcast intents. We demonstrate the lifecycle hook category with the following example. Note that Example 1 is also a lifecycle hook.

Example 2: The `resolve_activity` protection event occurs within the Package Manager Service. The ASM authorization hook for `resolve_activity` is placed in the PMS after the intent has been resolved by the OS, but before a chooser with the resolved activities is presented to the user. This hook is motivated by systems such as Saint [24] and Aquifer [22], which refine the list of resolved applications based on access control policies. Note that refining the chooser list requires data modification, and therefore, `resolve_activity` is one of few hooks that only provide a modify version.

Listing 2 shows the callback prototypes defined for `resolve_activity`. The callback received by the ASM Bridge from the Android OS contains the list of resolved components. The ASM Bridge then executes an RPC to the ASM app callbacks registered for this hook. The RPC provides a modifiable resolved component list and Bundle extras. The other parameters are immutable. It is important to prevent the ASM from adding new apps to the list, thereby overriding the OS's restrictions (Goal **G2**). Therefore, we compute the set intersection of the original list and the modified list, and return the result to the authorization hook. When multiple ASM apps register for this hook, the ASM Bridge calls the hook callback for each ASM app, providing the modified data from the previous invocation as input.

5.4.2 OS Service Hooks

Lifecycle hooks include mediation for inter-component communication using intent messages. However, ASM apps also require mediation for OS APIs providing functionality such as getting the geographic location and taking pictures. Android implements this functionality in different service components designated as *system services*, e.g., location and telephony services.

ASM uses Android's AppOps subsystem to place the authorization hooks for many OS service hooks. AppOps is a very recent addition to AOSP. While there have been several popular media stories of hobbyist developers using AppOps to control per-application permissions, AppOps remains largely undocumented and is not yet available for public use. Based on our code inspection, AppOps appears to be an effort by Google to provide more flexible control of permission related events. Conceptually, AppOps is an Android security enhancement and could be implemented as an ASM app. We discuss AppOps as an ASM app further in Section 7.

The ASM authorization hooks for services use the AppOps syntax. AppOps defines opcodes for different operations, e.g., `OP_READ_CONTACTS` or `OP_SEND_SMS`. To identify the application performing an operation, the Linux uid and the package name of the application are used. ASM uses a single authorization hook in AppOps to call the ASM Bridge. The ASM Bridge decodes the opcode and translates it into an ASM hook.

AppOps supports graceful enforcement. That is, it returns empty data instead of throwing a Security Exception wherever possible (e.g., in Cursors). As a result, apps do not crash when they are denied access to resources. On the other hand, AppOps does not allow data values to be modified at runtime. Therefore, ASM adds specific data modification hooks. We also needed to extend AppOps with several hooks for privacy sensitive operations (e.g., `getDeviceId()`, `onLocationChanged()`). We now discuss two examples, including both regular AppOps hooks and ASM's data modification hooks.

Example 3: Listing 3 shows the callback prototype for the AppOps hook for sending an SMS (`OP_SEND_SMS`). The ASM Bridge receives the generic `appOpsQuery()` callback and translates the opcode to the `sendSms()` hook. ASM apps registered for the `sendSms()` hook receive a callback whenever an SMS message is sent.

Example 4: Listing 4 shows the data modification callback prototype for the `getDeviceId()` OS API call in the PhoneSubInfo (i.e., telephony) service. The ASM Bridge receives a callback from the authorization hook and executes the `getDeviceId_mod()` callback in ASM apps. ASM apps receiving this callback can return *deny* or *allow*. If the return value is *allow*, the ASM app can also place a custom value in the first index of the `device_ids` array. This value will be sent to the Android application that invoked `getDeviceId()`, instead of the real device ID.

```
1 // Callback received by the ASM Bridge:
2 int appOpsQuery(int opcode, int callingUid, String
   packageName);
3 // Here, opcode = OP_SEND_SMS
4 // Callback to individual ASMs:
5 int sendSms(int callingUid, String packageName);
```

Listing 3: AppOps Hook for Sending SMS

```
1 // Callback received by the ASM Bridge:
2 int getDeviceId(int callingUid, out String[]
   device_ids);
3 // Callback to individual ASMs (Modify data):
4 int getDeviceId_mod(int callingUid, out String[]
   device_ids);
```

Listing 4: getDeviceId Hook

5.4.3 Content Provider Hooks

Content provider components are daemons that provide a relational database interface for sharing information with other applications. The ASM Bridge receives callbacks from the OS content provider components (e.g., Calendar, Contacts, and Telephony). Separate hooks are required for the insert, update, delete and query functions. Authorization hooks for insert, update and delete must be invoked *before* the action is performed, to preserve the integrity of the provider's data. In contrast, the query function's hook is invoked *after* the execution, to allow filtering of the returned data.

The content provider query RPC returns a database Cursor object. The Cursor object not a *parcelable* type, and therefore the entire query response is not returned to the caller in a single Binder message. Therefore, ASM apps cannot filter the query. To account for this, we extract the Cursor contents into a parcelable *ASMCursor* wrapper around a *CursorWindow* object to include in the callback to the ASM Bridge.

The following example demonstrates the query interface. ASM only provides normal (i.e., no data modification) hooks for insert, delete, and update.

Example 5: Listing 5 shows the callback prototypes for the `CallLogProvider` OS content provider. The ASM Bridge receives the original query and the result wrapped in an ASMCursor. The callback is split into normal and modify hook variants. ASM apps that register for the normal hook get read access to the query and the result. ASM apps registered for the data modify hook can also modify the ASMCursor object. Both the hooks return allow and deny decisions via the return value.

Finally, we note that this use of a CursorWindow object to copy the entire content provider query response

```
// Callback received by the ASM Bridge:
int callLogQuery(inout ASMCursor cursor, in Uri uri,
 in String[] projection, in String selection, in
 String[] selectionArgs, in String sortOrder, int
 callingUid, int callingPid);
// Callback to individual ASMs (No modify data):
int callLogQuery(in ASMCursor cursor, in Uri uri, in
 String[] projection, in String selection, in String[]
  selectionArgs, in String sortOrder, int callingUid,
 int callingPid);
// Callback to individual ASMs (Modify data):
int callLogQuery_mod(inout ASMCursor cTemp, in Uri
 uri, in String[] projection, in String selection, in
 String[] selectionArgs, in String sortOrder, int
 callingUid, int callingPid);
```

Listing 5: CallLogProvider query hook

```
// Callbacks received by the ASM Bridge:
int hook_handler(in String name, in Bundle b);
int hook_handler_mod(in String name, inout Bundle b);
// Callback to individual ASMs (No modify data):
int hook_handler(in String name, in Bundle b);
// Callback to individual ASMs (Modify data):
int hook_handler_mod(in String name, inout Bundle b);
```

Listing 6: Third Party Hooks

into the ASM hook may lead to additional overhead when query responses are large. This is because Android uses a lazy retrieval of Cursor contents, only transferring portions of the response over Binder IPC as needed. One way to improve ASM query performance is to intercept the actual data access via Binder to modify data, rather than serializing the entire response. However, this will increase the number of callbacks to ASM apps, resulting in a trade-off. We will explore this and other methods of performance improvement in future work.

5.4.4 Third Party Hooks

ASM allows third-party Android applications to dynamically add hooks to the ASM Bridge. These hooks are valuable for extending enforcement into Google and device manufacturer applications (which are not in AOSP), as well as third-party applications downloaded from application markets (e.g., Google Play Store). Third-party hooks are identified by 1) a hook name, and 2) the package name of the application implementing the authorization hook. The complete hook name is a character string of the format `package_name:hook_name`. This naming convention provides third parties with their own namespaces for hooks. Note that third parties do not specify their package name; ASM obtains it using the registering application's uid received from Binder.

To receive callbacks for third-party hooks, ASM apps implement two generic third-party hook methods, shown in Listing 6. One method handles normal hook callbacks; the other method handles data modification hook callbacks. When the third-party application's authorization hook calls the ASM Bridge callback, it passes a generic Bundle object. The ASM forwards the Bundle to registered ASM apps for access control decisions. As with other ASM authorization hooks, third-party hooks are only activated when an ASM app registers for it.

ASM apps receive hook callbacks for all of their registered third-party hooks via a single interface (technically two callbacks, as in Listing 6). Within this callback, ASM apps must identify the third-party hook by name and must interpret the data in the Bundle based on the third-party application's specification. We assume that ASM apps that register for third-party hooks are aware of the absolute hook name and the contained attributes. The ASM app returns allow, deny, or allow along with a modification of the Bundle (for data modification hooks).

Finally, the third-party application developer must implement a special service component to receive hook activation and deactivation callbacks from the ASM Bridge. The ASM Bridge sends messages to this service to update the status of a hook. Third-party application developers must follow the message codes exposed by ASM for proper hook management.

5.4.5 LSM Hooks

ASM apps sometimes require mediation of UNIX-level objects such as files and network sockets. ASM cannot define authorization hooks for such objects in the userspace portion of the Android OS. Instead, authorization hooks must be placed in the Linux kernel. Fortunately, the Linux kernel already has the LSM reference monitor interface for defining kernel reference monitors. For example, `file_permission` and `socket_connect` LSM hooks mediate file and network socket operations, respectively.

The main consideration for ASM is how to allow ASM apps to interface with these LSM hooks. Several potential approaches exist. First, ASM could allow ASM apps to load LSM kernel modules directly. This approach is appropriate when the ASM app developer also has the ability to rebuild the device firmware. For example, one target audience for ASM is security researchers prototyping new reference monitors. In this case, the ASM app developer can create userspace and kernel components and provide communication between the two.

However, we would like to also allow ASM apps to mediate kernel-level objects without rebuilding the device firmware. Therefore, a second option is to develop a small mediation programming language that is interpreted by an ASM LSM. In this model, the ASM app developer programs access control logic within the interpreted language, and the logic is loaded along with the ASM on boot. Using an interpreted language would ensure kernel integrity (Goal **G3**).

Our current implementation uses a third option. We define a special ASM LSM that implements LSM hooks and performs synchronous upcalls to the ASM Bridge to complete the access control decision. Consistent with the

rest of the ASM design, the upcall is only activated when an ASM app registers for the corresponding reference monitor hook. To integrate our ASM LSM into the kernel without removing SEAndroid (Goal **G2**), we used an unofficial multi-LSM patch [27]. We implemented authorization hooks for many commonly used LSM hooks, including `file_permission` and `socket_connect`.

While the upcall approach initially sounds like it would have very slow performance, our key observation is that many ASM apps will require very few, if any, LSM hooks. For example, an ASM app for Aquifer [22] would only require the `file_permission` and `socket_connect` LSM hooks. Section 6.2 shows that both of the aforementioned hooks can be evaluated in userspace with reasonable performance overhead. Furthermore, placing all ASM app logic in one place (i.e., userspace) simplifies reference monitor design.

To improve access performance for large files, we implemented a cache with an expiration policy, where file accesses (euid, pid, inode, access_mask) and decisions received from ASM apps on those accesses are cached; and are invalidated if the accesses do not repeat within a timeout period of 1 ms. Since we cache and match the file inode as well as the accessing subject's effective uid and pid, we do not provide an attacker the opportunity of taking advantage of a race condition (i.e., requesting for a file less than 1ms after its access is granted).

Note that this approach may lead to a case where file access control is too coarse grained for a particular ASM app. For example, consider a situation where an application on the device reads a file continuously. An ASM app grants this application access, but if at some point during these accesses it wants to deny the access to this file, the `file_permission` hook is not triggered since the file is read before the timeout expires resulting in cache hits. To address this problem, we allow ASM apps to set this timeout. If multiple ASM apps set a timeout, the master policy can determine the timeout, e.g., the smallest timeout. ASM apps may also disable the cache, which provides all file access control callbacks to the ASM, but also degrades the performance of file reads.

5.5 ASM LSM

Finally, the ASM LSM provides two security features in addition to the LSM hook upcalls. First, it implements the `task_kill` LSM hook to prevent registered ASM apps from being killed. As we discuss in Section 6.1, some existing security enhancements can be disabled by killing their processes. Second, it implements the `inode_*xattr` LSM hooks to provide ASM apps access to their own unique extended attribute namespaces. That is, an ASM app can use file xattrs with a prefix matching its package name. No other applications can access these xattrs. File xattrs are needed by security enhancements such as Aquifer [22].

6 Evaluation

We evaluate the ASM framework in two ways. First, we evaluate the utility of ASM via case study by implementing two recent security enhancements for Android as ASM apps. Second, we evaluate the resource impact of ASM with respect to both performance and energy consumption. We implemented ASM on Android version 4.4.1, hence we use the Android 4.4.1 AOSP build as our baseline. All the experiments were performed on an LG Nexus 4 (GSM). The source code for ASM is available at `http://androidsecuritymodules.org`.

6.1 Case Studies

In this section, we evaluate the utility of ASM by implementing existing security solutions as ASM apps. We implement and study two examples: 1) MockDroid [6] and 2) AppLock [13]. Finally, we conclude this section with a summary of lessons learned.

6.1.1 MockDroid

MockDroid [6] is a system-centric security extension for the Android OS that allows users to gracefully revoke the privileges requested by an application without the app crashing. To do so, MockDroid provides a graphical user interface that allows the user to decide whether individual applications are presented real or fake responses when accessing sensitive system components.

Original Implementation: MockDroid extends Android's permissions model for accessing sensitive services by providing alternative "mock" versions. When users install an application, they choose to use the real or mock version of permissions. However, users can also revise this decision later using a graphical user interface. MockDroid stores the mapping between applications and permissions in an extension to Android's Package Manager Service. This policy store is the primary policy decision point in MockDroid.

MockDroid places enforcement logic in relevant Android OS components, as well as the kernel. If an application is assigned a mock permission, the Android OS component will return fake information. For example, if an application attempts to get the device IMEI, and it is assigned the mock version of `READ_PHONE_STATE`, then the telephony service will return a fake static IMEI instead of the device's real IMEI.

MockDroid also modifies the Linux kernel with enforcement logic. Recall from Section 2 that some permissions are enforced in the Linux kernel based on GIDs assigned to applications. MockDroid defines additional

Table 2: Hooks registered by the MockDroidASM app

Access to Fake	ASM Hook	ASM Callback
IMEI	device_id_mod	int getDeviceId_mod(String fake_imei[])
Fine/Coarse Location update	on_location_changed_mod	int onLocationChanged_mod(int uid, Location loc)
Internet Connection	socket_connect	int socket_connect(String family, String type, int uid)
Contacts Query	contacts_query_mod	int query_contacts_mod (ASMCursor c, String projection, ...)
Contacts Insert	contacts_insert	int contactsInsert(Uri uri, ContentValues values)
Contacts Delete	contacts_delete	int contactsDelete(Uri uri, String selection, String selectionArgs[], ...)
Contacts Update	contacts_update	int contactsUpdate(Uri uri, ContentValues values, String selection, ...)
Receive Broadcast	resolve_broadcast_mod	int resolveBroadcastReceivers_mod(List resolvedList, String resolvedtype, ..)

GIDs for mock permissions enforced by GID. For example, if the user selects to assign the mock version of the INTERNET permission to an application, it is assigned to the mock_inet group instead of the inet group. To enforce this mock permission, MockDroid modifies the inet runtime check in the Linux kernel (a check added by Android to Linux). In the modified check, if the application is in the mock_inet group, a socket timeout error is returned, simulating an unavailable network server.

MockDroidASM: We implemented an ASM app version of MockDroid called MockDroidASM. In addition to ASM permissions for hook registration, MockDroidASM must register for the PACKAGE_INSTALL hook to receive the package name and the list of requested permissions when each new application is installed. A MockDroidASM GUI also allows the user to configure which permissions to gracefully revoke from an application (e.g., INTERNET, READ_PHONE_STATE).

Instead of using additional mock permissions, MockDroidASM registers for the modify version of ASM hooks that are triggered when an application attempts to access sensitive system components. Since MockDroidASM needs to modify values returned to apps, it requests the REGISTER_ASM_MODIFY permission, as described in Section 5.3.

Table 2 shows the most important hooks used by MockDroidASM. For example, the device_id_mod hook allows MockDroidASM to fake the IMEI number of the device. On the kernel-level, MockDroidASM registers for the socket_connect hook to receive a callback when an application tries to connect to a network server. If INTERNET is revoked by the user, the MockDroidASM returns deny to the ASM LSM, which returns a socket timeout error to the application.

6.1.2 AppLock

AppLock [13] is an application available on the Google Play Store. It allows users to protect the user interface components of applications with a password. Users set a password to access the AppLock. They then selectively lock other third-party and system applications through AppLock's user interface. When the user tries to open a protected application, AppLock presents a password prompt, and the user must enter the correct password before the application can be used.

Original Implementation: AppLock requests install-time permissions for 1) getting the list of running apps, 2) overlaying its user interface over other applications, and 3) killing application processes. While AppLock does not require any modifications to Android's source code, it is uses energy very inefficiently. It can also be circumvented using an ADB shell (e.g., "am force-stop com.domobile.applock").

AppLock's *LockService* uses a busy loop to continuously query the Android operating system for the list of running applications while the screen is on. If the top application is protected by AppLock's policy, LockService overlays the current screen with a password prompt user interface. This interface stays on the screen, trapping all input until the correct password is entered. If the user decides to return from the lock screen without entering his password, AppLock kills the protected application. We have verified this execution via static analysis using ApkTool [1] as well as with another monitoring ASM app that registers for the start_service hook.

AppLockASM: We implemented an ASM app version of AppLock called AppLockASM. To provide the password-protected application functionality, AppLockASM simply registers for the start_activity hook. It then receives a callback whenever an activity component is started. When this occurs, AppLockASM displays its own lock screen. If the user enters the correct password, the start_activity event is allowed. If the user decides not to enter a password, it is denied. Unlike AppLock, AppLockASM never starts the target activity component without the correct password.

6.1.3 Summary

ASM considerably simplifies development of security modules such as AppLock and MockDroid. For example, the original AppLock app performs its functionality by starting a service in an infinite loop, a design that is inefficient in terms of power as well as latency. AppLockASM on the other hand needs to simply register for a callback with the ASM Framework. The AppLock implementation also prompts a lock screen after the app has already been started, and has to kill the app when the lock

Table 3: Performance - Unmodified AOSP, ASM with no reference monitor, and ASM with a reference monitor app

		ASM (ms)		Overhead (%)		Overhead (ms)	
Protection Event	**AOSP (ms)**	**w/o ASM app**	**w/ ASM app**	**w/o ASM app**	**w/ ASM app**	**w/o ASM app**	**w/ ASM app**
Start Activity	19.03±1.51	20.01±1.39	22.74±1.77	5.15	19.50	0.98	3.71
Start Service	3.89±0.31	4.6±0.41	8.42±0.61	18.25	116.45	0.71	4.53
Send Broadcast	2.18±0.24	4.48±0.69	6.45±0.55	105.50	196.71	2.30	4.27
Contacts Insert	121.41±5.98	120.48±5.25	135.39±6.35	-0.76	11.51	-0.93	13.98
Contacts Query	17.41±3.88	21.10±3.13	29.50±4.36	21.19	69.44	3.69	12.09
File Read	59.13±1.97	62.27±2.86	65.39±2.93	5.31	10.59	3.14	6.26
File Write	57.68±3.01	57.98±2.76	59.03±3.60	0.52	2.34	0.30	1.35
Socket Create	0.65±0.086	0.79±0.13	4.26±0.56	21.54	555.38	0.14	3.61
Socket Connect	1.61±0.21	1.65±0.22	5.13±0.32	2.48	218.63	0.04	3.52
Socket Bind	2.00±0.17	1.93±0.64	5.15±0.34	-3.5	157.50	-0.07	3.15

screen returns. This arbitrary killing of apps is prevented in the AppLockASM case, where the callback happens before the activity is started, and the activity starts only if the AppLockASM allows. This is also beneficial from the security point of view, as an AppLockASM-like app does not need to register for the permission to kill other apps, reducing the risk in case the locking app itself is malicious or malfunctions.

The original MockDroid implementation requires modifications to the Package Manager Service, and has to implement an entire parallel mock permission framework. This effort can be reduced by registering for a small number of ASM hooks, without having to modify system services.

A general lesson learned from these case studies is that the ASM architecture enables developers to easily implement complex system-centric security enhancements without the need for third party support. This broadens the outreach of ASM, and encourages third-party developers to engage in the development of sophisticated security solutions for Android-based devices.

6.2 Performance Overhead

To understand the performance implications of ASM, we micro benchmarked the most common ASM protection events for modules in Table 1. We performed each experiment 50 times in three execution environments: 1) AOSP, 2) ASM with no ASM app, and 3) ASM with one ASM app. The ASM app only registers for the callback of the tested protection event; all other callbacks remain deactivated. Since we are only interested in the performance overhead caused by framework, our test callback immediately returns *allow*. Table 3 shows the mean results with the 95% confidence intervals.

Lifecycle protection events: To test lifecycle protection events (i.e., start activity, start service, and send broadcast), we created an intent message and added a byte array as its data payload (i.e., extras Bundle). Each test type registered for the modify version of the ASM hook. We sent the intent for the respective type, pausing for five seconds between consecutive executions. Potential areas of overhead for using the hook include: 1) cost of establishing two additional IPCs, 2) marshalling and unmarshalling this data across the two IPCs, 3) ASM copying the extras Bundle when sending it to the ASM app, and 4) setting the returned Bundle back to the original intent. To estimate worst case performance, we chose a very large array (4KB) and registered our test ASM for modify data hooks. This worst case overhead, though relatively high, is not noticeable by the user due to its low absolute value. Additionally, most applications use files to share very large data values. We note that while send broadcast has a high overhead percentage, the wall clock overhead is in the order of milliseconds, which is negligible overhead for broadcasts.

Content provider protection events: Micro benchmarks for content providers were performed on the *Contacts Provider*. For this experiment, our ASM app registers for the `contacts_insert` callback. It proceeds to insert a new contact (first and last name) into the contacts database exposed by the ContactsProvider. The overhead observed is 11.51% and negligible in terms of its absolute value. We then registered for the `contacts_query_mod` hook, and performed a query on the same contact. Query has a greater overhead, which is attributable to marshalling/unmarshalling the data between the two IPC calls, and serialization of the Cursor object into a parcelable. A major cause of this overhead is also that the Content Provider Cursor is not populated when the query result is returned to the calling application, but is instead filled as and when the application uses it to retrieved values. As discussed in Section 5.4.3, future work will consider alternative methods of mediating query responses.

File access protection events: File micro benchmarks tested the `file_permission` hook, which uses an upcall from the kernel. To test file access performance, our test app performs an access (read/write) on a 5MB file. We pause for a second between successive executions. For writes, we do not see considerable overhead as the file is written in one shot to disk. Reads used a 16KB buffer and the default 1ms expiration time for caching access control decisions, as discussed Section 5.4.5.

Table 4: Energy overhead of ASM.

	Average Power Consumption (mW)	Overhead (%)
AOSP	670.42	-
ASM w/o ASM app	692.83	3.34
ASM w/ ASM app	732.98	9.33

Socket protection events: For socket operations, we tested the performance overhead for creating, binding and connecting to an IPv6 socket. Our test ASM app registered for the `socket_create`, `socket_bind`, and `socket_connect` callbacks. The absolute overhead is mainly caused by the callback to the userspace, and is a constant overhead for socket operations.

6.3 Energy Consumption

Energy consumption is a growing concern for mobile devices. To measure ASM's impact on energy consumption, we perform energy measurements in same three test environments as performance: 1) AOSP, 2) ASM with no ASM app, 3) ASM with one ASM app. The ASM app registers for all the hooks from the performance experiments. We use the Trepn profiler 4.1 [25] provided by Qualcomm to perform power measurements. Trepn uses an interface exposed by the Linux kernel to the power management IC used on the System on a Chip to measure energy consumption, a feature that is supported on a limited set of devices, including the LG Nexus 4. Trepn samples power consumption measurements every 100 ms. Average values are shown in the Table 4.

We monitor system energy consumption while running the test applications from Section 6.2. When the hooks are deactivated, we measured an energy consumption overhead of about 3.34%. Our ASM app used for the performance and energy consumption experiments measured an overhead of about 9.33%. This overhead is caused by the active authorization hooks in the relevant OS components and kernel, as well as the communication between the authorization hooks, the ASM Bridge, and the ASM app.

It should be noted that performing accurate energy consumption measurements on smartphones is a challenge. While we consider the individual measurements to be accurate, we acknowledge that the low sampling rate used by the Trepn profiler is problematic. However, each individual experiment is performed 50 times, therefore we believe Trepn's measurements to at least provide a rough estimate of the energy consumption overhead introduced by ASM.

7 Related Work

Section 4 discussed Android security enhancements that modify the Android firmware to achieve security mediation. As an alternative approach, Aurasium [35], AppGuard [5], RetroSkeleton [11] and Dr. Android and Mr. Hide [20] repackage applications with inline reference monitors (IRMs). While IRMs do not require firmware modification, rewriting frequently breaks applications, and the resulting mediation may be circumvented if API coverage is incomplete or native libraries are used. Placing access control mediation within the OS provides stronger guarantees.

ASM follows the methodology of the LSM [34] and TrustedBSD [32] reference monitor interface frameworks. Both frameworks have been highly successful. In Linux, LSM is widely used to extend Linux security enforcement. Version 3.13 of Linux kernel source includes SELinux [28], AppArmor [3], Tomoyo [31], Smack [30], and Yama [36] LSMs. TrustedBSD is not only used by FreeBSD, but also by Apple to implement seatbelt in Mac OS X and iOS [33].

FlaskDroid [9] also shares motivation with ASM. It provides an SELinux-style Type Enforcement (TE) policy language for extending Android security. FlaskDroid also allows third-party application developers to specify TE policies to protect their applications. However, FlaskDroid is limited to TE access control policies. By providing a programmable interface, ASM enables an extensible interface that allows not only TE, but also novel security models not yet invented. Specifically, we believe the ability to replace data values will become vital in protecting new operating systems such as Android.

Concurrent to and independent of our work on ASM, the Android Security Framework (ASF) [4] also provides an extensible interface to implement security modules. ASM and ASF are conceptually very similar: both promote the need for a programmable interface, authorization hooks that replace data (called edit automata in ASF), and third-party hooks (via *callModule()* in ASF). However, their individual approaches differ. A key difference is that ASM seeks to ensure existing security guarantees (Goal **G2**), whereas ASF assumes the module writer is completely trusted (e.g., can load kernel modules). Goal **G2** is motivated by our vision of enterprise IT and researchers loading ASM apps on production phones without root access. ASF does not support this vision. Furthermore, a vulnerable ASF module can undermine secrecy and integrity of the system and all installed applications. That said, ASF does provide expressibility that ASM does not. Specifically, ASF provides a programmable interface to adding inline reference monitors to apps. While IRMs run the risk of breaking apps, they do support sub-application policies that ASM cannot express (e.g., forcing an app to use *https* over *http*).

Finally, Section 5.4 identified the AppOps security enhancement that is currently under development in AOSP. AppOps adds authorization hooks throughout the Android OS. However, AppOps does not provide a programmable interface for enhancing OS security. Instead,

we envision separating the authorization hooks from AppOps and implementing AppOps as an ASM app. A similar process occurred during the creation of LSM when it was split away from SELinux.

8 Conclusion

This paper has presented the Android Security Modules framework as a programmable interface for extending Android's security. While similar reference monitor interfaces have been proposed for Linux and TrustedBSD, ASM is novel in how it addresses the semantically rich OS APIs provided by new operating systems such as Android. We studied over a dozen research proposals that enhance Android security to motivate the reference monitor interface hooks provided by ASM. Of particular note is the ability for hooks to replace data, as well as for third-party application developers to define new hooks.

ASM promotes the creation of novel security enhancements to Android without restricting OS consumers (e.g., consumers, enterprise, government) to specific policy languages (e.g., type enforcement). ASM currently allows researchers with the ability to recompile Android to rapidly prototype novel reference monitors without needing to consider authorization hook placement. If ASM is adopted into the AOSP source code, it potentially allows researchers and enterprise IT to add new reference monitors to production Android devices without requiring root access, a significant limitation of existing bring-your-own-device solutions.

Abstract

We present an app automation tool called Brahmastra for helping app stores and security researchers to test third-party components in mobile apps at runtime. The main challenge is that call sites that invoke third-party code may be deeply embedded in the app, beyond the reach of traditional GUI testing tools. Our approach uses static analysis to construct a page transition graph and discover execution paths to invoke third-party code. We then perform binary rewriting to "jump start" the third-party code by following the execution path, efficiently pruning out undesired executions. Compared with the state-of-the-art GUI testing tools, Brahmastra is able to successfully analyse third-party code in 2.7× more apps and decrease test duration by a factor of 7. We use Brahmastra to uncover interesting results for two use cases: 175 out of 220 children's apps we tested display ads that point to web pages that attempt to collect personal information, which is a potential violation of the Children's Online Privacy Protection Act (COPPA); and 13 of the 200 apps with the Facebook SDK that we tested are vulnerable to a known access token attack.

1 Introduction

Third-party libraries provide a convenient way for mobile application developers to integrate external services in the application code base. Advertising that is widely featured in "free" applications is one example: 95% of 114,000 popular Android applications contain at least one known advertisement library according to a recent study [22]. Social media add-ons that streamline or enrich the user experience are another popular family of third-party components. For example, `Facebook Login` lets applications authenticate users with their existing Facebook credentials, and post content to their feed.

Despite this benefit, the use of third-party components is not without risk: if there are bugs in the library or the way it is used then the host application as a whole becomes vulnerable. This vulnerability occurs because the library and application run with the same privileges and without isolation under existing mobile application models. This behavior is especially problematic because a number of third-party libraries are widely used by many applications; any vulnerability in these libraries can impact a large number of applications. Indeed, our interest in this topic grew after learning that popular SDKs provided by Facebook and Microsoft for authentication were prone to misuse by applications [30], and that applications often make improper use of Android cryptography libraries [20].

In this paper, we present our solution to the problem of *third-party component integration testing at scale*, in which one party wishes to test a large number of applications using the same third-party component for a potential vulnerability. To be useful in the context of mobile app stores, we require that a successful solution test many applications without human involvement. Observe that it is *not* sufficient to simply test the third-party library for bugs in isolation. This is because vulnerabilities often manifest themselves due to the interaction of the application and the third-party component. Thus our focus is to develop tools that enable testers to observe *in situ* interactions between the third-party component and remote services in the context of a specific application at runtime.

We began our research by exploring automated runtime analysis tools that drive mobile UIs (e.g., [5, 23, 26]) to exercise the third-party component, but quickly found this approach to be insufficient. Although these tools are effective at executing *many* different code paths, they are often unable to reach *specific* interactions deep within the applications for a number of reasons that we explore within this paper. Instead, our approach leverages the structure of the app to improve test hit rate and execution speed. To do this, we characterize an app by statically building a graph of its pages and transitions between them. We then use path information from the graph to guide the runtime execution towards the third-

party component under test. Rather than relying on GUI manipulation (which requires page layout analysis) we rewrite the application under test to directly invoke the callback functions that trigger the desired page transitions.

We built Brahmastra to implement our approach for Android apps. Our tool statically determines short execution paths, and dynamically tests them to find one that correctly invokes a target method in the third-party library. At this stage, behavior that is specific to the library is checked. Because our techniques do not require human involvement, Brahmastra scales to analyze a large number of applications. To show the benefits of our approach, we use our tool for two new studies that contribute results to the literature: 1) checking whether children's apps that source advertisements from a third-party comply with COPPA privacy regulations; and 2) checking that apps which integrate the Facebook SDK do not have a known security vulnerability [30].

From our analysis of advertisements displayed in 220 kids apps that use two popular ad providers, we find that 36% apps have displayed ads whose content is deemed inappropriate for kids—such as offering free prizes, or displaying sexual imagery. We also discover that 80% apps have displayed ads with landing pages that attempt to collect personal information from the users, such as name, address, and online contact information—which can be a violation of the Children's Online Privacy Protection Act [6]. Apart from creating an unsafe environment for kids, this also leaves the app developers vulnerable to prosecution, since they are considered liable for all content displayed by their app.

For our analysis of a vulnerability in third party login libraries, we run a test case proposed by Wang et al. [30] against 200 Android apps that bundle Facebook SDK. We find that 13 of the examined apps are vulnerable.

Contributions: We make two main contributions. The first is Brahmastra, which embodies our hybrid approach of static and dynamic analysis to solve the third-party component integration testing problem for Android apps. We discuss our approach and key techniques in §4 and their implementation in §5. We show in §6 that our techniques work for a large fraction of apps while existing tools such as randomized testing (Monkey) often fail. We have made the static analysis part of Brahmastra available at `https://github.com/plum-umd/redexer`.

Our second contribution is an empirical study of two security and privacy issues for popular third-party components. We find potential violations of child-safety laws by ads displayed in kids apps as discussed in §7; several apps used in the wild display content in potential violation of COPPA due to the behavior of embedded components. We find that several popular Android apps are vulnerable to the Facebook access token attack as discussed in §8; A Facebook security team responded immediately to our findings on 2/27/2014 and had contacted the affected developers with the instructions to fix.

2 Background

As our system is developed in the context of Android, we begin by describing the structure of Android apps and support for runtime testing.

Android app structure: An Android app is organized as a set of pages (e.g., Figure 1) that users can interact with and navigate between. In Android, each page is represented by an `activity` object. Each activity class represents one kind of page and may be initialized with different data, resulting in different `activity instances`. We use the terms page and activity instance interchangeably. Each page contains various GUI elements (e.g., buttons, lists, and images), known as `views`. A view can be associated with a callback function that is invoked when a user interacts with the view. The callback function can instantiate a new activity by using a late binding mechanism called `intent`. An intent encapsulates the description of a desired action (e.g., start a target activity) and associated parameters. The main `activity` (or the first page) of an app, defined in its manifest file, is started by the application launcher by passing a `START` intent to it.

For example, in Figure 1, clicking the "Done" button on activity `A1` invokes its event handler, which calls a callback function defined by the app developer. The callback constructs an intent to start activity `A2` with necessary parameter `P12`. The `Activity Manager` then constructs an instance of `A2`, and starts it with `P12` as parameters. We refer to the documentation of Android internals for more details [2].

Automated dynamic analysis: Recent works have used a class of automation tools, commonly called a Monkey, that, given a mobile app binary, can automatically execute it and navigate to various parts (i.e., states) of the app. Examples include PUMA [23], DECAF [25], AppsPlayground [26], A3E [14], and VanarSena [27]. A Monkey launches the app in a phone or an emulator, interacts with it by emulating user interactions (e.g., clicking a button or swiping a page) to recursively visit various pages, and performs specific tasks (e.g., checking ad frauds in the page or injecting faults) on each page.

In Figure 1, a Monkey may be able to visit the sequence of states `A1` $\rightarrow$ `A2` $\rightarrow$ `A3`$\rightarrow$ `A4` if it knows the right UI actions (e.g., type in mother's name and select "Due Date" in `A1`) to trigger each transition. However, if Monkey clicks a button in `A3` other than "Account", the app would navigate to a different activity. If the goal of testing is to invoke specific methods (e.g., Facebook login as shown in the example), then without knowing the structure of the app, a Monkey is likely to wander around

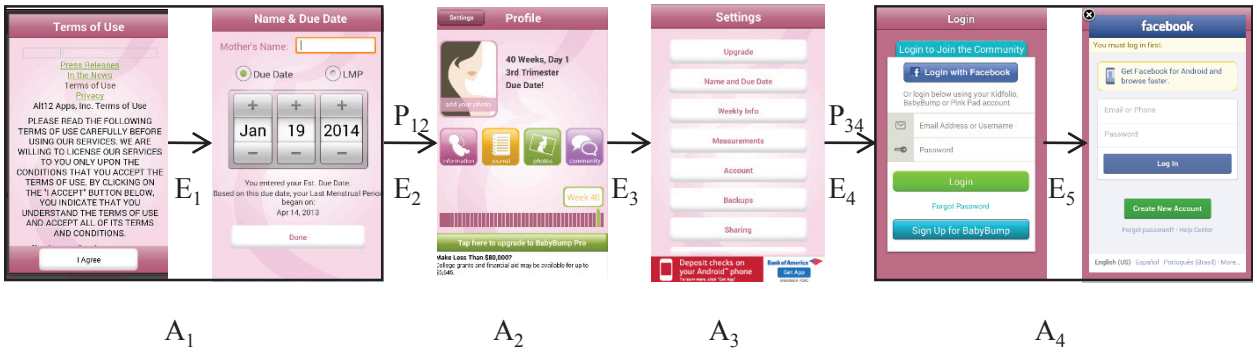

Figure 1: Activity sequences of `com.alt12.babybumpfree` that invoke Facebook single sign-on window in the forth activity (`A4`): Clicking "I Agree" (`E1`) then clicking "Done" (`E2`) opens up `A2` with the parameter, `fromLoader : tru` (`P12`). Clicking "Settings" (`E3`) in `A2` opens up the settings activity, `A3` and then clicking "Account" (`E4`) opens up the login activity, `A4` with the parameter, `WHICHCLASS : com.alt12.babybumpcore.activity.settings.Settings`. Finally, clicking "Login with Facebook" (`E5`) opens up the sign-on window within the same activity, `A4`.

many activities until it reaches `A4`, if it ever does.

3 Problem and Insights

Our goal is to develop the ability to automatically and systematically test a large set of mobile apps that embed a specific third-party component for a potential vulnerability associated with the use of that component. This ability would let app store operators rapidly vet apps to contain security vulnerabilities caused by popular libraries. It would let component developers check how apps use or misuse their interfaces. It would also let security researchers such as ourselves empirically assess vulnerabilities related to third-party libraries.

A straightforward approach is to use existing Monkeys. Unfortunately, this approach does not work well: it often fails to exercise the target third-party component of the app under test. Although recent works propose techniques to improve various types of *coverages*, computed as the fraction of app activities or methods invoked by the Monkey, coverage still remains far from perfect [26, 14, 13, 25, 27]. Moreover, in contrast to traditional coverage metrics, our success metric is binary for a given app indicating whether the target third-party component (or a target method in it) is invoked (i.e., *hit*) or not (i.e., *miss*). Our experiments show that even a Monkey with a good coverage can have a poor hit rate for a target third-party component that may be embedded deep inside the app. We used an existing Monkey, PUMA that reports a $> 90\%$ activity coverage compared to humans [23], but in our experiments it was able to invoke a target third-party component only in 13% of the apps we tested (see §6 for more details). On a close examination, we discovered several reasons for this poor hit rate of existing Monkeys:

R1. Timeout: A Monkey can exhaust its time budget before reaching the target pages due to its trial-and-error search of the application, especially for apps with many pages that "blow up" quickly.

R2. Human inputs: A Monkey is unable to visit pages that are reached after entering human inputs such as login/password, or gestures beyond simple clicks that the automated tester cannot produce.

R3. Unidentified elements: A Monkey fails to explore clickable UI elements that are not visible in the current screen (e.g., hidden in an unselected tab) or are not activated yet (e.g., a "Like" button that is activated only after the user registers to the app) or are not identified by underlying UI automation framework (e.g., nonstandard custom control).

R4. Crashes: By stressing the UI, a Monkey exacerbates app crashes (due to bugs and external dependencies such as the network) that limit exploration.

Note that, unlike existing Monkeys, our goal is not to exhaustively execute all the possible code paths but to execute *particular code paths* to invoke methods of interest in the third-party library. Therefore, our insight is to improve coverage by leveraging ways how third party components are integrated with application code base. These components are incorporated into an app at the activity level. Even if the same activity is instantiated multiple times with different contents, third-party components typically behave in the same way in all those instantiations. This allows us to restrict our analysis at the level of *activity* rather than *activity instances*. Further, even if an app contains a large number of activities, only a small number of them may actually contain the third-party component of interest. Invoking that compo-

nent requires successfully executing any and only one of those activities.

Using this insight, our testing system, Brahmastra, uses three techniques described below to significantly boost test hit rate and speed compared to a Monkey that tries to reach all pages of the app.

Static path pruning: Brahmastra considers only the "useful" paths that eventually invoke the target third-party methods and ignores all other "useless" paths. In Figure 1, Brahmastra considers the execution path `A1` → `A2` → `A3`→ `A4` for exploration and ignores many other paths that do not lead to a target activity, `A4`.

Such useful paths need to be identified statically *before* dynamic analysis is performed. The key challenges in identifying such paths by static analysis arise due to highly asynchronous nature of Android apps. We discuss the challenges and our solution in §4.

Dynamic node pruning: Brahmastra opportunistically tries to start from an activity in the middle of the path. If such "jump start" is successful, Brahmastra can ignore all preceding activities of the path. For example, in Figure 1, Brahmastra can directly start activity `A3`, which can lead to the target activity `A4`.

Dynamic node pruning poses several challenges — first, we need to enable jump-starting an arbitrary activity directly. Second, jump starting to the target activity may fail due to incorrect parameters in the intent, in which case we need to find a different activity that is close to the target, for which jump start succeeds. We discuss these in detail in next section.

Self-execution of app: Brahmastra rewrites the app binary to automatically call methods that cause activity transitions. The appropriate methods are found by static analysis. In Figure 1, instead of clicking on the button with label "Done" in `A1`, Brahmastra would invoke the `onClick()` method that would make the transition from `A1` to `A2`. The advantage over GUI-driven automation is that it can discover activity-transitioning callbacks even if they are invisible in the current screen.

In summary, our optimizations can make dynamic analysis fast by visiting only a small number of activities of an app. More importantly, they also improve the test hit rate of such analysis. Faster analysis helps to avoid any timeouts (**R1**). Dynamic node pruning can bypass activities that require human inputs (**R2**). In Figure 1, Brahmastra can jump to `A3` and bypass `A1` that requires selecting a *future* due date. Intent-driven navigation helps Brahmastra to make transitions where a Monkey fails due to unidentified GUI elements (**R3**). Finally, visiting fewer activities reduces the likelihood of crashes (**R4**). We quantitatively support these claims in §6.

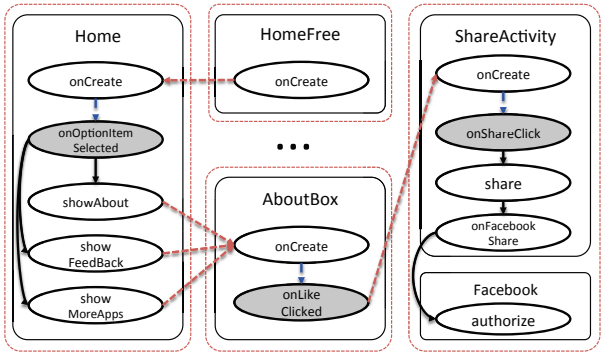

Figure 2: A simplified call graph of `ch.smalltech.battery.free` that shows multiple transition paths composed of multiple activities. Boxes and ovals represent classes and methods. Solid edges correspond to synchronous calls; (red) dotted edges indicate activity transitions; and (blue) dashed edges represent implicit calls due to user interactions. Three different paths starting from `Home.onOptionItemSelected()` reach `AboutBox.onCreate()` and share the remaining part.

4 Design

Brahmastra requires as input: a test application binary; the names of target methods to be invoked within the context of the application; and the plug-in of a specific security analysis to run once the target method is reached. Our system is composed of three parts:

1. *Execution Planner* statically analyzes the test app binary and discovers an execution path to invoke the target third-party method.
2. *Execution Engine* receives execution paths from the Planner and launches the test app in one or multiple emulators and automatically navigates through various pages according to the execution path.
3. *Runtime Analyzer* is triggered when the test app invokes the target method. It captures the test app's runtime state (e.g., page content, sensors accessed, network trace) and runs the analysis plug-in.

4.1 Execution Planner

The job of the Execution Planner is to determine: (1) the activities that invoke the target third-party method; and (2) the method-level execution paths that lead to the target activities. To accomplish these tasks, we statically analyze the app binary to construct a *call graph* that encompasses its activities and interactions that cause activity transitions.

Constructing call graph: A call graph is a graph where vertices are methods and edges are causal relationship between method invocation. More precisely, there exists

```
ImageButton b = (ImageButton)
              findViewById(R.id.b1);
b.setOnClickListener(new OnClickListener() {
  public void onClick(View v) {
    ...
  }});
```

Figure 3: Example of a programmatic handler registration. `onClick()` is bound to `setOnClickListener()`

an edge from method m_1 to m_2 if m_1 invokes m_2. Based on how m_2 is invoked by m_1, there are three types of edges: (1) synchronous edges, if m_1 directly calls m_2, (2) asynchronous edges, if m_1 invokes m_2 asynchronously, and (3) activity transition edges, if m_1 starts an activity that automatically calls m_2. Figure 2 depicts a call graph of one real app.

While synchronous edges can be identified easily by scanning the app binary code, discovering other edges can be difficult. To find activity transition edges, we rely on the fact that one activity can start another activity by generating an intent and passing it to the `startActivity()` method. We perform constant propagation analysis [12] so as to track such intent creations and detect activity transitions. We also conduct class hierarchy analysis [19] to conservatively determine possible receiver types for dynamic dispatch, where the target call sites depend on the runtime types of the receivers.

To discover asynchronous edges, we need to consider all the different ways asynchronous methods can be invoked by a mobile app:

1. Programmatic handler registrations: These are callbacks explicitly bound to methods (e.g., event handler of GUI elements) within the code. Figure 3 shows an example.
2. XML-based handler registrations: These are callbacks specified in the layout or resource XML files. Figure 4 shows an example.
3. Lifetime methods: These are methods provided by the underlying framework that automatically make transitions to other methods on specific events. Examples are splash screens and message boxes that transition to next activities after a timeout or after user acknowledgment, respectively.

To discover the first and third types, we use constant propagation analysis to trace callbacks attached to various event handlers. To handle the second case, we parse layout XML files corresponding to each activity to figure out the binding between UI elements and callback methods.

Efficient call graph computation: A call graph can be extremely large, thus computing the entire call graph can

```
// layout/about_box_share.xml
<Button android:id="@id/mShareFacebook"
  style="@style/ABB_Black_ShareButton" ... />
<Button android:id="@id/mShareTwitter"
  style="@style/ABB_Black_ShareButton" ... />
// values/styles.xml
<style name="ABB_Black_ShareButton ... >
  <item name="android:onClick">onShareClick</item>
</style>
// ch.smalltech.common.feedback.ShareActivity
public void onShareClick(View v){
  // different behavior depending on argument v
}
```

Figure 4: Example of a XML-based handler registration observed from `ch.smalltech.battery.free`. Two buttons share the `onShareClick` callback. The binding between `onShareClick` and `setOnClickListener` of each button can be determined through layout and styles XML files.

be very expensive. For example, the app shown in Figure 1 declares 74 activities in the manifest; we find at least 281 callbacks over 452 registering points; and its call graph is composed of 1,732 nodes and 17,723 edges. To address this, we use two optimizations to compute a *partial* call graph that includes target methods and the start activity methods. First, we exclude system's static libraries and other third-party libraries that are not related to the target methods. Second, we search transition paths backwards on call graph. We pinpoint call sites of target methods while walking through bytecodes. We then construct a partial call graph, taking into accounts component transitions via intent and bindings between views and listeners. Finally, starting from the call sites, we build backward transition paths, until public components including the main activity are reached. If failed, partial paths collected at the last phase will be returned.

Determining target activity(s): Given the call graph and a target method, we determine the activities that invoke the method as follows. From the call graph, we can identify the activity boundaries such that all methods within the same boundary are invoked by the same activity. Since an activity can be started only through an activity transition edge in the call graph, any maximal connected component whose edges are either synchronous or asynchronous define the boundary of an activity. In Figure 2, bigger rectangles denote the activity boundaries. Given the boundaries, we identify the activities that contain the target method.

Finding activity transition paths: Reaching a target activity from the start activity may require several transitions between multiple activities. For example, in Figure 2, navigating from the start activity (`HomeFree`) to a target activity (`ShareActivity`) requires three transi-

tions. This implies that Brahmastra requires techniques for automatic activity transitions, which we describe in the next subsection. Second, a target activity may be reachable via multiple transition paths. While the shortest path is more attractive for fast exploration, the path may contain blocking activities and hence not executable by Brahmastra. Therefore, Brahmastra considers all transition paths (in increasing order of their length); if execution of a short path fails, it tries a longer one.

Given the call graph G, the Planner computes a small set P of acyclic transition paths that the Execution Engine need to consider. P includes a path if and only if it terminates at a target activity without a cycle and is not a suffix of any other path in P. This ensures that P is useful, complete (i.e., Execution Engine does not need to consider any path not in P), and compact. For instance Figure 5 shows one out of three paths contained in P.

```
     HomeFree;.onCreate
---> Home;.onCreate
-#-> Home;.onOptionsItemSelected
---> Home;.showAbout
---> AboutBox;.onCreate
-#-> AboutBox;.onLikeClicked
---> ShareActivity;.onCreate
-#-> ShareActivity;.onShareClick
---> ShareActivity;.share
---> ShareActivity;.onFacebookShare
```

Figure 5: An example path information for `ch.smalltech.battery.free` Dashed arrows stand for explicit calls or activity transition, whereas arrows with a hash tag represent implicit invocations, which are either callbacks due to user interactions or framework-driven callbacks, such as lifecycle methods.

P can be computed by breadth-first traversals in G, starting from each target activity and traversing along the reverse direction of the edges.

4.2 Execution Engine

The useful paths P produced by the Execution Planner already give an opportunity to prune exploration: Brahmastra considers only paths in P (and ignore others), and for each path, it can simply navigate through its activities from the beginning of the path (by using techniques described later). Exploration can stop as soon as a target method is invoked.

Rewriting apps for self-execution: One might use a Monkey to make activity transitions along useful paths. Since a Monkey makes such transitions by interacting with GUI elements, this requires identifying mapping between GUI elements and transitioning activities and interact with only the GUI elements that make desired transitions.

We address this limitation with a technique we develop called *self execution*. At a high level, we rewrite app binaries to insert code that automatically invokes the callbacks that trigger desired activity transitions, even if their corresponding GUI elements are not visible. Such code is inserted into all the activities in a useful path such that the rewritten app, after being launched in a phone or an emulator, would automatically make a series of activity transitions to the target activity, without any external interaction with its GUI elements.

Jump start: Brahmastra goes beyond the above optimization with a node pruning technique called "jump start". Consider a path $p = (a_0, a_1, \ldots, a_t)$, where a_t is a target activity. Since we are interested only in the target activity, success of Brahmastra is not affected by what activity a_i in p the execution starts from, as long as the last activity a_t is successfully executed. In other words, one can execute any suffix of p without affecting the hit rate. The jump start technique tries to execute a suffix — instead of the whole — useful path. This can improve Brahmastra's speed since it can skip navigating through few activities (in the prefix) of a useful path. Interestingly, this can also improve the hit rate of Brahmastra. For example, if the first activity a_0 requires human inputs such as user credentials that an automation system cannot provide, any effort to go beyond state a_0 will fail.

Note that directly executing an activity $a_i, i > 0$, without navigating to it from the start activity a_0, may fail. This is because some activities are required to be invoked with specific intent parameters. In such cases, Brahmastra tries to jump start to the previous activity a_{i-1} in the path. In other words, Brahmastra progressively tries to execute suffixes of useful paths, in increasing order of lengths, until the jump start succeeds and the target activity a_t is successfully reached or all the suffixes are tried.

Algorithm 1 shows the pseudocode of how execution with jump start works. Given the set of paths, the algorithm first generates suffixes of all the paths. Then it tries to execute the suffixes in increasing order of their length. The algorithm returns true on successful execution of any suffix. Note that Algorithm 1 needs to know if a path suffix has been successfully executed (line 9). We inject lightweight logging into the app binary to determine when and whether target methods are invoked at runtime.

4.3 Runtime Analyzer

Runtime Analyzer collects various runtime states of the test app and makes it available to custom analysis plug-ins for scenario-specific analysis. Runtime states include UI structure and content (in form of a DOM tree) of the current app page, list of system calls and sensors invoked by the current page, and network trace due to the current page. We describe two plug-ins and analysis results in

Algorithm 1 Directed Execution

```
1:  INPUT: Set of useful paths P from the Planner
2:  OUTPUT: Return true if execution is successful
3:  S ← set of suffixes of all paths in P
4:  for i from 0 to ∞ do
5:      S_i ← set of paths of length i in S
6:      if S_i is empty then
7:          return false
8:      for each path suffix p in S_i do
9:          if Execute(p) = true then
10:             return true
11:
12: return false
```

```
1  // { v3 →this }
2  new-instance v0, Landroid/content/Intent;
3  // { v0 →Intent(), ... }
4  const-class v1, ...AboutBox;
5  // { v1 →Clazz(AboutBox), ... }
6  invoke-direct {v0, v3, v1}, ...Intent;.<init>
7  // { v0 →Intent(AboutBox), ... }
8  invoke-virtual {v3, v0}, ...;.startActivity
9  // { ... }
```

later sections.

5 Implementation of Brahmastra

We implement Brahmastra for analyzing Android apps, and use the tool to perform two security analyses which we will describe in §7 and §8. This section describes several highlights of the tool, along with practical challenges that we faced in the implementation process and how we resolved them.

5.1 Execution Planner

Static analyses for constructing a call graph and finding transition paths to target methods are performed using Redexer [24], a general purpose bytecode rewriting framework for Android apps. Redexer takes as input an Android app binary (APK file) and constructs an in-memory data structure representing `DEX` file for various analyses. Redexer offers several utility functions to manipulate such `DEX` file and provides a generic engine to perform data-flow analysis, along with call graph and control-flow graph.

For special APIs that trigger activity transitions, e.g., `Context.startActivity()`, we perform constant propagation analysis (see Appendix A for details) and identify a target activity stored inside the intent. Figure 6 depicts example bytecode snippets that create and initialize an intent (lines 2 and 6), along with the target activity (line 4), and starts that activity via `startActivity()` (line 8). Mappings between each bytecode show how we accumulate data-flow information, from empty intent through class name to intent with the specific target activity. We apply the same analysis to bindings between views and listeners.

5.2 App Rewriting

We use the Soot framework [29] to perform the bytecode rewriting that enables self execution. Dexpler [7] converts an Android app binary into Soot's intermediate representation, called Jimple, which is designed to ease analysis and manipulation. The re-writing tool is composed of Soot's class visitor methods and an Android XML parser. Given an app binary and an execution path, the rewriter generates a rewritten binary which artificially invokes a callback method upon the completion of the exercising the current activity, triggering the next activity to be launched. The inserted code depends on the type of the edge found by the Planner (Recall three kinds of asynchronous edges described in §4.1). For programmatic and XML-based registrations, the rewriter finds the `view` attached to it — by parsing the activity code, and the manifest respectively — and invokes the appropriate UI interaction on it after it has completed loading. Lifetime methods are invoked by the Android framework directly, and the rewriter skips code insertion for these cases. In other cases, the rewriter inserts a timed call to the transition method directly, to allow the activity and any dependencies of the method to load completely.

5.3 Jump Start

Jump start requires starting an activity even if it is not defined as the `Launcher` activity in the app. To achieve that, we manipulate the manifest file of the Android app. The `Intent.ACTION_MAIN` entry in the manifest file declares activities that Android activity manager can start directly. To enable jump start, we insert an `ACTION_MAIN` entry for each activity along the path specified, so that it can be started by the Execution Engine. Manifest file also declares an intent filter, which determines the sources from which an activity may be started, which we modify to allow the Execution Engine to launch the activity. The Engine then invokes desired activity by passing an intent to it. We use the Android Debug Bridge (ADB) [4] for performing jump start. ADB allows us to create an intent with the desired parameters and target, and then passes it to the Android Activity Manager. The activity manager in turn loads the appropriate app data and invokes the specified activity. Starting the (jump started) activ-

ity immediately activates self execution from that activity onwards.

6 Evaluation of Brahmastra

We evaluate Brahmastra in terms of two key metrics: (1) hit rate, i.e., the fraction of apps for which Brahmastra can invoke any of target methods, and (2) speed, i.e., time (or number of activity transitions) Brahmastra takes to invoke a target method in an app for which Brahmastra has a hit. Since we are not aware of any existing tool that can achieve the same goal, we compare Brahmastra against a general Android app exploration tool called, PUMA [23]. This prototype is the best-performing Monkey we were able to find that is amenable to experimentation. In terms of speed and coverage, PUMA is far better than a basic "random" Monkey. PUMA incorporates many key optimizations in existing Monkeys such as AppsPlayground [26], A3E [14], and VanarSena [27] and we expect it to perform at least on a par with them.

6.1 Experiment Methodology

Target method: For the experiments in this section, we configure Brahmastra to invoke authentication methods in the Facebook SDK for Android.[1] We choose Facebook SDK because this is a popular SDK and its methods are often invoked only deep inside the apps. Using the public documentation for the Facebook SDK for Android, we determined that it has two target methods for testing. Note that apps in our dataset use the Facebook SDK version 3.0.2b or earlier[2]

```
Lcom/facebook/android/Facebook;->authorize
Lcom/facebook/android/Facebook;->dialog
```

Figure 7: Target methods for evaluation

Apps: We crawled 12,571 unique apps from the Google Play store from late December 2012 till early January 2013. These apps were listed as 500 most popular free apps in each category provided by the store at the time. Among them, we find that 1,784 apps include the Facebook SDK for Android. We consider only apps that invoke the authentication method—Over 50 apps appear to have no call sites to Facebook APIs, and over 400 apps use the API but do not invoke any calls related to authorization. We also discard apps that do not work with our tool chain, e.g., crash on the emulator or have issues with `apktool` [1] since our analysis depends on the disassembled code of an apk file. This leaves us with 1,010 apps.

[1] `https://developers.facebook.com/docs/android/login-with-facebook`

[2] The later version of Facebook SDK was released in the middle of data collection and appears to use different methods to display a login screen. However, we find that almost no apps in our data set had adapted the new version yet.

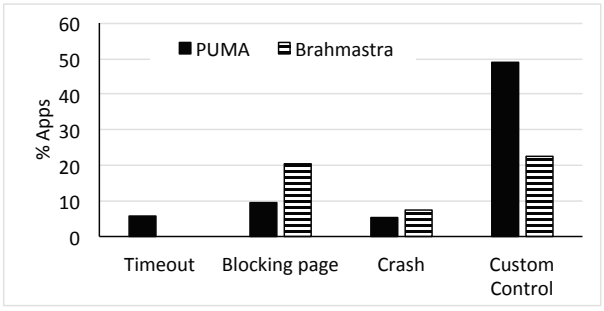

Figure 8: Failure causes of Brahmastra and PUMA.

App execution: In order to determine if Brahmastra or PUMA is able to reach a program point that invokes the target method, we instrument apps. The instrumentation detects when any of the target methods are invoked during runtime, by comparing signatures of executing methods with signatures of target methods. For Brahmastra, we consider only 5 of all paths generated by the Execution Planner. For PUMA, we explore each app for up to 250 steps; higher timeouts significantly increase overall testing time for little gain in hit rate.

6.2 Hit Rate

In our experiments, PUMA was able to successfully invoke a target method in 127 apps (13%). Note that PUMA's hit rate is significantly lower than its activity coverage ($>$ 90% compared to humans) reported in [23], highlighting the difficulty in invoking specific program points deep inside an app. In contrast, Brahmastra was successfully able to invoke a target method in 344 (34%) apps, a 2.7$\times$ improvement over PUMA. A closer examination of our results, as shown in Table 1, reveals that Brahmastra's technique can help circumventing all the root causes for PUMA's poor hit rate as mentioned in §3.

We now investigate why PUMA and Brahmastra sometimes fail to invoke the target method. For PUMA, this is due to the aforementioned four cases. Figure 8 shows the distribution of apps for which PUMA fails due to specific causes. As shown, all the causes happen in practice. The most dominant cause is the failure to find UI controls to interact with, which is mostly due to complex UI layouts of the popular apps we tested. Figure 8 also shows the root causes for Brahmastra's failure. The key reasons are as follows:

Blocking page: Even if jump start succeeds, successive activity transition may fail on a blocking page. Brahmastra fails for 20% of the apps due to this cause. We would like to emphasize that Brahmastra experiences more blocking pages than PUMA only because Brahmastra explores many paths that PUMA does not (e.g., because those paths are behind a custom control that

Case	Apps
R1: Timeout in PUMA, success in Brahmastra	62%
R2: Blocking page in PUMA, success in Brahmastra	48%
R3: Unknown control in PUMA, success in Brahmastra	43%
R4: Crash in PUMA, success in Brahmastra	30%

Table 1: % of apps for which Brahmastra succeeds but PUMA fails due to various reasons mentioned in §3.

PUMA cannot interact with, but Brahmastra can find and invoke the associated callback) and many of these paths contain blocking pages. If PUMA tried to explore those paths, it would have failed as well due to these blocking pages.

Crash: Jump start can crash if the starting activity expects specific parameters in the intent and Brahmastra fails to provide that. Brahmastra fails for 7% of the apps due to this cause.

Custom components: Execution Planner may fail to find useful paths if the app uses custom components[3], which can be used to override standard event handlers, thus breaking our model of standard Android apps. Without useful paths, Brahmastra can fail to invoke the target methods. In our experiments, this happens with 16% of the apps. We leave as future work a task to extend Execution Planner to handle custom components. We find that PUMA also failed 91% on these apps, proving the difficulty of navigating apps with custom components. In fact, PUMA suffers much more than Brahmastra due to custom components.

Improving the hit rate: There are several ways we can further improve the hit rate of Brahmastra. First, 16% failures of Brahmastra come because the static analysis fails to identify useful paths. A better static analysis that can discover more useful paths can improve Brahmastra's hit rate. Second, in our experiments, Brahmastra tried only up to 5 randomly selected useful paths to invoke the target method and gave up if they all failed. In many apps, our static analysis found many tens of useful paths, and our results indicate that the more paths we tried, the better was the hit rate. More specifically, Brahmastra succeeded for 207 apps after considering only one path, and for 344 apps after considering up to five paths. This suggests that considering more paths is likely to improve the hit rate. Additionally, we should select the paths to avoid any nodes or edges for which exploration failed in previously considered paths instead of choosing them randomly. In 72 apps, Brahmastra was unable to find the binding between a callback method and the UI element associated with it, causing it to fall back on a direct invocation of the callback method. A better static analysis can help in this case as well. In 22 apps, Brahmastra deemed a page blocked due to UI elements in the Android SDK (e.g., list elements) whose behavior was not encoded in the instrumentation engine. An engineering effort in special-case handling of these and more views would increase hit rate. We plan to explore such optimizations in future. Finally, PUMA (and other Monkeys) and Brahmastra use fundamentally different techniques to navigate between app pages and it might be possible to combine them in a single system where PUMA is used if Brahmastra fails (or vice versa). In our experiments, such a hybrid approach would give an overall hit rate of 39% (total 397 apps).

[3] http://developer.android.com/guide/topics/ui/custom-components.html

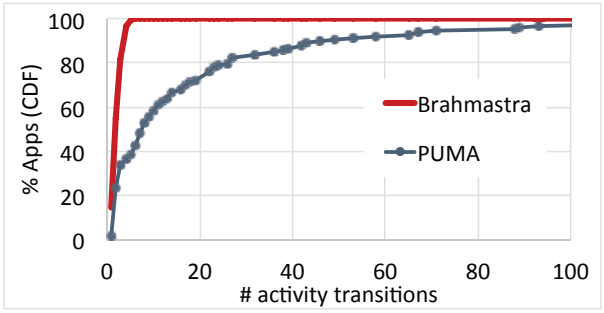

Figure 9: Test speed comparison of Brahmastra and PUMA

6.3 Speed

We use the number of activity transitions required to reach the target activity as a proxy for speed, since the actual time will vary depending on a variety of computational factors (e.g., network speed, device specifications). In Figure 9, we plot the CDF of the number of transitions required to reach the target activity for the apps which are successfully tested by both Brahmastra and PUMA. Since Brahmastra prunes away many unnecessary paths using static analysis, it runs faster than PUMA that suffers from uninformed activity transitions and large fanout in the activity transition graphs. On average, PUMA requires 18.7 transitions per app, while Brahmastra requires 2.5 transitions per app, resulting in 7 fold speedup.

7 Analysis of Ads in Kids Apps

Our first scenario is to use Brahmastra to study whether ad libraries for Android apps meet guidelines for protecting the online privacy of children. We give results for two popular ad components embedded in 220 kids apps. Our analysis shows that 80% of the apps displayed ads with a link to landing pages that have forms for collecting personal information, and 36% apps displayed ads deemed inappropriate to children.

7.1 Motivation and Goals

The Children's Online Privacy Protection Act (COPPA) lays down a variety of stipulations that mobile app developers must follow if their apps are directed at children under 13 years old [6]. In particular, COPPA disallows the collection of personal information by these apps unless the apps have first obtained parental consent.

COPPA holds the app developer responsible for the personal information collected by the embedded third party components as well as by the app's code [6]. Since it is common to see ad components included in free apps, we aim to measure the extent of potentially non-COPPA-compliant ad components in kids apps. Specifically, our first goal is to determine *whether in-app ads or landing pages pointed by these ads present forms that collect personal information*. Although displaying collection forms itself is not a violation, children might type in requested personal information, especially if these websites claim to offer free prizes or sweepstakes. In such cases, if these ads or landing pages do collect personal information without explicit parental consent, this act could be considered as a violation according to COPPA. Since it is difficult to model these legal terms into technical specifications, we only report potential concerns in this section. Our second goal is to test *whether content displayed in in-app ads or landing pages is appropriate for children*. Since this kind of judgement is fundamentally subjective, we show the breakdown of content categories as labeled by human testers.

Note that runtime observation is critical for this testing, since ads displayed within apps change dynamically depending on the inventory of ads at the time of request.

7.2 Testing Procedure

The testing has two steps. For a given app, we first collect ads displayed within apps and landing pages that are pointed by the ads. Second, for each ad and landing page, we determine: (1) whether they present forms to collect personal information such as first and last name, home address, and online contact as defined in COPPA; and (2) whether their content appears inappropriate to children and if so why.

Driving apps to display ads: We use Brahmastra to automatically drive apps to display ads. In this study, we focus on two popular ad libraries, AdMob and Millennial Media, because they account for over 40% of free Android apps with ads [11]. To get execution paths that produce ads, we use the following target methods as input to Brahmastra:

```
Lcom/google/ads/AdView;-><init>
Lcom/millennialmedia/android/MMAdView;-><init>
```

Collecting ads & landing pages: We redirect all the network traffic from executing test apps through a `Fiddler` proxy [8]. We install the `Fiddler` SSL certificate on the phone emulator as a trusted certificate to allow it to examine SSL traffic as well. We then identify the requests made by the ad libraries to their server component using domain names. Once these requests are collected, we replay these traces (several times, over several days), to fetch ad data from the ad servers as if these requests were made from these apps. This ad data is generally in the form of a JSON or XML object that contains details about the kind of ad served (image or text), the content to display on the screen (either text or the URL of an image), and the URL to redirect to if the ad is clicked upon. We record all of above for analysis.

Analyzing ads & landing pages: We use two methods to characterize ads and landing pages. First, for each landing page URL collected, we probe the Web of Trust (WoT) database [9] to get the "child safety" score. Second, to better understand the reasons why landing pages or ads may not be appropriate for children, we use crowdsourcing (via Amazon Mechanical Turk [3]) to label each ad and landing page and to collect detailed information such as the type of personal information that landing pages collect. As data collected from crowds may include inconsistent labeling, we use majority voting to filter out noise.

7.3 Results

Dataset: We collected our dataset in January 2014. To find apps intended for children, we use a list of apps categorized as "Kids" in Amazon's Android app store[4]. Since apps offered from the Amazon store are protected with DRM and resist bytecode rewriting, we crawled the Play store for apps with the same package name.

Starting from slightly over 4,000 apps in the Kids category, we found 699 free apps with a matching package name in the Play store. Among these, we find 242 apps that contain the AdMob or Millennial Media ad libraries. Using Brahmastra, we were successfully able to retrieve at least one ad request for 220 of these apps (also in January 2014), for which we report results in this section. For the remaining 22 apps, either Brahmastra could not navigate to the correct page, or the app did not serve any ad despite reaching the target page.

Results: We collected ads from each of the 220 apps over 5 days, giving us a total collection of 566 unique ads, and 3,633 unique landing pages. Using WoT, we determine that 183 out of the 3,633 unique landing pages have the child-safety score below 60, which fall in the "Unsatisfactory", "Poor" or "Very Poor" categories. 189 out of the 220 apps (86%) pointed to at least one of these pages during the monitoring period. Note that WoT did not contain child-safety ratings for 1,806 pages, so these

[4] Google Play store does not have a separate kids category.

Info Type	Landing Pages	Apps
Home address	47	58
First and last name	231	174
Online contact	100	94
Phone number	17	15
Total	235	175

Table 2: Personal information collected by landing pages

numbers represent a lower bound. We then used Amazon Mechanical Turk to characterize all 566 ads, and 2,111 randomly selected landing pages out of the 3,633. For each ad and landing page, we asked Amazon Mechanical Turk to check whether they collect personal information (of each type) and whether they contain inappropriate content for children (see Appendix B for the task details). We offered 7 cents (US) per each task (which involves answering various questions for each website or banner ad) and collected three responses per data point. As discussed above, we only counted responses that were consistent across at least two out of three respondents, to filter out noise.

Table 2 summarizes the types of personal information that landing pages ask users to provide as labeled by Amazon Mechanical Turk. We find that at least 80% of the apps in the dataset had displayed ads that point to landing pages with forms to collect personal information. On a manual examination of a subset of these pages, we found no labeling errors. We also found that none of the sites we manually checked attempt to acquire parental consent when collecting personal information. See Appendix B for examples.

Table 3 breaks down child-inappropriate content of the ads displayed in apps as labeled by Amazon Mechanical Turk. Although COPPA does not regulate the content of online services, we still find it concerning that 36% (80 out of 220) of the apps display ads with content deemed inappropriate for children. In particular 26% (58 apps) displayed ads that offer free prizes (e.g., Figure 13), which is considered a red flag of deceptive advertising, especially in ads targeting children as discussed in guidelines published by the Children's Advertising Review [10]. We also analysed the content displayed on the landing pages, and found a similar number of content violations as the ad images.

8 Analysis of Social Media Add-ons

Our second use case is to test apps against a recently discovered vulnerability associated with the Facebook SDK [30]. Our testing with Brahmastra shows that 13 out of 200 Android apps are vulnerable to the attack. Fixing it requires app developers to update the authentication logic in their servers as recommended by [30].

Content Type	Image Ads	Apps
Child exploitation	2	8
Gambling, contests, lotteries or sweepstakes	3	2
Misleading users about the product being advertised	7	16
Violence, weapons or gore	4	5
Alcohol, tobacco or drugs	3	3
Profanity and vulgarity	0	0
Free prize	39	58
Sexual or sexually suggestive content	12	29
Total	62	80

Table 3: Breakdown of child-inappropriate content in ads

8.1 Testing Goal

The Facebook access token vulnerability discussed in [30] can be exploited by attackers to steal the victim's sensitive information stored in vulnerable apps. For instance, if a malicious-yet-seemingly benign news app can trick the victim *once* to use the app to post a favorite news story on the victim's Facebook wall (which is a common feature found in many news apps), then the malicious app can use the access token obtained from the Facebook identity service to access sensitive information stored by *any* vulnerable apps that the victim had interacted with and have been associated with the victim's Facebook account. This attack can take place offline—once the malicious app obtains an access token, then it can send the token to a remote attacker who can impersonate as the victim to vulnerable apps.

Figure 10 gives the steps that allow a malicious application to steal `Victim`'s information from $\texttt{VulApp}_\text{s}$. The fact that the online service ($\texttt{VulApp}_\text{s}$) is able to retrieve the user's information from Facebook only means that the client ($\texttt{MalApp}_\text{c}$) possesses the privilege to the Facebook service, but is not a proof of the client app's identity ($\texttt{MalApp}_\text{c} \neq \texttt{VulApp}_\text{c}$). The shaded boxes in Figure 10 highlight the vulnerability. See [30] for more detail.

Wang et al. [30] manually tested 27 Windows 8 apps and showed that 78% of them are vulnerable to the access token attack. Our goal is to scale up the testing to a large number of Android applications. Note that testing for this vulnerability requires runtime analysis because the security violation assumptions are based on the interactions among the application, the application service, and Facebook service.

8.2 Testing Procedure

The testing has three steps. For a given app, we first need to drive apps to load a Facebook login screen. Second, we need to supply valid Facebook login credentials to observe interactions between the test application and Face-

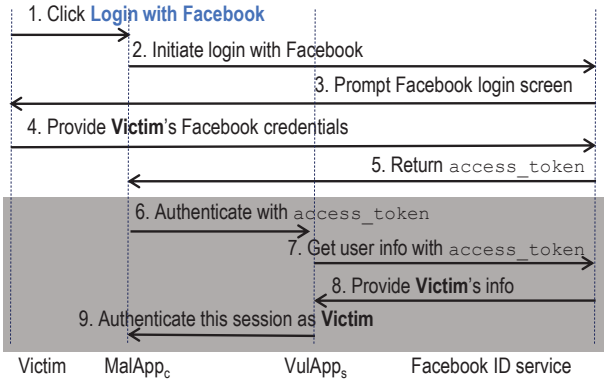

Figure 10: Facebook's access token, intended for authorizing access to `Victim`'s info, is used by `VulApp`$_s$ to authenticate the session as `Victim`. From step 9, `MalApp`$_c$ can steal `Victim`'s sensitive information in `VulApp`$_s$.

```
1  if(oSession.url.Contains("m.facebook.com")) {
2   var toReplace = "access_token=CAAHOi...";
3   ...
4   if(oSession.oResponse.headers.
5    ExistsAndContains("Location", "access_token"))
6   {
7    oSession.oResponse.headers["Location"] =
8     oSession.oResponse.headers["Location"].
9       replace(oRegEx, toReplace);
10   oSession["ui-customcolumn"] = "changed-header";
11  } }
```

Figure 11: A script used to manipulate `access_token`: We only show the first 6 bytes of the access token used in the attack.

book ID service. Third, we need to determine whether the test application misuses a Facebook access token for authenticating a client (steps 7-9) by monitoring network traffic and application behavior after providing a fraudulent access token.

Driving apps to display Facebook login: We use Brahmastra to automatically drive apps to invoke the Facebook SDK's authentication methods shown in Figure 7. Once the authentication methods open the sign-in window, we supply valid Facebook credentials.

Manipulating traffic with MITM proxy: As before, we direct all network traffic through a `Fiddler` proxy. Since Facebook sign-in traffic is encrypted over SSL, we also install a `Fiddler` SSL certificate on the phone emulator to decrypt all SSL traffic.

To manipulate the login, we record an `access_token` from a successful login session associated with another application (and therefore simulating an attacker as illustrated in the steps 1-5 of Fig. 10) and use the script shown in Fig. 11. It runs over HTTP responses, and overwrites an incoming `access_token` with a recorded one.

8.3 Experiments

Dataset: We randomly draw 200 apps from the dataset used in §6 for this testing.

Results: We find that 18 out of 200 apps use a Facebook access token for authentication, and among them 13 apps are vulnerable to a fraudulent access token (72%). 5 apps appear not vulnerable, and show some sort of error message when given a fraudulent access token. The remaining 182 apps use the Facebook SDK merely to post content to the user's wall, and not as an authentication mechanism. We determined this by looking at the network traffic at the login event, and observing that all of it is sent only to Facebook servers.

To understand how widespread the vulnerability is, we look at the statistics for the number of downloads on the Google Play store. Each of the 13 vulnerable apps has been downloaded more than 10,000 times, the median number of app downloads is over 500,000, and the most popular ones have been downloaded more than 10 million times. Further, these 13 apps have been built by 12 distinct publishers. This shows that the problem is not restricted to a few naïve developers. We shared the list of vulnerable apps with a Facebook security team on 2/27/2014 and got a response immediately that night that they had contacted the affected developers with the instructions to fix. The privacy implications of the possessing the vulnerability are also serious. To look at what user data can potentially be exfiltrated, we manually investigated the 13 vulnerable apps. Users of these apps may share a friends list, pictures, and messages (three dating apps); photos and videos (two apps); exercise logs and stats (one app); homework info (one app) or favorite news articles, books or music preferences (remaining six apps). By exploiting the vulnerability, a malicious app could exfiltrate this data.

9 Related Work

Automated Android app testing: A number of recent efforts proposed improvements over Android Monkey: AndroidRipper [13] uses a technique known as GUI ripping to create a GUI model of the application, and explores its state space. To improve code coverage, AndroidRipper relies on human testers to type in user credentials to get through blocking pages. However, despite this manual effort, the tool shows less than 40% code coverage after exploring an app for 4.5 hours. AppsPlayground [26] employs a number of heuristics—by guessing the right forms of input (e.g., email address, zip code) and by tracking widgets and windows in order to

reduce duplicate exploration. It shows that these heuristics are helpful although the coverage is still around 33%. SmartDroid [31] uses a combination of static and dynamic analysis to find the UI elements linked to sensitive APIs. However, unlike Brahmastra, SmartDroid explores every UI element at runtime to find the right view to click. A3E [14] also uses static analysis to find an activity transition graph and uses the graph to efficiently explore apps. We leveraged the proposed technique when building an execution path. However, similarly to the tools listed above, A3E again uses runtime GUI exploration to navigate through activities. In contrast to these works, Brahmastra determines an execution path using static analysis and rewrites an app to trigger a planned navigation, bypassing known difficulties related to GUI exploration.

Security analysis of in-app ads: Probably because only recently COPPA [6] had been updated to include mobile apps[5], we are not aware of any prior work looking into the issues around COPPA compliance of advertisements (and the corresponding landing pages) displayed within apps directed at children. However, several past works investigated security and privacy issues with respect to Android advertising libraries. AdRisk [22] is a static analysis tool to examine advertising libraries integrated with Android apps. They report that many ad libraries excessively collect privacy-sensitive information and expose some of the collected information to advertisers. Stevens et al. examine thirteen popular Android ad libraries and show the prevalent use of tracking identifiers and the collection of private user information [28]. Worse, through a longitudinal study, Book et al. show that the use of permissions by Android ad libraries has increased over the past years [18].

Analyzing logic flaws in web services and SDKs: The authentication vulnerability discussed in §8 falls into the category of logic flaws in web programming. Recent papers have proposed several technologies for testing various types of logic flaws [16, 17, 21]. However, these techniques mainly target logic flaws in *two-party web programs*, i.e., programs consisting of a client and a server. Logic flaws become more complicated and intriguing in multi-party web programs, in which a client communicating with multiple servers to accomplish a task, such as the Facebook-based authentication that we focus in this paper. AuthScan is a recently developed technique to automatically extract protocol specifications from concrete website implementations, and thus discover new vulnerabilities in the websites [15]. In contrast, our goal is not to discover any new vulnerability on a website, but to scale up the testing of a known vulnerability to a large number of apps.

[5]The revision was published on July 2013.

10 Discussion

Limitations: Although Brahmastra improves test hit rates over Monkey-like tools, we discover several idiosyncratic behaviors of mobile apps that challenge runtime testing. Some apps check servers upon launching and force upgrading if newer versions exist. Some apps constantly load content from remote servers, showing transient behaviors (e.g., extremely slow at times). We also have yet to implement adding callbacks related to sensor inputs. Another challenge is to isolate dependent components in the code. We assume that each activity is more or less independent (except that they pass parameters along with intent) and use our jump start technique to bypass blocking pages and to speed up testing. However, we leave as future work a task to statically determine dependent activities to find activities to jump-start to without affecting the program behavior.

Other runtime security testing of mobile apps: As mobile apps are highly driven by user interaction with visual components in the program, it is important to analyze the code behavior in conjunction with runtime UI states. For instance, malicious third-party components can trick users into authorizing the components to access content (e.g., photos) that the users intended to share with the application. Brahmastra can be used to capture visual elements when certain APIs are invoked to check against such click jacking attempts. Brahmastra can also automate the testing to check whether privacy-sensitive APIs are only invoked with explicit user interactions.

11 Conclusion

We have presented a mobile app automation tool, Brahmastra, that app store operators and security researchers can use to test third-party components at runtime as they are used by real applications. To overcome the known shortcomings of GUI exploration techniques, we analyze application structure to discover desired execution paths. Then we re-write test apps to follow a short path that invokes the target third-party component. We find that we can more than double the test hit rate while speeding up testing by a factor of seven compared to a state-of-the-art Monkey tool.

We use Brahmastra for two case studies, each of which contributes new results: checking if third-party ad components in kids apps are compliant with child-safety regulations; and checking whether apps that use Facebook Login are vulnerable to a known security flaw. Among the kids apps, we discover 36% of 220 kids apps display ads deemed inappropriate for children, and 80% of the apps display ads that point to landing pages which attempt to collect personal information without parental consent. Among the apps that use Facebook Login, we find that 13 applications are still vulnerable to the Face-

book access token attack even though the attack has been known for almost a year. Brahmastra let us quickly check the behavior of hundreds of apps for these studies, and it can easily be used for other studies in the future—checking whether privacy-sensitive APIs can be invoked without explicit user interaction, discovering visible UI elements implicated in click jacking attempts, and more.

A Constant Propagation Analysis

We extend the existing constant propagation analysis so as to trace `intents`, UI elements, and listeners. In addition to traditional value types, such as numerical or string constant, we add meta-class, object, and intent sorts, which track class ids, object references, and intent instances, respectively. For instructions that create objects; load class ids; or invoke special APIs such as `Intent.setClass()`, we add their semantics into the data-flow transfer function.

Figure 12 illustrates how we extend data-flow lattice; how we conform to *meet* operation property; and how we define semantics of relevant instructions.

```
type lattice = ...
  | Clazz of string (* const−class *)
  | Object of string (* instance *)
  | Intent of string (* Intent for a specific component *)
  | ...
let meet l1 l2 = match l1, l2 with ...
  | Clazz c1, Clazz c2 when 0 = compare c1 c2 → l1
  | Object o1, Object o2 when 0 = compare o1 o2 → l1
  | Intent i1, Intent i2 when 0 = compare i1 i2 → l1
  | ...
let transfer (inn: lattice Map.t) (op, opr) = ...
  else if OP_NEW = op then (* NEW *)
  (
    let dst :: id ::[] = opr in
    let cname = Dex.get_ty_name id in
    if 0 = compare cname '' Intent ''
    then Map.add dst (Intent ``'') inn
    else Map.add dst (Object cname) inn
  ) ...
```

Figure 12: Abbreviated source code of extended constant propagation analysis. Meta-class, object, and intent sorts maintain information as string, and they can be merged only if internal values are identical, hence *must*-analysis. As an example, this shows how to handle opcode `NEW`.

Abstract

The security of smartphone GUI frameworks remains an important yet under-scrutinized topic. In this paper, we report that on the Android system (and likely other OSes), a weaker form of GUI confidentiality can be breached in the form of UI state (not the pixels) by a background app without requiring any permissions. Our finding leads to a class of attacks which we name *UI state inference attack*. The underlying problem is that popular GUI frameworks by design can potentially reveal every UI state change through a newly-discovered public side channel — shared memory. In our evaluation, we show that for 6 out of 7 popular Android apps, the UI state inference accuracies are 80–90% for the first candidate UI states, and over 93% for the top 3 candidates.

Even though the UI state does not reveal the exact pixels, we show that it can serve as a powerful building block to enable more serious attacks. To demonstrate this, we design and fully implement several new attacks based on the UI state inference attack, including hijacking the UI state to steal sensitive user input (*e.g.,* login credentials) and obtain sensitive camera images shot by the user (*e.g.,* personal check photos for banking apps). We also discuss non-trivial challenges in eliminating the identified side channel, and suggest more secure alternative system designs.

1 Introduction

The confidentiality and integrity of applications' GUI content are well recognized to be critical in achieving end-to-end security [1–4]. For instance, in the desktop and browser environment, window/UI spoofing (*e.g.,* fake password dialogs) breaks GUI integrity [3, 4]. On the Android platform, malware that takes screenshots breaches GUI confidentiality [5]. Such security issues can typically lead to the direct compromise of the confidentiality of user input (*e.g.,* keystrokes). However, a weaker form of confidentiality breach has not been thoroughly explored, namely the knowledge of the application UI state (*e.g.,* knowing that the application is showing a login window) *without knowing the exact pixels of the screen*, especially in a smartphone environment.

Surprisingly, in this paper we report that on the Android system (and likely on other OSes), such GUI confidentiality breach is indeed possible, leading to serious security consequences. Specifically, we show that *UI state* can be inferred without requiring any Android permissions. Here, *UI state* is defined as a mostly consistent user interface shown in the window level, reflecting a specific piece of program functionality. An example of a UI state is a login window, in which the text content may change but the overall layout and functionality remain the same. Thus, we call our attack *UI state inference attack*. In this attack, an attacker first builds a UI state machine based on UI state signatures constructed offline, and then infers UI states in real time from an unprivileged background app. In Android terminology, the UI state is known as *Activity*, so we also call it *Activity inference attack* in this paper.

Although UI state knowledge does not directly reveal user input, due to a lack of direct access to the exact pixels or screenshots, we find that it can effectively serve as a building block and enable more serious attacks such as stealing sensitive user input. For example, based on the inferred UI states, we can further break the GUI integrity by carefully exploiting the designed functionality that allows UI preemption, which is commonly used by alarm or reminder apps on Android.

The fundamental reason for such confidentiality breach is in the Android GUI framework design, where every UI state change can be unexpectedly observed through publicly accessible side channels. Specifically, the major enabling factor is a newly-discovered *shared-memory side channel*, which can be used to detect window events in the target application. This side channel exists because shared memory is commonly adopted by window managers to efficiently receive window changes or updates from running applications. For more details, please refer to §2.1 where we summarize the design and implementation of common window managers, and §3.2 where we describe how shared memory plays a critical role. In fact, this design is not specific to Android: nearly all popular OSes such as Mac OS X, iOS, and Windows also adopt this shared-memory mechanism for their win-

dow managers. Thus, we believe that our attack on Android is likely to be generalizable to other platforms.

Since the window manager property we exploit has no obvious vulnerabilities in either design or implementation, it is non-trivial to construct defense solutions. In §9, we discuss ways to eliminate the identified side channels, and also suggest more secure alternative system designs.

Our discovered Activity inference attack enables a number of serious follow-up attacks including (1) *Activity hijacking attack* that can unnoticeably hijack the UI state to steal sensitive user input (*e.g.,* login credentials), and (2) *camera peeking attack* that captures sensitive camera images shot by the user (*e.g.,* personal check photos for banking apps). We have fully designed and implemented these attacks and strongly encourage readers to view several short video demos at **`https://sites.google.com/site/uistateinferenceattack/demos`** [6].

Furthermore, we demonstrate other less severe but also interesting security consequences: (1) existing attacks [5, 7–10] can be enhanced in stealthiness and effectiveness by providing the target UI states; (2) user behavior can be inferred through tracking UI state changes. Previous work has demonstrated other interesting Android side-channel attacks, such as inferring the web pages a user visits [11] as well as the identity, location, and disease information of users [12]. However, these attacks are mostly application-specific with limited scope. For instance, Memento [11] only applies to web browsers, and Zhou *et al.* [12] reported three side channels specific to three different apps. In contrast, the UI state concept in this paper applies generally to all Android apps, leading to not only a larger attack coverage but also many more serious attacks, such as the Activity hijacking attack which violates GUI integrity.

The contributions of this paper are as follows:

- We formulate the general UI state inference attack that violates a weaker form of GUI confidentiality, aimed at exposing the running UI states of an application. It exploits the unexpected interaction between the design and implementation of the GUI framework (mainly the window manager) and a newly-discovered shared-memory side channel.
- We design and implement the Android version of this attack and find an accuracy of 80–90% in determining the foreground Activity for 6 out of 7 popular apps. The inference itself does not require any permissions.
- We develop several attack scenarios using the UI state inference technique and demonstrate that an attacker can steal sensitive user input and sensitive camera images shot by the user when using Android apps.

For the rest of the paper, we first provide the attack background and overview in §2. The newly-discovered side channel and Activity transition detection are detailed in §3, and based on that, the Activity inference technique is described in §4. In §5, we evaluate this attack with popular apps, and §6, §7 and §8 show concrete follow-up attacks. We cover defense in §9, followed by related work in §10, before concluding in §11.

2 Background and Overview

2.1 Background: Window Manager

Window manager is system software that interacts with applications to draw the final pixels from all application windows to the frame buffer, which is then displayed on screen. After evolving for decades, the most recent design is called *compositing window manager*, which is used virtually in all modern OSes. Unlike its predecessors, which allow individual applications to draw to the frame buffer directly, a compositing window manager requires applications to draw the window content to *off-screen buffers* first, and use a dedicated window compositor process to combine them into a final image, which is then drawn to the frame buffer.

Client-drawn and server-drawn buffer design. There are two types of compositing window manager design, as shown in Fig. 1. In this figure, *client* and *server* refer to an application and the window compositor[1] respectively. In the client-drawn buffer design, the applications draw window content to off-screen buffers, and use IPC to communicate these buffers with the server, where the final image is composited and written to the frame buffer. This design is very popular and is used in Mac OS X, iOS, Windows, Android, and Wayland for the future Linux [13, 14]. In the server-drawn buffer design, the main difference is that the off-screen buffers are allocated and drawn by the window compositor instead of by the applications. Applications send commands to the window compositor to direct the drawing process. Only the X window system on the traditional Linux and Mir for the future Linux [15] use this design.

Both designs have their advantages. The client-drawn buffer design provides better isolation between applications, more flexible window drawing and more balanced overhead between the client and the server. For the server-drawn buffer design, the server has control over all applications' window buffers, which is better for centralized resource management. Interestingly, some prior work choose the former to enhance GUI security [1], but we find that it actually enables our attacks (shown in §3).

2.2 Background: Android Activity and Activity Transition

In Android, the UI state our attack infers is called *Activity*. An Activity provides a user interface (UI) for user in-

[1] For traditional Linux the server is an X server, and the window compositor is a separate process talking to the X server. In Fig. 1 we refer to the combination of them as the window compositor.

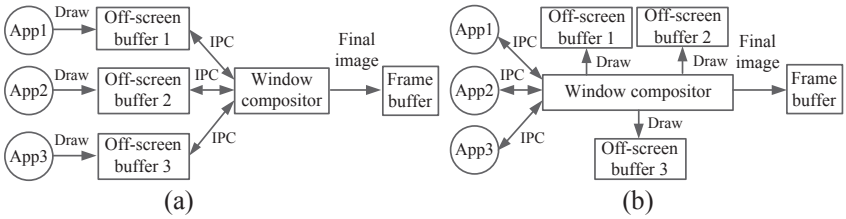

Figure 1: Two types of compositing window manager design: (a) client-drawn buffer design, and (b) server-drawn buffer design. *Client* refers to the application, and *server* refers to the window compositor.

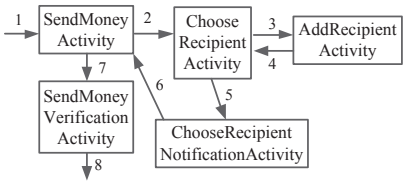

Figure 2: Activities involved in sending money in Android Chase app. The numbers denote the action order.

teractions, and is typically a full-screen window serving as a functionality unit in Android. We denote Activities as $a, b, ...$, and the set of Activities for an app as A. Due to security concerns, by default apps cannot know which Activity is currently shown in the foreground unless they are the owners or the central Activity manager.

An Activity may display different content depending on the app state. For instance, a dictionary app may have a single "definition" Activity showing different texts for each word lookup. We call these distinct displays *ViewStates*, and denote the set of them for Activity a as $a.VS$.

Activity transition. In Android, multiple Activities typically work together and transition from one to another to support the functionality of an app as a whole. An example is shown in Fig. 2. During a typical transition, the current foreground Activity pauses and a new one is created. A Back Stack [16] storing the current and past Activities is maintained by Android. To prevent excessive memory usage, at any point in time, only the top Activity has its window buffer allocated. Whenever an Activity transition occurs, the off-screen buffer allocation for the new Activity window and the deallocation for the existing Activity window take place.

Activity transitions can occur in two ways: a new Activity is created (*create* transition), or an existing one resumes when the BACK key is pressed (*resume* transition), corresponding to push and pop actions in the Back Stack. Fig. 3 shows the major function calls involved in these two transition types. Both transition types start by pausing the current foreground Activity, and then launching the new one. During launch, the *create* transition calls both `onCreate()` and `onResume()`, while the *resume* transition only calls `onResume()`. Both `onCreate()` and `onResume()` are implemented by the app. After that, `performTraversal()` is called, in which `measure()` and `layout()` calculate the sizes and locations of UI components, and `draw()` puts them into a data structure as the new Activity UI. Finally, the *create* transition pushes the new Activity into the Back Stack and stops the current one, while the *resume* transition pops the current one and destroys it.

Activity transition graph. Immediately after a transition, the user lands on one of the ViewStates of the new Activity, which we call a *LandingState*. We denote the set of LandingStates for Activity a as $a.LS$, and $a.LS \subseteq a.VS$. Individual LandingStates are denoted as $a.ls_1, a.ls_2, ...$ Activity transition is a relationship $a.VS \rightarrow b.LS, a, b \in A$. As the ViewState before the transition is not of interest in this study, we simplify it to $a \rightarrow b.LS$, which forms the graph in Fig. 4. Note that our definition is slightly different from that in previous work [17] as the edge tails in our graph are more fine-grained: they are LandingStates instead of Activities.

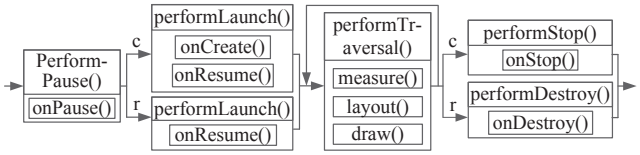

Figure 3: The function call trace for *create* (denoted by c) and *resume* (denoted by r) transitions.

2.3 Attack Overview

Our proposed UI state inference is a general side-channel attack against GUI systems, aimed at exposing the running UI state of an application at the window level, *i.e.,* the currently displayed window (without knowing the exact pixels). To achieve that, the attack exploits a newly-discovered shared-memory side channel, which may exist in nearly all popular GUI systems used today (shown in §3). In this paper, we focus on the attack on the Android platform: Activity inference attack. We expect the technique to be generalizable to all GUI systems with the same window manger design as that in Android, such as the GUI systems in Mac OS X, iOS, Windows, *etc.*

Threat model. We require an attack app running in the background on the victim device, which is a common requirement for Android-based attacks [7–11, 18]. To ensure stealthiness, the app should be low-overhead, not draining the battery too quickly. Also, as the purpose of permissions is to alert users to privacy- or security-invasive apps [19], the attack should not require any additional permissions besides a few very common ones, for example the INTERNET permission.

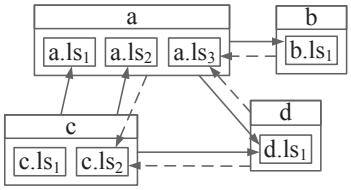

Figure 4: An example Activity transition graph. Solid and dotted edges denote *create* and *resume* transitions respectively.

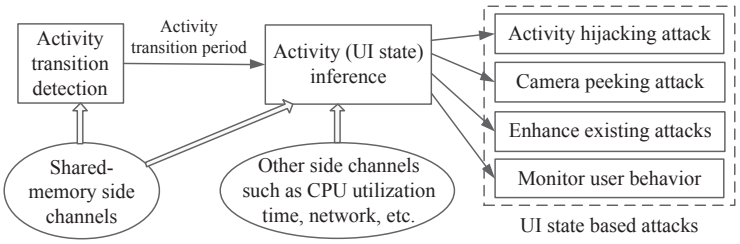

Figure 5: Activity inference attack overview.

General steps. As shown in Fig. 5, Activity inference is performed in two steps:

1. Activity transition detection: we first detect an Activity transition event, which reports a single bit of information on whether an Activity transition just occurred. This is enabled by the newly-discovered shared-memory side channel. As shown later in §3.3, the change observed through this channel is a highly-distinct "signal".

2. Activity inference: upon detecting an Activity transition, we need to differentiate which Activity is entering the foreground. To do so, we design techniques to train the "signature" for the landing Activity, which roughly characterizes its starting behavior through publicly observable channels, including the new shared-memory side channel, CPU utilization time, and network activity (described in §4).

Finally, using our knowledge of the foreground Activity in real time, we develop novel attacks that can effectively steal sensitive user input as well as other information as detailed in §6, §7 and §8.

3 Shared-Memory Side Channel and Activity Transition Detection

In this section, we first report the newly-discovered side channel along with the fundamental reason for its existence, and then detail the transition detection technique.

3.1 Shared-Memory Side Channels

As with any modern OS design, the memory space of an Android app process consists of the private space and the shared space. Table 1 lists memory counters in */proc/pid/statm* and their names used in the Linux command *top* and the Linux source code. Inherited from Linux, these counters can be freely accessed without any privileges. With these counters, we can calculate both the private and shared sizes for virtual memory and physical memory. In this paper, we leverage `mm->shared_vm` and `file_rss` as our shared-memory side channels, the former for virtual memory and the latter for physical memory. For convenience, we refer to them as *shared_vm* and *shared_pm*. In this section, we focus on using *shared_vm* to detect Activity transition events. In §4.1, we use both *shared_vm* and *shared_pm* to infer Android Content Provider usages in the Activity inference, which is another use case we discovered.

3.2 Android Window Events and Shared-Memory Side Channel

We find that *shared_vm* changes are correlated with Android window events. In this section, we detail its root cause and prevalence in popular GUI systems.

Shared-memory IPC used in the Android window manager. As mentioned earlier in §2.1, Android adopts the client-drawn buffer design, where each client (app) needs to use a selected IPC mechanism to communicate their off-screen buffers with the window compositor. In practice, we find that shared memory is often used, since it is the most efficient channel (without large memory copy overhead). On Android, when an Activity transition occurs, *shared_vm* size changes can be found in both the app process and the window compositor process named *SurfaceFlinger*. More investigations into Android source code reveal that the size changes correspond to the allocations and deallocations of a data structure named *GraphicBuffer*, which is the off-screen buffer in Android. In the Android window drawing process shown in Fig. 3, GraphicBuffer is shared between the app process and the SurfaceFlinger process using `mmap()` at the beginning of `draw()` in `performTraversal()`.

Interestingly, this implies that if we know the GraphicBuffer size for a target window, we can detect its allocation and deallocation events by monitoring the size changes of *shared_vm*. Since the GraphicBuffer size is proportional to the window size, and an Activity is a full-screen window, its GraphicBuffer size is fixed for a given device, which can be known beforehand.

It is noteworthy that different from private memory space, shared memory space changes only when shared files or libraries are mapped into the virtual memory. This keeps our side channel clean; as a result, the changes in *shared_vm* are distinct with minimum noise.

Shared-memory side-channel vulnerability on other OSes. To understand the scope, we investigate other OSes besides Android. On Linux, Wayland makes it clear that it uses shared buffers as IPC between the win-

Item in */proc/-pid/statm*	Description	Name in *top*	Name in Linux source code
VmSize	Total virtual memory size	VIRT	`mm->total_vm`
drs	Private virtual memory size	/	`mm->total_vm-mm->shared_vm`
resident	Total physical memory size	RES	`file_rss+anon_rss`
share	Shared physical memory size	SHR	`file_rss`

Table 1: Android/Linux memory counters in */proc/pid/statm* and their names in the Linux command *top*, and the Linux source code (obtained from `task_statm()` in `task_mmu.c`). The type of `mm` is `mm_struct`.

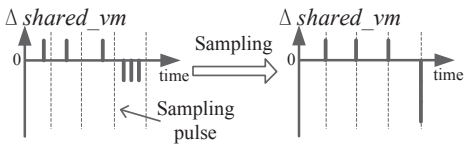

Figure 6: A successful sampling of an Activity transition signal for the Activity transition detection

dow compositor and clients to render the windows [13]. Similar to Android, attackers can use */proc/pid/statm* to get the shared memory size and detect window events.

Mac OS X, iOS and Windows neither explain this IPC in their documentations nor have corresponding source code for us to explore, so we did some reverse engineering using memory analysis tools such as VMMap [20]. On Windows 7, we found that whenever we open and close a window, a memory block appears and disappears in the shared virtual memory space of both the window compositor process, *Desktop Window Manager*, and the application process. Moreover, the size of this memory block is proportional to the window size on the screen. This strongly implies that this memory block is the off-screen buffer and shared memory is the IPC used for passing it to the window compositor. Thus, using the `GetProcessMemoryInfo()` API that does not require privilege, similar inference may be possible.

Mac OS X is similar to Windows except that the memory block in shared memory space is named *CG backing store*. On iOS this should be the same as Mac OS X since they share the same window compositor, *Quartz Compositor*. But on Mac OS X and iOS, only system-wide aggregated memory statistics seem available through `host_statistics()` API, which may still be usable for this attack but with a less accuracy.

3.3 Activity Transition Detection

With the above knowledge, detecting Activity transition is simply a matter of detecting the corresponding window event pattern by monitoring *shared_vm* size changes.

The left half of Fig. 6 shows the typical *shared_vm* changing pattern for an Activity transition, and we name it *Activity transition signal*. In this signal, the positive and negative spikes are increases and decreases in *shared_vm* respectively, corresponding to GraphicBuffer allocations and deallocations. The GraphicBuffer allocation for the new Activity usually happens before the deallocation for the current Activity, which avoids user-visible UI delays. Since Activity windows all have full-screen sizes, the increase and decrease amount are the same. With the multiple buffer mechanism for UI drawing acceleration on Android [21], 1–3 GraphicBuffer allocations or deallocations can be observed during a single transition, resulting in multiple spikes in Fig. 6. The delay between allocations is usually 100–500 ms due to measurement and layout computations, while the delay between deallocations is usually under 10 ms. An example result of a successful sampling is shown on the right half of Fig. 6 with the sampling period being 30–100 ms.

To detect this signal, we monitor the changes of *shared_vm*, and conclude an *Activity transition period* by observing (1) both full-screen size *shared_vm* increase and decrease events, (2) the idle time between two successive events is longer than a threshold *idle_thres*. A successful detection is shown on the top of Fig. 10.

We evaluate this method and find a very low false positive rate, which is mainly because the *shared_vm* channel is clean. In addition, it is rare that the following unique patterns happen randomly in practice: (1) the *shared_vm* increase and decrease amounts are exactly the same as the full-screen GraphicBuffer size (920 pages for Samsung Galaxy S3); (2) both the increase and decrease events occur very closely in time.

On the other hand, this method may have false negatives due to a cancellation effect — when an increase and a decrease are in the same sampling period, they cancel each other and the *shared_vm* size stays unchanged. Raising the sampling rate can overcome this problem, but at the cost of increased sampling overhead. Instead, we solve the problem using the number of minor page faults (*minflt*), in */proc/pid/stat*. When allocating memory for a GraphicBuffer, the physical memory is not actually allocated until it is used. At time of use, the same number of pages faults as the allocated GraphicBuffer page size is generated. Since *minflt* monotonically increases as a cumulative counter, we can use it to deduce the occurrence of a cancellation event.

4 Activity Inference

After detecting an Activity transition, we infer the identity of the new Activity using two kinds of information:

1. Activity signature. Among functions involved in the transition (as shown in Fig. 3), `onCreate()` and `onResume()` are defined in the landing Activity, and the execution of `performTraversal()` depends on the UI elements and layout in its LandingState. Thus, every transition has behavior specific to the landing Activ-

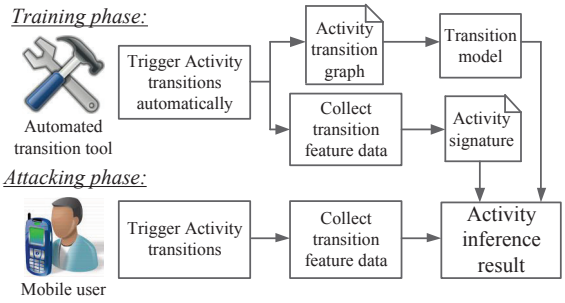

Figure 7: Overview of the Activity inference

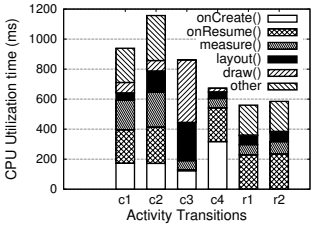

Figure 8: CPU utilization time breakdown for 6 Activity transitions in WebMD

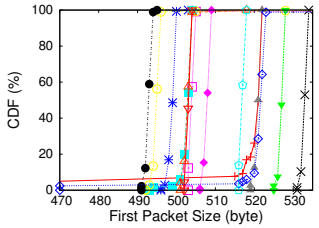

Figure 9: CDF of the first packet sizes for various LandingStates in H&R Block

ity, giving us opportunities to infer the landing Activity based on feature data collected during the transition.

2. Activity transition graph. If the Activity transition graph of an app is sparse, once the foreground Activity is known, the set of the next candidate Activities is limited, which can ease the inference difficulty. Thus, we also consider Activity transition graph in the inference.

Fig. 7 shows an overview of the Activity inference process. This process has two phases, the training phase and the attacking phase. The training phase is executed first offline. We build a tool to automatically generate Activity transitions in an app, and at the same time collect feature data to build the Activity signature and construct the Activity transition graph. In the attacking phase, when a user triggers an Activity transition event, the attack app first collects feature data like in the training phase, then leverages Activity signature and a transition model based on the Activity transition graph to perform inference.

4.1 Activity Signature Design

During the transition, we identify four types of features described below and use them jointly as the signature.

Input method events. Soft keyboard on smartphones is commonly used to support typing in Activities. It usually pops up automatically at the landing time. There is also a window event for the keyboard process, which again can be inferred through *shared_vm*. This is a binary feature indicating whether the LandingState requires typing.

Content Provider events. Android component Content Provider manages access to a structured set of data using SQLite as backend. To deliver content without memory copy overhead, Android uses anonymous shared memory (*ashmem*) shared by the Content Provider and the app process. Similar to the compositing window manger design, by monitoring *shared_vm*, we can detect the query and release events of the Content Provider. Specifically, in Android design, we found that the virtual memory size of ashmem allocated for a Content Provider query is a fixed large value, *e.g.,* 2048 KB for Android 4.1, which creates a clear signal. Usually its content only constitutes a small portion. To know the content size, we also monitor *shared_pm* introduced in §3.1, which indicates the physical memory allocation size for the content.

The Content Provider is queried in `onCreate()` and `onResume()` to show content in the landing Activity. For signature construction, we collect Content Provider query events and the corresponding content size by monitoring *shared_vm* and *shared_pm*. As *shared_pm* may be noisy, we use a normal distribution to model the size.

CPU utilization time. Fig. 8 shows the CPU utilization time collected by DDMS [22] for each function in Fig. 3 during the transition. For the 6 transitions, c and r denote *create* and *resume* transition, and 1–4 denote 4 different LandingStates. The time collected may be inflated due to the overhead added by DDMS profiling. The figure shows that CPU utilization time spent in each function differs across distinct LandingStates due to distinct drawing complexity, and for the same LandingState, *resume* transitions usually take less time than *create* ones since the former lacks `onCreate()`. Thus, the CPU utilization time can be used to distinguish Activity transitions with different transition types and LandingStates.

To collect data for this feature, we record the user space CPU utilization time value (*utime*), in */proc/pid/stat* for the Activity transition. Similar to previous work [23, 24], we find that the value for the same repeated transition roughly follows normal distribution. Thus, we model it using a normal distribution.

Network events. For LandingStates with content from the network, network connection(s) are initiated in `performLaunch()` during the transition. For a given LandingState, the request command string such as HTTP GET is usually hard-coded, with only minor changes from app states or user input. This leads to similar size of the first packet immediately after the connection establishment. We do not use the response packet size, since the result may be dynamically generated. Fig. 9 shows the CDF of the first packet sizes for 14 Activity LandingStates in H&R Block. As shown, most distributions are quite stable, with variations of less than 3 bytes.

To capture the first packet size, we monitor the send packet size value in */proc/uid_stat/uid/tcp_snd*. We con-

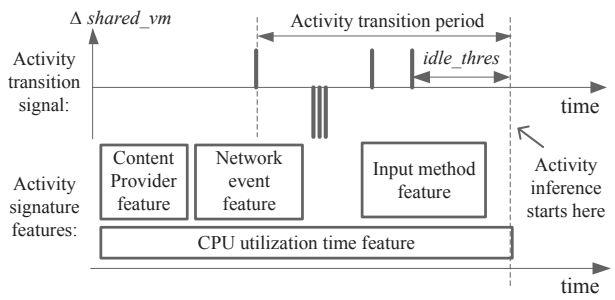

Figure 10: Signature feature data collection timeline.

currently monitor */proc/net/tcp6*, which contains network connection information such as the destination IP address and app uid for all apps. We use the uid to find the app which the connection belongs to, and use time correlation to match the first packet size to the connection. For the LandingState with multiple connections, we use the *whois* IP address registry database [25] to get the organization names and thus distinguish connections with different purpose. To read first packet sizes accurately, we raise the sampling rate to be 1 in 5 ms during the transition period. Since this period usually lasts less than 1 second, the overall sampling overhead is still low.

For signature construction, we keep separate records for connections with different organization names and occurrence ordering. For each record, we use the first packet size appearance frequencies to calculate the probability for this feature.

Fig. 10 shows the data collection timeline for these feature data and their relationship with the *shared_vm* signal. The Content Provider event feature is collected before the first *shared_vm* increase, and the input method event feature is collected after the first *shared_vm* decrease. Network events are initiated before the first *shared_vm* increase, while the first packet size is usually captured after that. The CPU utilization time feature is collected throughout the whole transition period.

With these four types of features, our signature probability $Prob(\langle\cdot, a.ls_i\rangle)$, $a \in A$, $a.ls_i \in a.LS$ is obtained by computing the product of each feature's probability, based on the observation that they are fairly independent. In §5, we evaluate our signature design with these four features both jointly and separately.

4.2 Transition Model and Inference Result

Transition model. In our inference, the states (*i.e.,* Activities) are not visible, so we use Hidden Markov Model (HMM) to model Activity transitions. We denote the foreground Activity trace with n Activity transitions as $\{a_0, a_1, ..., a_n\}$. The HMM can be solved using the Viterbi algorithm [26] with initialization $Prob(\{a_0\}) = \frac{1}{|A|}$, and inductive steps $Prob(\{a_0, ..., a_n\}) = \underset{a_n.ls_i \in a_n.LS}{\arg\max} Prob(\langle\cdot, a_n.ls_i\rangle) Prob(a_n|a_{n-1}) Prob(\{a_0, ..., a_{n-1}\})$.

In inductive steps, $Prob(\langle\cdot, a_n.ls_i\rangle)$ denotes the probability calculated from Activity signature, and $Prob(a_n|a_{n-1})$ denotes the probability that a_{n-1} transitions to a_n. If a_{n-1} has x egress edges in the transition graph, $Prob(a_n|a_{n-1}) = \frac{1}{x}$, assuming that user choices are uniformly distributed.

The typical Viterbi algorithm [26] calculates the most likely Activity trace $\{a_0, a_1, ..., a_n\}$, with computation complexity $O((n+1)|A|^2)$. However, for our case, only the new foreground Activity a_n is of interest, so we modify the Viterbi algorithm by only calculating $Prob(\{a_{n-c+1}, ..., a_n\})$, where c is a constant. This reduces the computation complexity to $O(c|A|^2)$. In our implementation, we choose $c = 2$.

Inference result. After inference, our attack outputs a list of Activities in decreasing order of their probabilities.

4.3 Automated Activity Transition Tool

By design, both the Activity signature and Activity transition graph are mostly independent of user behavior; therefore, the training phase does not need any victim participation. Thus, we also develop an automated tool to accelerate the training process offline.

Implementation. Our tool is built on top of `ActivityInstrumentationTestCase`, an Android class for building test cases of an app [27]. The implementation has around 4000 lines of Java code.

Activity transition graph generation with depth-first search. To generate the transition graph, we send and record user input events to Activities to drive the app in a depth-first search (DFS) fashion like the depth-first exploration described in [17]. The DFS graph has ViewStates as nodes, user input event traces as edges (*create* transitions), and the BACK key as the back edge (*resume* transitions). Once the foreground Activity changes, transition information such as the user input trace and the landing Activity name is recorded. The graph generated is in the form of the example shown in Fig. 4.

Activity transition graph traversal. With the transition graph generated, our tool supports automatic graph traversals in deterministic and random modes. In the random mode, the tool chooses random egress edges during the traversal, and goes back with some probabilities.

Tool limitations. We assume Activities are independent from each other. If changes in one Activity affect Activity transition behavior in another, our tool may not be aware of that, leading to missed transition edges. For some user input such as text entering, the input generation is only a heuristic and cannot ensure 100% coverage. To address such limitations, some human effort is involved to ensure that we do not miss the important Activities and ViewStates.

Application name	Activity number	Activity transitions					Activity LandingStates			
		create type	*resume* type	Total	Graph density	Average egress edge per Activity	Number	w/ content provider	w/ input method	w/ network
WebMD	38	274	129	403	14.0%	10.0	92	18.7%	15.3%	70.3%
Chase	34	257	39	296	17.4%	8.71	50	4%	0.00%	44.0%
Amazon	19	209	190	399	55.3%	21.0	39	0.00%	7.69%	74.3%
NewEgg	55	242	253	495	8.2%	9.0	80	0.00%	8.75%	97.5%
GMail	7	10	10	20	20.4%	2.86	17	0.00%	5.71%	5.8%
H&R Block	20	58	39	97	12.1%	4.85	42	0.00%	2.3%	100%
Hotel.com	24	29	41	70	6.1%	2.92	35	0.00%	2.8%	100%

Table 2: Characteristics of Activity, Activity LandingStates and Activity transitions of selected apps (numbers are obtained manually as the ground truth). The CPU utilization time feature is omitted since it is always available.

Application name	Activity transition detection			Activity inference accuracy		
	Accuracy	FP	FN	Top 1 cand.	Top 2 cand.	Top 3 cand.
WebMD	99%	0.50%	1.0%	84.5%	91.4%	93.6%
Chase	99.5%	0.53%	0.63%	83.1%	91.8%	95.7%
Amazon	99.3%	4%	0.7%	47.6%	65.6%	74.1%
NewEgg	98.4%	0.1%	1.6%	85.9%	92.6%	96.3%
GMail	99.2%	0%	0.8%	92.0%	98.3%	99.3%
H&R Block	97.7%	2%	2.3%	91.9%	96.7%	98.1%
Hotel.com	96.5%	0.6%	3.5%	82.6%	92.7%	96.7%

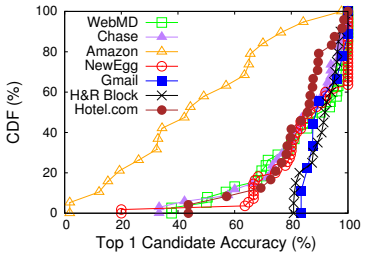

Figure 11: CDF of the average accuracy for top 1 candidates

5 Evaluation

In this section, we evaluate (1) the effectiveness of the automated Activity transition tool, (2) the performance of the Activity inference, and (3) the attack overhead.

Attack implementation. We implement the Activity inference attack with around 2300 lines of C++ code compiled with Android NDK packaged in an attack app.

Data collection. We use the automated tool in §4.3 to generate Activity transitions. We use random traversals to simulate user behavior, and deterministic traversals in controlled experiments for training and parameter selection, *e.g.,* the sampling rate. We run all experiments on Samsung Galaxy S3 devices with Android 4.2. We do not make use of any device-specific features and expect our findings to apply to other Android phones.

App selection and characteristics. In our experiments, we choose 7 Android apps, WebMD, GMail, Chase, H&R Block, Amazon, NewEgg, and Hotel.com, all of which are popular and also contain sensitive information. Table 2 characterizes these apps according to properties relevant to our attack techniques. NewEgg and GMail have the highest and the lowest number of Activities, and Amazon has the highest graph density. Chase app is the only one with no automatic soft keyboard pop-up during the transition among these apps. The Content Provider is only extensively used by WebMD. Except GMail, the percentage of the network feature is usually high.

5.1 Activity Transition Tool Evaluation

For Activity transition graph generation, the tool typically spends 10 minutes to 1 hour on a single Activity, depending on the UI complexity. For all apps except WebMD, the generated transition graphs are exactly the same as the ones we generate manually. The transition graph of WebMD misses 4 *create* transition edges and 3 *resume* transition edges, which is caused by dependent Activity issues described in §4.3. Our tool generates no fake edges for all selected apps.

5.2 Activity Inference Attack Evaluation

Evaluation methodology. We run the attack app in the background while the tool triggers Activity transitions. The triggered Activity traces are recorded as the ground truth. To simulate the real attack environment, the attack is launched with popular apps such as GMail and Facebook running in the background. For the Activity transition detection, we measure the accuracy, false positive (FP) and false negative (FN) rates. For the Activity inference, we consider the accuracy for the top N candidates — the inference is considered correct if the right Activity is ranked top N on the result candidate list.

5.2.1 Activity Transition Detection Results

Aggregated Activity transition detection results are shown in columns 2–4 in Table 3. For all selected apps, the detection accuracies are more than 96.5%, and the FP and FN rates are both less than 4%.

When changing the sampling period from 30 to 100 ms in our experiment, for all apps the increases of FP and FN rates are no more than 5%. This shows a small impact of the sampling rate on the detection; thus, a lower sampling rate can be used to reduce sampling overhead.

We also measure Activity transition detection delay, which is the time from the first *shared_vm* increase to the moment when the Activity transition is detected in

Fig. 10. For all apps, 80% of the delay is shorter than 1300 ms, which is fast enough for Activity tracking.

5.2.2 Activity Inference Results

The aggregated Activity transition inference result is shown in column 5–7 in Table 3. For all apps except Amazon, the average accuracies for the top 1 candidates are 82.6–92.0%, while the top 2 and top 3 candidates' accuracies exceed 91.4% and 93.6%. Amazon's accuracy remains poor, and can achieve 80% only when considering the top 5 candidates. In the next section, we will investigate more into the reason of these results.

Fig. 11 shows the CDF of the accuracy for top 1 candidates per Activity in the selected apps. Except Amazon, all apps have more than 70% of Activities with more than 80% accuracy. For WebMD, NewEgg, Chase and Hotel.com, around 20% Activities have less than 70% accuracy. For these Activities, they usually lack some signature features, or the features they have are too common to be distinct enough. However, such Activities usually do not have sensitive data due to a lack of important UI features such as text fields for typing, and thus are not relevant to the proposed attacks. For example, in Hotel.com, the two Activities with less than 70% accuracy are CountrySelectActivity for switching language and OpinionLabEmbeddedBrowserActivity for rating the app.

5.2.3 Breakdown Analysis and Discussion

To better understand the performance results, we break down the contributions of each signature feature and the transition model further. Table 4 shows the decrease of the average accuracy for top 1 candidates if leaving out certain features or the transition model. Without the CPU utilization time feature, the accuracy decreases by 36.2% on average, making it the most important contributor. Contributions from the network feature and the transition model are also high, which generally improves the accuracy by 12–30%. As low-entropy features, the Content Provider and the input method contribute under 5%. Thus, the CPU utilization time, the network event and the transition model are the three most important contributors to the final accuracy. Note that though the Content Provider and input method features have lower contributions, we find that the top 2 and top 3 candidates' accuracies benefit more from them. This is because they are more stable features, and greatly reduce the cases with extremely poor results due to the high variance in the CPU utilization time and the network features.

Thus, considering that the CPU utilization time is always available, apps with a high percentage of network features, or a sparse transition graph, or both, should have a high inference accuracy. In Table 2 and Table 3, this rule applies to all the selected apps except Amazon.

Application name	Δ Accuracy for top 1 candidates				
	no IM	no CP	no Net	no CPU	no HMM
WebMD	-3.8%	-2.6%	-19.1%	-25.7%	-16.6%
Chase	-0%	-2.0%	-12.8%	-71.5%	-28.7%
Amazon	-10.2%	-0%	-3.2%	-32.0%	-5.9%
NewEgg	-0.5%	-0%	-31.7%	-20.0%	-13.0%
GMail	-13.7%	-0%	-0.9%	-58.6%	-19.4%
H&RBlock	-0.7%	-0%	-30.7%	-27.9%	-16.5%
Hotel.com	-0.3%	-0%	-28.8%	-17.9%	-12.2%

Table 4: Breakdown of individual contributions to accuracy. IM, CP, Net, and CPU stand for input method, Content Provider, network event and CPU utilization time.

Amazon has a low accuracy mainly because it benefits little from either the transition model or the network event feature due to high transition graph density and infrequent network events. The reason for the high transition graph density is that in Amazon each Activity has a menu which provides options to transition to nearly all other Activities. The infrequent network events are due to its extensively usage of caching, presumably because much of its content is static and cacheable. However, we note that many network events are typically not cacheable, *e.g.,* authentication events and dynamic content (generated depending on the user input and/or the context). Compared to the other 6 apps, we find that these two properties for Amazon are not typical, not present in another shopping app NewEgg.

The Amazon app case indicates that our inference method may not work well if certain features are not sufficiently distinct, especially the major contributors such as the transition model and the network event feature. To better understand the general applicability of our inference technique, a more extensive measurement study about the Activity and Activity transition graph properties is needed, which we leave as future work.

5.2.4 Attack overhead

We use the Monsoon Power Monitor [28] to measure the attack energy overhead. Using an Activity trace of WebMD on the same device, with our attack in the background the power level increases by 2.2 to 6.0% when the sampling period changes from 100 to 30 ms.

6 Enabled Attack: Activity Hijacking

In this section, based on the UI state tracking, we design a new Android attack which breaches GUI integrity — Activity hijacking attack — based on a simple idea: stealthily inject into the foreground a phishing Activity at the right timing and steal sensitive information a user enters, *e.g.,* the password in login Activity.

Note that this is not the first attack popping up a phishing Activity to steal user input, but we argue that it is the first general one that can hijack any Activities during an app's lifetime. Previous study [29] pops up a fake login

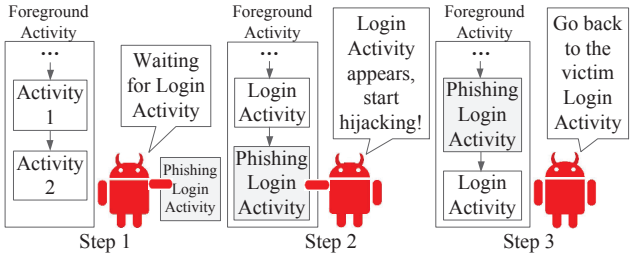

Figure 12: General steps of the Activity hijacking attack

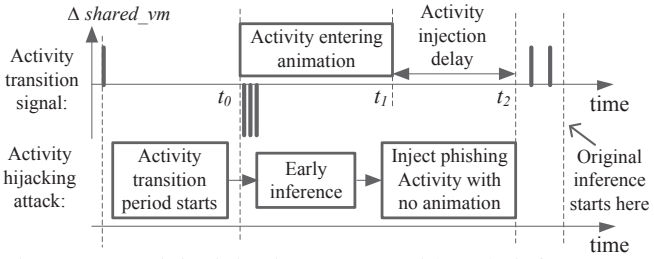

Figure 13: Activity injection process with early inference

Activity every time the attack app detects the launching of the target app, tricking users into entering login credentials. However, this can easily cause user suspicion due to the following: (1) most apps nowadays do not require login right after the app starts, even for banking apps like Chase; (2) the attack requires suspicious permissions such as BOOT_COMPLETED to be notified of system boot, based on the assumption that login is expected after the system reboot. With the Activity inference attack, we no longer suffer from these limitations.

6.1 Activity Hijacking Attack Overview

Fig. 12 shows the general steps of Activity hijacking attack. In step 1, the background attack app uses Activity inference to monitor the foreground Activity, waiting for the attack target, for example, LoginActivity in Fig. 12.

In step 2, once the Activity inference reports that the target victim Activity, *e.g.,* LoginActivity, is about to enter the foreground, the attack app simultaneously injects a pre-prepared phishing LoginActivity into the foreground. Note that the challenge here is that this introduces a race condition where the injected phishing Activity might enter the foreground too early or too late, causing visual disruption (*e.g.,* broken animation). With carefully designed timing, we prepare the injection at the perfect time without any human-observable glitches during the transition (see video demos [6]). Thus, the user will not notice any differences, and continue entering the password. At this point, the information is stolen and the attack succeeds.

In step 3, the attack app ends the attack as unsuspiciously as possible. Since the attack app now becomes the foreground app, it needs to somehow transition back to the original app without raising much suspicion.

6.2 Attack Design Details

Activity injection. To understand how it is possible to inject an Activity from one app into the foreground and preempt the existing one, we have to understand the design principle of smartphone UI. If we think about apps such as the alarm and reminder apps, they indeed require the ability to pop up a window and preempt any foreground Activities. In Android, such functionality is supported in two ways without requiring any permissions: (1) starting an Activity with a restricted launching mode "SingleInstance" [30]; (2) starting an Activity from an Android broadcast receiver [31]. In our design, since the timing of the injection is critical, we choose the former as it can be launched 30 ms faster.

UI phishing. To ensure that the phishing Activity's UI appears the same as the victim Activity, we disassemble the victim app's apk using *apktool* [32] and copy all related UI resources to the attack app. However, sometimes the Activity UI may have dynamically loaded areas which are not determined by the UI resources, *e.g.,* the account verification image in banking apps. To solve that, the attacker can make those areas transparent, given that Android supports partially transparent Activity [33].

Activity transition animation modifying. Since our injection introduces an additional Activity transition which is racing with the original transition, the animation of the additional transition would clearly disrupt the flow. Fortunately, this problem can be solved by disabling the transition animation (allowed by Android) by modifying an Activity configuration of the attack app without needing any permissions. This helps the injection become totally seamless, and as will be discussed in §9, enforcing this animation may be a feasible mitigation of our attack.

Injection timing constraint. For the attack to succeed, the Activity injection needs to happen before any user interaction begins, otherwise the UI change triggered by it may be disrupted by the injected Activity. Since the injection with the current inference technique takes quite long (the injected Activity will show up after around 1300 ms from the first detected *shared_vm* increase as measured in §5), any user interaction during this period would cause disruptions. To reduce the delay, we adapt the inference to start much earlier. As shown in Fig. 13, we now start the inference as soon as the *shared_vm* decrease is observed (roughly corresponding to the Activity entering animation start time). In contrast, our original inference starts after the last *shared_vm* increase.

Note that this would limit the feature collection up to the point of the *shared_vm* decrease, thus impacting the inference accuracy. Fortunately, as indicated in Fig. 10, such change does allow the network event feature, the

majority of the CPU utilization time features, and the transition model to be included in the inference, which are the three most important contributors to the final accuracy as discussed in §5.2.3. Based on our evaluation, this would reduce the delay to only around 500 ms.

Unsuspicious attack ending. As described in §6.1, in step 3 we try to transition from the attack app back to the victim unsuspiciously. Since the phishing Activity now has the information entered on the screen, it is too abrupt to directly close it and jump back to the victim. In our design, we leverage "benign" abnormal events to hide the attack behavior, *e.g.,* the attack app can show "server error" after the user clicks on the login button, and then quickly destroy itself and fall back to the victim.

Deal with cached user data. It is common that some sensitive data may be cached, thus won't be entered at all, *e.g.,* the user name in login Activity. Without waiting for them to expire, it is difficult to capture any fresh input.

Note that we can simply inject the phishing Activity with all fields left blank. The challenge is to not alert the user with any other observable suspicious behavior. Specifically, depending on the implementation, we find that the cached user data sometimes show up immediately in the very first frame of the Activity entering animation (t_0 in Fig. 13). Thus, our later injection would clear the cached fields, which causes visual disruption.

Our solution is to pop up a tailored cache expiration message (replicating the one from the app), and then clear such cached data, prompting users to re-enter them.

6.3 Attack Implementation and Evaluation

Implementation. We implement Activity hijacking attack against 4 Activities: H&R Block's LoginActivity and RefundInfoActivity for stealing the login credentials and SSN, and NewEgg's ShippingAddressAddActivity and PaymentOptionsModifyActivity for stealing the shipping/billing address and credit card information. The latter two Activities do not appear frequently in the check-out process since the corresponding information may be cached. Thus, to force the user to re-enter them, our attack injects these two Activities into the check-out process. The user would simply think that the cached information has expired. In this case the fake cache expiration messages are not needed, since the attack can fall back to the check-out process naturally after entering that information. Attack demos can be found in [6].

Evaluation. The most important metric for our attack is the Activity injection delay, which is the time from t_1 to t_2 in Fig. 13. In Android, it is hard to know precisely the animation ending time t_1, so the delay is measured from t_0 to t_2 as an upper bound. In the evaluation the Activity injection is performed 50 times for the LoginActivity of H&R Block app, and the average injection delay is 488 ms. Most of the delay time is spent in `onCreate()` (242 ms) and `performTraverse()` (153 ms). From our experience, the injection is fast enough to complete before any user interaction starts.

7 Enabled Attack: Camera Peeking

In this section, we show another new attack enabled by the Activity inference: camera peeking attack.

7.1 Camera Peeking Attack Overview

Due to privacy concerns, many apps store photo images shot by the camera only in memory and never make them publicly accessible, for example by writing them to external storage. This applies to many apps such as banking apps (*e.g.,* Chase), shopping apps (*e.g.,* Amazon and Best Buy), and search apps (*e.g.,* Google Goggles). Such photo images contain highly-sensitive information such as the user's life events, shopping interests, home address and signature (on the check). Surprisingly, we show that with Activity tracking such sensitive and well-protected camera photo images can be successfully stolen by a background attack app. Different from PlaceRaider [34], our attack targets at the camera photo shot by the user, instead of random ones of the environment.

Our attack follows a simple idea: when an Activity is using the camera, the attack app quickly takes a separate image while the camera is still in the same position. In the following, we detail our design and implementation.

7.2 Attack Design Details

Background on Android camera resource management. With the camera permission, an Android app can obtain and release the camera by calling `open()` and `release()`. Once the camera is obtained, an app can then take pictures by calling `takePicture()`. There are two important properties: (1) exclusive usage. The camera can be used by only one app at any point in time; (2) slow initialization. Camera initialization needs to work with hardware, so `open()` typically takes 500–1000 ms (measured on Samsung Galaxy S3 devices).

Obtain camera images in the background. In the Android documentation, taking pictures in the background is explicitly disallowed due to privacy concerns [35]. Though PlaceRaider [34] succeeded in doing so, we find that their technique is restricted to certain devices running old Android systems which do not follow the documentation correctly, *e.g.,* Droid 3 with Android 2.3.

Interestingly, we find *camera preview frames* to be the perfect alternative interface for obtaining camera images without explicitly calling `takePicture()`. When using the camera, the preview on the screen shows a live video stream from the camera. Using `PreviewCallback()`, the video stream frames are returned one by one, which are actually the camera images we want. SurfaceTexture is used to capture this

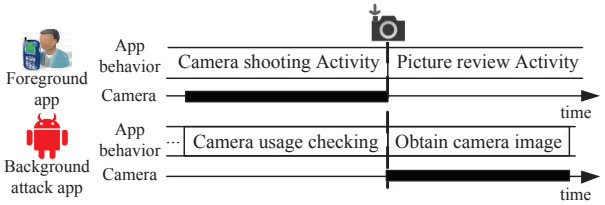

Figure 14: Camera peeking attack process when the foreground Activity is using the camera

Camera peeking attack type	Success rate	DoS rate	# of camera possession per round
Blind attack (3s idle time)	81%	19%	30.5
Blind attack (4s idle time)	83%	14%	20.9
Blind attack (5s idle time)	79%	8%	18.9
UI state based attack	99%	0%	1.4

Table 5: User study evaluation result for the camera peeking attack

image stream, and we find that it can be created with a nonexistent OpenGL texture object name, thus preventing any visible preview on the screen. We suspect that the less restrictive interface is managed by OpenGL library which bypasses the Android framework and its associated security checks. Compared to PlaceRaider [34], this technique not only has no requirement of the sensitive MODIFY_AUDIO_SETTINGS permission to avoid shutter sound, but also has much faster "shutter speed" of 24 frames per second. Note that even if this interface is blocked, our attack can still use techniques in §6 to inject an Activity to the foreground to get the preview frames.

Obtain photo images shot by the user. Fig. 14 shows how our attack gets the photo image the user shoots in the victim app. The photo taking functionality usually involves a camera shooting Activity and a picture review Activity. Once the user clicks on the shutter button in the former, the latter pops up with the picture just taken. Due to the exclusive usage property, when the foreground Activity is using the camera the attack app cannot get the camera. Thus, once knowing that the camera is in use, the attack app keeps calling `open()` to request the camera until it succeeds right after the user presses the shutter button and the camera gets released during the Activity transition. Since the delay to get a camera preview frame is only the initialization time (500–1000 ms), the camera is very likely still pointing at the same object, thus obtaining a similar image.

Capture the camera usage time. To trigger the attack process in Fig. 14, the attack app needs to know when the camera is in use in the foreground. However, due to the slow initialization, a naive solution which periodically calls `open()` to check the camera usage will possess the camera for 500–1000 ms for each checking action when the camera is not in use. During that time, if the foreground app tries to use the camera, a denial of service (DoS) will take place. With 12 popular apps, we find that when failing to get the camera, most apps pop up a "camera error" or "camera is used by another app" message and some even crash immediately. These errors may indicate that an attack is ongoing and alert the user. Besides, the frequent camera resource possessing behavior is easily found suspicious with increasing concerns about smartphone camera usage [34].

To solve the problem, our attack uses Activity inference to capture the camera usage time by directly waiting for the camera shooting Activity. To increase the inference accuracy for Activities using the camera, we add camera usage as a binary feature (true or false on the camera usage status) and it is only tested when the landing Activity is very likely to be the camera shooting Activity based on other features to prevent DoS and overly frequent camera possessions.

7.3 Attack Evaluation

Implementation. We implement the camera peeking attack against the check deposit functionality in Chase app, which allows users to deposit personal checks by taking a picture of the check. Besides the network permission, the attack app also needs the the camera permission to access camera preview frames. On the check photo, the attacker can steal much highly-sensitive personal information, including the user name, home address, bank routing/account number, and even the user's signature. A video demo is available at [6].

Evaluation methodology. We compare our UI state based camera peeking attack against the blind attack, which periodically calls `open()` to check the foreground camera usage as described in §7.2. We add parameter *idle time* for the blind attack as the camera usage checking period. The longer the idle time is, the lower the DoS possibility and the camera possession frequency are. However, the idle time cannot be so long that the attack misses the camera shooting events. Thus, the blind attack faces a trade-off between the DoS risk, the camera possession frequency, and the attack success rate.

User study. We evaluate our attack with a user study of 10 volunteers. In the study we use 4 Samsung Galaxy S3 phones with Android 4.1. Three of them use the blind attacks with idle time being 3, 4 and 5 seconds respectively, and the last one uses the UI state based attack. Each user performs 10 rounds, and in each round, the users are asked to first interact with the app as usual, and then go to the check deposit Activity and take a picture of a check provided by us. We emphasize that they are expected to perform as if it is their own check. The IRB for this study has been approved and we took steps to ensure that no sensitive user data were exposed, *e.g.,* by using a fake bank account and personal checks.

Performance metrics. For evaluation we measure: (1)

DoS rate, the ratio that when the user wants to use the camera but fails; (2) number of camera possessions, the number of events that the camera is possessed by the attack app; (3) success rate, the ratio that the attacker gets the check image after the user shoots the check.

Result. Table 5 shows the user study evaluation results. With the camera usage feature, the UI state based attack can achieve 99% success rate, and the only failure case is due to a failure in detecting the Activity transition. For the blind attack, the success rate is less than 83%, and when the idle time increases, the success rate increases then decreases. The increase is due to lower DoS probability, and the decrease is because the users usually finish shooting in around 4 seconds (found in our user study), so when the idle time increases to 5 seconds, the blind attack misses some camera shooting events.

UI state based attack causes no DoS during the user study. For the blind attack, the DoS rate is around 8–19%, and decreases when the idle time increases. Considering that a single DoS case may likely cause "sudden death" for the attack app, this risk is high, especially compared to the UI state based attack.

The camera possession number for the UI state based attack is also a magnitude lower. Every round, except the necessary one for camera shooting, the UI state based attack only needs 0.4 excessive camera possessions, which is mainly caused by inaccurate inference. For the blind attack, to ensure a high success rate, the camera possession number is proportional to time, making it hard to avoid suspicious frequent camera possessions.

Fig. 15 includes an average quality check image "stolen" from a real user, showing that the image is clear enough to read all the private information.

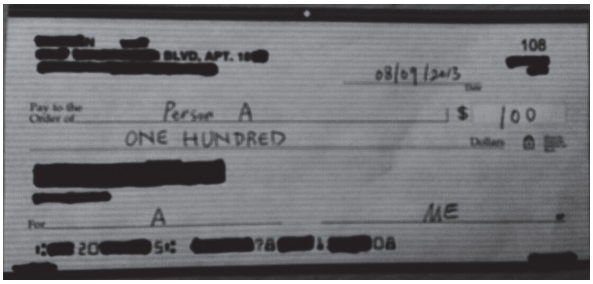

Figure 15: An example check image "stolen" using the camera peeking attack.

8 Other Attack Scenarios

Enhance existing attacks. Generally, a class of existing attacks that are launched only at specific timings benefits from UI state information. Since many attacks need to be launched at a specific timing, with the UI state information, both stealthiness and effectiveness can be achieved. For example, for the phishing attack using TCP connection hijacking [9, 10], the attack app can precisely target at connections established in Activities with web pages instead of unrelated ones, *e.g.,* database updating, keepalive messages, *etc.* The attack thus becomes more efficient and less suspicious by avoiding frequently sending large amounts of attack traffic [9]. Similar enhancement can also be applied to keystroke inference attacks [7, 8] and screenshot taking attack [5] where only keystrokes entered in login Activities may be of interest.

User behavior monitoring and analysis. UI states themselves are user behavior related internal states of an app. As shown in Fig. 2, due to the limited screen size on the smartphone, full-screen window-level UI state information breaks user-app interaction to very fine-grained states. Thus, by tracking UI states, a background app can monitor and analyze user behavior, *e.g.,* in a health app the user is more often looking for drugs or physicians.

In addition, with Activity tracking, the attacker can even infer which choice is made inside an Activity (*e.g.,* which medical condition a user is interested in). This is achieved using the size of the request packet obtained by the technique described in §4.1. For example, for QAListActivity of H&R Block app, we can infer which tax question a user is interested in based on the length of the question that is embedded in the query packet. In this question list, we find that 10 out of 11 question queries are distinguishable (with different lengths).

A similar technique was proposed recently [12], but built upon a network event based state machine, with two limitations: (1) packet size itself can be highly variable (ads connections may co-occur) and different Activities may generate similar packet size traces, *e.g.,* login Activities and user account Activities both have the authentication connection thus may have similar packet size trace. UI state knowledge would limit the space of possible connections significantly as we infer the Activity based on a more comprehensive set of features; (2) not all user choices in Android are reflected in network packets — database/Content Provider can also be used to fetch content. With our UI state machine, we can further extend the attack to the Content Provider based user choice inference. For example, in WebMD, DrugSearchMainActivity has a list of letter A to Z. Once one letter is clicked, Content Provider is queried to fetch a list of drug names starting from that letter. With the Content Provider query event and content size inference technique (described in §4.1), we characterized all of the choices and found fairly good entropy: the responding content sizes have 16 different values for the 26 letters, corresponding to 4 bits out of 4.7 bits of information for the user choice.

9 Defense Discussion

In this section, we suggest more secure system designs to defend against the attacks found in this paper.

Proc file system access control. In our attack, *shared_vm* and features of Activity signature such as CPU and network all rely on freely accessible files in proc file system. However, as pointed out by Zhou *et al.* [12], simply removing them from the list of public resources may not be a good option due to the large amount of existing apps depending on them. To better solve the problem, Zhou *et al.* [12] proposed a mitigation strategy which reduces the attack effectiveness by rounding up or down the actual value. This can work for the network side channel, but may not be effective for *shared_vm* and *shared_pm*, which are already rounded to pages (4KB) but still generate a high transition detection accuracy. This is mainly because the window buffer size is large enough to be distinct and the side channel is pretty clean, as discussed in §3.3. Thus, Android system may need to reconsider its access control strategy for these public accessible files to better balance functionality and security. In fact, Android has already restricted access to certain proc files that are publicly accessible in the standard Linux, *e.g., /proc/pid/smaps*. However, our work indicates that it is still far from being secure.

Window manager design. As described in §3.2, the existence of the shared-memory side channel is due to the requirement of the window buffer sharing in the client-drawn buffer design. Thus, a fundamental way of defending against the UI state inference attack in this paper is to use the server-drawn buffer design in GUI systems, though this means that any applications that are exposed to the details of the client-drawn buffer design need to be updated, which may introduce other side effects.

Window buffer reuse. The Activity transition signal consists of *shared_vm* increases and decreases, corresponding to window buffer allocations and deallocations. To eliminate such signal, the system can avoid them by pre-allocating two copies of the buffers and reuse them for all transitions in an app. Note that this is at the cost of much more memory usage for each app, as each buffer is several megabytes in size. However, with increasingly larger memory size in future mobile devices [36], we think this overhead may be acceptable.

In this paper, the most serious security breaches are caused by follow-up attacks based on UI state inference. Thus, we provide suggestions as follows that can mitigate the attacks even if the UI state information is leaked.

Enforce UI state transition animation. Animation is an important indicator for informing users about app state changes. In the Activity hijacking attack in §6, the seamless Activity injection is possible because this indicator can be turned off in Android. With UI state tracking, the attacker can leverage this to replace the foreground UI state with a phishing one without any visible indications. Thus, one defense on GUI system design side is to always keep this indicator on by enforcing animation in all UI state transitions. This helps reduce the attack stealthiness though it cannot fully eliminate the attack.

Limit background application functionality. In GUI systems, background applications do not directly interact with users, so they should not perform privacy-sensitive actions freely. In §7, a background attacker can still get camera images, indicating that Android did not sufficiently restrict the background app functionality. With UI state tracking, an attacker can leverage precise timing to circumvent app data isolation. Thus, more restrictions should be imposed to limit background applications' access to sensitive resources like camera, GPS, sensor, *etc.*

To summarize, we propose solutions that eliminate dependencies of the attack such as the proc file side channel, which may prevent the attack. However, more investigation is required to understand their effectiveness and most of them do require significant changes that have impact on either backward-compatibility or functionality.

10 Related Work

Android malware. The Android OS, like any systems, contains security vulnerabilities and is vulnerable to malware [37–39]. For instance, the IPC mechanisms leave Android vulnerable to confused deputy attacks [38, 39]. Malware can collect privacy-sensitive information by requesting certain permissions [37, 40]. To combat these flaws, a number of defenses have been proposed [38, 41], such as tracking the origin of inter-process calls to prevent unauthorized apps from indirectly accessing privileged information. Our attack requires neither specific vulnerabilities nor privacy-sensitive permissions, so known defense mechanisms will not protect against it.

Side-channel attacks. Much work has been done on studying side channels. **Proc file systems** have been long abused for side-channel attacks. Zhang *et al.* [24] found that the ESP/EIP value can be used to infer keystrokes. Qian *et al.* [10] used "sequence-number-dependent" packet counter side channels to infer TCP sequence number. In memento [11], the memory footprints were found to correlate with the web pages a user visits. Zhou *et al.* [12] found three Android/Linux public resources to leak private information. These attacks are mostly app-dependent, while in this paper the UI state inference applies generally to all Android apps, leading to not only a larger attack coverage but also many more serious attacks. **Timing** is another popular form of side channels. Studies have shown that timing can be used to infer keystrokes as well as user information revealed by web applications [23, 42–44]. **Sensors** are more recent, popular side-channel sources. The sound made by the keyboard [45], electromagnetic waves [46], and special software [47] can be used to infer keystrokes. More recently, a large number of sensor-based side channels have been discovered on Android, including the micro-

phone [18], accelerometer [7, 8] and camera [34]. Our attack does not rely on sensors which may require suspicious permissions. Instead, we leverage only data from the proc file system, which is readily available with no permission requirement.

Root causes of side-channel attacks. All side-channel attacks exist because of certain behavior in the software/hardware stack that can be distinguished through some forms of observable channels by attackers. For example, the inter-keystroke timing attack exploits the application and OS behavior that handles user input. SSH programs will send whatever keys the user types immediately to the network, so the timing is observable through a network packet trace [23]. For VIM-like programs, certain program routines are triggered whenever a new key is captured, so the timing can be captured through snapshots of the program's ESP/EIP values [24]. The TCP sequence number inference attack [10] exploits the TCP stack of the OS that exposes internal states through observable packet counters. In our attack, we exploit a new side channel caused by popular GUI framework behavior, in particular how user interaction and window events are designed and implemented.

11 Conclusion

In this paper, we formulate the UI state inference attack designed at exposing the running UI state of an application. This attack is enabled by a newly-discovered shared-memory side channel, which exists in nearly all popular GUI systems. We design and implement the Android version of this attack, and show that it has a high inference accuracy by evaluating it on popular apps. We then show that UI state tracking can be used as a powerful attack building block to enable new Android attacks, including Activity hijacking and camera peeking. We also discuss ways of eliminating the side channel, and suggest more secure system designs.

Gyrophone: Recognizing Speech From Gyroscope Signals

Yan Michalevsky Dan Boneh

National Research & Simulation Center
Rafael Ltd.

Abstract

We show that the MEMS gyroscopes found on modern smart phones are sufficiently sensitive to measure acoustic signals in the vicinity of the phone. The resulting signals contain only very low-frequency information (<200Hz). Nevertheless we show, using signal processing and machine learning, that this information is sufficient to identify speaker information and even parse speech. Since iOS and Android require no special permissions to access the gyro, our results show that apps and active web content that cannot access the microphone can nevertheless eavesdrop on speech in the vicinity of the phone.

1 Introduction

Modern smartphones and mobile devices have many sensors that enable rich user experience. Being generally put to good use, they can sometimes unintentionally expose information the user does not want to share. While the privacy risks associated with some sensors like a microphone (eavesdropping), camera or GPS (tracking) are obvious and well understood, some of the risks remained under the radar for users and application developers. In particular, access to motion sensors such as gyroscope and accelerometer is unmitigated by mobile operating systems. Namely, every application installed on a phone and every web page browsed over it can measure and record these sensors without the user being aware of it.

Recently, a few research works pointed out unintended information leaks using motion sensors. In Ref. [34] the authors suggest a method for user identification from gait patterns obtained from a mobile device's accelerometers. The feasibility of keystroke inference from nearby keyboards using accelerometers has been shown in [35]. In [21], the authors demonstrate the possibility of keystroke inference on a mobile device using accelerometers and mention the potential of using gyroscope measurements as well, while another study [19] points to the benefits of exploiting the gyroscope.

All of the above work focused on exploitation of motion events obtained from the sensors, utilizing the expected kinetic response of accelerometers and gyroscopes. In this paper we reveal a new way to extract information from gyroscope measurements. We show that gyroscopes are sufficiently sensitive to measure acoustic vibrations. This leads to the possibility of recovering speech from gyroscope readings, namely using the gyroscope as a crude microphone. We show that the sampling rate of the gyroscope is up to 200 Hz which covers some of the audible range. This raises the possibility of eavesdropping on speech in the vicinity of a phone without access to the real microphone.

As the sampling rate of the gyroscope is limited, one cannot fully reconstruct a comprehensible speech from measurements of a single gyroscope. Therefore, we resort to automatic speech recognition. We extract features from the gyroscope measurements using various signal processing methods and train machine learning algorithms for recognition. We achieve about 50% success rate for speaker identification from a set of 10 speakers. We also show that while limiting ourselves to a small vocabulary consisting solely of digit pronunciations ("one", "two", "three", ...) and achieve speech recognition success rate of 65% for the speaker dependent case and up to 26% recognition rate for the speaker independent case. This capability allows an attacker to substantially leak information about numbers spoken over or next to a phone (i.e. credit card numbers, social security numbers and the like).

We also consider the setting of a conference room where two or more people are carrying smartphones or tablets. This setting allows an attacker to gain simultaneous measurements of speech from several gyroscopes. We show that by combining the signals from two or more phones we can increase the effective sampling rate of the acoustic signal while achieving better speech recognition rates. In our experiments we achieved 77% successful recognition rate in the speaker dependent case based on the digits vocabulary.

The paper structure is as follows: in Section 2 we provide a brief description of how a MEMS gyroscope works and present initial investigation of its properties as a microphone. In Section 3 we discuss speech analysis and describe our algorithms for speaker and speech recognition. In Section 4 we suggest a method for audio signal recovery using samples from multiple devices. In Section 5 we discuss more directions for exploitation of gyroscopes' acoustic sensitivity. Finally, in Section 6 we discuss mitigation measures of this unexpected threat. In

particular, we argue that restricting the sampling rate is an effective and backwards compatible solution.

2 Gyroscope as a microphone

In this section we explain how MEMS gyroscopes operate and present an initial investigation of their susceptibility to acoustic signals.

2.1 How does a MEMS gyroscope work?

Standard-size (non-MEMS) gyroscopes are usually composed of a spinning wheel on an axle that is free to assume any orientation. Based on the principles of angular momentum the wheel resists to changes in orientation, thereby allowing to measure those changes. Nonetheless, all MEMS gyros take advantage of a different physical phenomenon – the Coriolis force. It is a fictitious force (d'Alembert force) that appears to act on an object while viewing it from a rotating reference frame (much like the centrifugal force). The Coriolis force acts in a direction perpendicular to the rotation axis of the reference frame and to the velocity of the viewed object. The Coriolis force is calculated by $F = 2m\vec{v} \times \vec{\omega}$ where m and v denote the object's mass and velocity, respectively, and ω denotes the angular rate of the reference frame.

Generally speaking, MEMS gyros measure their angular rate (ω) by sensing the magnitude of the Coriolis force acting on a moving proof mass within the gyro. Usually the moving proof mass constantly vibrates within the gyro. Its vibration frequency is also called the resonance frequency of the gyro. The Coriolis force is sensed by measuring its resulting vibration, which is orthogonal to the primary vibration movement. Some gyroscope designs use a single mass to measure the angular rate of different axes, while others use multiple masses. Such a general design is commonly called *vibrating structure gyroscope*.

There are two primary vendors of MEMS gyroscopes for mobile devices: STMicroelectronics [15] and InvenSense [7]. According to a recent survey [18] STMicroelectronics dominates with 80% market share. Teardown analyses show that this vendor's gyros can be found in Apple's iPhones and iPads [17, 8] and also in the latest generations of Samsung's Galaxy-line phones [5, 6]. The second vendor, InvenSense, has the remaining 20% market share [18]. InvenSense gyros can be found in Google's latest generations of Nexus-line phones and tablets [14, 13] as well as in Galaxy-line tablets [4, 3]. These two vendors' gyroscopes have different mechanical designs, but are both noticeably influenced by acoustic noise.

2.1.1 STMicroelectronics

The design of STMicroelectronics 3-axis gyros is based on a single driving (vibrating) mass (shown in Figure 1). The driving mass consists of 4 parts M_1, M_2, M_3 and M_4 (Figure 1(b)). They move inward and outward simultaneously at a certain frequency[1] in the horizontal plane. As shown in Figure 1(b), when an angular rate is applied on the Z-axis, due to the Coriolis effect, M_2 and M_4 will move in the same horizontal plane in opposite directions as shown by the red and yellow arrows. When an angular rate is applied on the X-axis, then M_1 and M_3 will move in opposite directions up and down out of the plane due to the Coriolis effect. When an angular rate is applied to the Y-axis, then M_2 and M_4 will move in opposite directions up and down out of the plane. The movement of the driving mass causes a capacitance change relative to stationary plates surrounding it. This change is sensed and translated into the measurement signal.

2.1.2 InvenSense

InvenSense's gyro design is based on the three separate driving (vibrating) masses[2]; each senses angular rate at a different axis (shown in Figure 2(a)). Each mass is a coupled dual-mass that move in opposite directions. The masses that sense the X and Y axes are driven out-of-plane (see Figure 2(b)), while the Z-axis mass is driven in-plane. As in the STMicroelectronics design the movement due to the Coriolis force is measures by capacitance changes.

2.2 Acoustic Effects

It is a well known fact in the MEMS community that MEMS gyros are susceptible to acoustic noise which degrades their accuracy [22, 24, 25]. An acoustic signal affects the gyroscope measurement by making the driving mass vibrate in the sensing axis (the axis which senses the Coriolis force). The acoustic signal can be transferred to the driving mass in one of two ways. First, it may induce mechanical vibrations to the gyros package. Additionally, the acoustic signal can travel through the gyroscope packaging and directly affect the driving mass in case it is suspended in air. The acoustic noise has the most substantial effect when it is near the resonance frequency of the vibrating mass. Such effects in some cases can render the gyro's measurements useless or even saturated. Therefore to reduce the noise effects vendors manufacture gyros with a high resonance frequency (above

[1] It is indicated in [1] that STMicroelectronics uses a driving frequency of over 20 KHz.

[2] According to [43] the driving frequency of the masses is between 25 KHz and 30 KHz.

20 KHz) where acoustic signals are minimal. Nonetheless, in our experiments we found that acoustic signals at frequencies much lower than the resonance frequency still have a measurable effect on a gyro's measurements, allowing one to reconstruct the acoustic signal.

2.3 Characteristics of a gyro as a microphone

Due to the gyro's acoustic susceptibility one can treat gyroscope readings as if they were audio samples coming from a microphone. Note that the frequency of an audible signal is higher than 20 Hz, while in common cases the frequency of change of mobile device's angular velocity is lower than 20 cycles per second. Therefore, one can high-pass-filter the gyroscope readings in order to retain only the effects of an audio signal even if the mobile device is moving about. Nonetheless, it should be noted that this filtering may result in some loss of acoustic information since some aliased frequencies may be filtered out (see Section 2.3.2). In the following we explore the gyroscope characteristics from a standpoint of an acoustic sensor, i.e. a microphone. In this section we exemplify these characteristics by experimenting with Galaxy S III which has an STMicroelectronics gyro [6].

2.3.1 Sampling

Sampling resolution is measured by the number of bits per sample. More bits allow us to sample the signal more accurately at any given time. All the latest generations of gyroscopes have a sample resolution of 16 bits [9, 12]. This is comparable to a microphone's sampling resolution used in most audio applications.

Sampling frequency is the rate at which a signal is sampled. According to the Nyquist sampling theorem a sampling frequency f enables us to reconstruct signals at frequencies of up to $f/2$. Hence, a higher sampling frequency allows us to more accurately reconstruct the audio signal. In most mobile devices and operating systems an application is able to sample the output of a microphone at up to 44.1 KHz. A telephone system (POTS) samples an audio signal at 8000 Hz. However, STMicroelectronics' gyroscope hardware supports sampling frequencies of up to 800 Hz [9], while InvenSense gyros' hardware support sampling frequency up to 8000 Hz [12]. Moreover, all mobile operating systems bound the sampling frequency even further – up to 200 Hz – to limit power consumption. On top of that, it appears that some browser toolkits limit the sampling frequency even further. Table 1 summarizes the results of our experi-

		Sampling Freq. [Hz]
Android 4.4	application	200
	Chrome	25
	Firefox	200
	Opera	20
iOS 7	application	100 [2]
	Safari	20
	Chrome	20

Table 1: Maximum sampling frequencies on different platforms

ments measuring the maximum sampling frequencies allowed in the latest versions of Android and iOS both for application and for web application running on common browsers. The code we used to sample the gyro via a web page can be found in Appendix B. The results indicate that a Gecko based browser does not limit the sampling frequency beyond the limit imposed by the operating system, while WebKit and Blink based browsers does impose stricter limits on it.

2.3.2 Aliasing

As noted above, the sampling frequency of a gyro is uniform and can be at most 200 Hz. This allows us to directly sense audio signals of up to 100 Hz. Aliasing is a phenomenon where for a sinusoid of frequency f, sampled with frequency f_s, the resulting samples are indistinguishable from those of another sinusoid of frequency $|f - N \cdot f_s|$, for any integer N. The values corresponding to $N \neq 0$ are called images or aliases of frequency f. An undesirable phenomenon in general, here aliasing allows us to sense audio signals having frequencies which are higher than 100 Hz, thereby extracting more information from the gyroscope readings. This is illustrated in Figure 3.

Using the gyro, we recorded a single 280 Hz tone. Figure 3(a) depicts the recorded signal in the frequency domain (x-axis) over time (y-axis). A lighter shade in the spectrogram indicates a stronger signal at the corresponding frequency and time values. It can be clearly seen that there is a strong signal sensed at frequency 80 Hz starting around 1.5 sec. This is an alias of the 280 Hz-tone. Note that the aliased tone is indistinguishable from an actual tone at the aliased frequency. Figure 3(b) depicts a recording of multiple short tones between 130 Hz and 200 Hz. Again, a strong signal can be seen at the aliased frequencies corresponding to 130 - 170 Hz[3]. We also observe some weaker aliases that do not correspond to the base frequencies of the recorded tones, and perhaps correspond to their harmonics. Figure 3(c) depicts the recording of a chirp in the range of 420 - 480 Hz. The aliased chirp is detectable in the range of 20 - 80 Hz; however it is a rather weak signal.

[3]We do not see the aliases corresponding to 180 - 200 Hz, which might be masked by the noise at low frequencies, i.e., under 20 Hz.

2.3.3 Self noise

The self noise characteristic of a microphone indicates what is the most quiet sound, in decibels, a microphone can pick up, i.e. the sound that is just over its self noise. To measure the gyroscope's self noise we played 80 Hz tones for 10 seconds at different volumes while measuring it using a decibel meter. Each tone was recorded by the Galaxy S III gyroscope. While analyzing the gyro recordings we realized that the gyro readings have a noticeable increase in amplitude when playing tones with volume of 75 dB or higher which is comparable to the volume of a loud conversation. Moreover, a FFT plot of the gyroscope recordings gives a noticeable peak at the tone's frequency when playing tone with a volume as low as 57 dB which is below the sound level of a normal conversation. These findings indicate that a gyro can pick up audio signals which are lower than 100 HZ during most conversations made over or next to the phone. To test the self noise of the gyro for aliased tones we played 150 Hz and 250 Hz tones. The lowest level of sound the gyro picked up was 67 dB and 77 dB, respectively. These are much higher values that are comparable to a loud conversation.

2.3.4 Directionality

We now measure how the angle at which the audio signal hits the phone affects the gyro. For this experiment we played an 80 Hz tone at the same volume three times. The tone was recorded at each time by the Galaxy S III gyro while the phone rested at a different orientation allowing the signal to hit it parallel to one of its three axes (see Figure 4). The gyroscope senses in three axes, hence for each measurement the gyro actually outputs three readings – one per axis. As we show next this property benefits the gyro's ability to pick up audio signals from every direction. For each recording we calculated the FFT magnitude at 80 Hz. Table 2 summarizes the results.

It is obvious from the table that for each direction the audio hit the gyro, there is at least one axis whose readings are dominant by an order of magnitude compared to the rest. This can be explained by STMicroelectronics gyroscope design as depicted in Figure 1[4]. When the signal travels in parallel to the phone's x or y axes, the sound pressure vibrates mostly masses laid along the respective axis, i.e. M_2 and M_4 for x axis and M_1 and M_3

[4]This is the design of the gyro built into Galaxy S III.

Recording direction:	x	y	z	x	y	z	x	y	z
Amplitude:	0.002	0.012	0.0024	0.01	0.007	0.004	0.007	0.0036	0.0003

Table 2: Sensed amplitude for every direction of a tone played at different orientations relative to the phone. For each orientation the dominant sensed directions are emphasized.

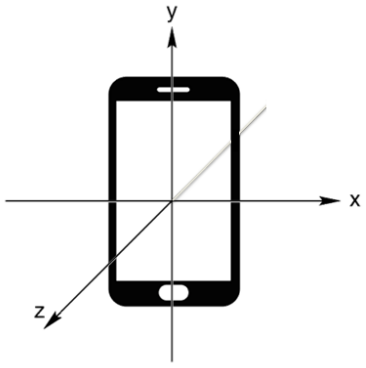

Figure 4: Coordinate system of Android and iOS.

for the y axis; therefore, the gyro primarily senses a rotation at the y or x axes, respectively (see Section 2.1.1). When the signal travels in parallel to the phone's z axis then the sound pressure vibrates all the 4 masses up and down, hence the gyro primarily senses a rotation at both x and y axes.

These findings indicate that the gyro is an omni-directional audio sensor allowing it to pick up audio signal from every direction.

3 Speech analysis based on a single gyroscope

In this section we show that the acoustic signal measured by a single gyroscope is sufficient to extract information about the speech signal, such as speaker characteristics and identity, and even recognize the spoken words or phrases. We do so by leveraging the fact that aliasing causes information leaks from higher frequency bands into the sub-Nyquist range.

Since the fundamentals of human voices are roughly in the range of 80 – 1100 Hz [20], we can capture a large fraction of the interesting frequencies, considering the results we observe in 2.3.2. Although we do not delve into comparing performance for different types of speakers, one might expect that given a stronger gyroscope response for low frequencies, typical adult male speech (Bass, Baritone, Tenor) could be better analyzed than typical female or child speech (Alto, Mezzo-Soprano, Soprano) [5], however our tests show that this is not necessarily the case.

The signal recording, as captured by the gyroscope, is not comprehensible to a human ear, and exhibits a mixture of low frequencies and aliases of frequencies beyond the Nyquist sampling frequency (which is 1/2 the sampling rate of the Gyroscope, i.e. 100 Hz). While the signal recorded by a single device does not resemble speech, it is possible to train a machine to transcribe the signal with significant success.

Speech recognition tasks can be classified into several types according to the setup. Speech recognition can handle fluent speech or isolated words (or phrases); operate on a closed set of words (finite dictionary) or an open set[6]; It can also be speaker dependent (in which case the recognizer is trained per speaker) or speaker in-

[5] For more information about vocal range see `http://www.wikipedia.org/wiki/Vocal_range`

[6] For example by identifying phonemes and combining them to words.

dependent (in which case the recognizer is expected to identify phrases pronounced by different speakers and possibly ones that were not encountered in the training set). Additionally, speech analysis may be also used to identify the speaker.

We focused on speaker identification (including gender identification of the speaker) and isolated words recognition while attempting both speaker independent and speaker dependent recognition. Although we do not demonstrate fluent speech transcription, we suggest that successful isolated words recognition could be fairly easily transformed into a transcription algorithm by incorporating word slicing and HMM [40]. We did not aim to implement a state-of-the-art speech recognition algorithm, nor to thoroughly evaluate or do a comparative analysis of the classification tests. Instead, we tried to indicate the potential risk by showing significant success rates of our speech analysis algorithms compared to randomly guessing. This section describes speech analysis techniques that are common in practice, our approach, and suggestions for further improvements upon it.

3.1 Speech processing: features and algorithms

3.1.1 Features

It is common for various feature extraction methods to view speech as a process that is stationary for short time windows. Therefore speech processing usually involves segmentation of the signal to short (10 – 30 ms) overlapping or non-overlapping windows and operation on them. This results in a time-series of features that characterize the time-dependent behavior of the signal. If we are interested in time-independent properties we shall use spectral features or the statistics of those time-series (such as mean, variance, skewness and kurtosis).

Mel-Frequency Cepstral Coefficients (MFCC) are widely used features in audio and speech processing applications. The Mel-scale basically compensates for the non-linear frequency response of the human ear[7]. The Cepstrum transformation is an attempt to separate the excitation signal originated by air passing through the vocal tract from the effect of the vocal tract (acting as a filter shaping that excitation signal). The latter is more important for the analysis of the vocal signal. It is also common to take the first and second derivatives of the MFCC as additional features, indicative of temporal changes [30].

Short Time Fourier Transform (STFT) is essentially a spectrogram of the signal. Windowing is applied to short overlapping segments of the signal and FFT is computed. The result captures both spectral and time-dependent features of the signal.

[7] Approximated as logarithmic by the Mel-scale

3.1.2 Classifiers

Support Vector Machine (SVM) is a general binary classifier, trained to distinguish to groups. We use SVM to distinguish male and female speakers. Multi-class SVMs can be constructed using multiple binary SVMs, to distinguish between multiple groups. We used a multi-class SVM to distinguish between multiple speakers, and to recognize words from a limited dictionary.

Gaussian Mixture Model (GMM) has been successfully used for speaker identification [41]. We can train a GMM for each group in the training stage. In the testing stage we can obtain a match score for the sample using each one of the GMMs and classify the sample according to the group corresponding to the GMM that yields the maximum score.

Dynamic Time Warping (DTW) is a time-series matching and alignment technique [37]. It can be used to match time-dependent features in presence of misalignment or when the series are of different lengths. One of the challenges in word recognition is that the samples may differ in length, resulting in different number of segments used to extract features.

3.2 Speaker identification algorithm

Prior to processing we converted the gyroscope recordings to audio files in WAV format while upsampling them to 8 KHz[8]. We applied silence removal to include only relevant information and minimize noise. The silence removal algorithm was based on the implementation in [29], which classifies the speech into voiced and unvoiced segments (filtering out the unvoiced) according to dynamically set thresholds for Short-Time Energy and Spectral Centroid features computed on short segments of the speech signal. Note that the gyroscope's zero-offset yields particularly noisy recordings even during unvoiced segments.

We used statistical features based on the first 13 MFCC computed on 40 sub-bands. For each MFCC we computed the mean and standard deviation. Those features reflect the spectral properties which are independent of the pronounced word. We also use delta-MFCC (the derivatives of the MFCC), RMS Energy and

[8] Although upsampling the signal from 200 Hz to 8 KHz does not increase the accuracy of audio signal, it is more convenient to handle the WAV file at higher sampling rate with standard speech processing tools.

Spectral Centroid statistical features. We used MIRToolbox [32] for the feature computation. It is important to note that while MFCC have a physical meaning for real speech signal, in our case of an narrow-band aliased signal, MFCC don't necessarily have an advantage, and were used partially because of availability in MIRToolbox. We attempted to identify the gender of the speaker, distinguish between different speakers of the same gender and distinguish between different speakers in a mixed set of male and female speakers. For gender identification we used a binary SVM, and for speaker identification we used multi-class SVM and GMM. We also attempted gender and speaker recognition using DTW with STFT features. All STFT features were computed with a window of 512 samples which, for sampling rate of 8 KHz, corresponds to 64 ms.

3.3 Speech recognition algorithm

The preprocessing stage for speech recognition is the same as for speaker identification. Silence removal is particularly important here, as the noisy unvoiced segments can confuse the algorithm, by increasing similarity with irrelevant samples. For word recognition, we are less interested in the spectral statistical features, but rather in the development of the features in time, and therefore suitable features could be obtained by taking the full spectrogram. In the classification stage we extract the same features for a sample y. For each possible label l we obtain a similarity score of the y with each sample X_i^l corresponding to that guess in the training set. Let us denote this similarity function by $D(y, X_i^l)$. Since different samples of the same word can differ in length, we use DTW. We sum the similarities to obtain a total score for that guess

$$S^l = \sum_i D(y, X_i^l)$$

After obtaining a total score for all possible words, the sample is classified according to the maximum total score

$$C(y) = \operatorname*{argmax}_l S^l$$

3.4 Experiment setup

Our setup consisted of a set of loudspeakers that included a sub-woofer and two tweeters (depicted in Figure 5). The sub-woofer was particularly important for experimenting with low-frequency tones below 200 Hz. The playback was done at volume of approximately 75 dB to obtain as high SNR as possible for our experiments. This means that for more restrictive attack scenarios (farther source, lower volume) there will be a need to handle low SNR, perhaps by filtering out the noise or applying some other preprocessing for emphasizing the speech signal. [9]

Figure 5: Experimental setup

3.4.1 Data

Due to the low sampling frequency of the gyro, a recognition of speaker-independent general speech would be an ambitious long-term task. Therefore, in this work we set out to recognize speech of a limited dictionary, the recognition of which would still leak substantial private information. For this work we chose to focus on the digits dictionary, which includes the words: zero, one, two..., nine, and "oh". Recognition of such words would enable an attacker to eavesdrop on private information, such as credit card numbers, telephone numbers, social security numbers and the like. This information may be eavesdropped when the victim speaks over or next to the phone.

In our experiments, we use the following corpus of audio signals on which we tested our recognition algorithms.

TIDIGITS This is a subset of a corpus published in [33]. It includes speech of isolated digits, i.e., 11 words per speaker where each speaker recorded each word twice. There are 10 speakers (5 female and 5 male). In total, there are $10 \times 11 \times 2 = 220$ recordings. The corpus is digitized at 20 kHz.

3.4.2 Mobile devices

We primarily conducted our experiments using the following mobile devices:

[9] We tried recording in an anechoic chamber, but it didn't seem to provide better recognition results compared to a regular room. We therefore did not proceed with the anechoic chamber experiments. Yet, further testing is needed to understand whether we can benefit significantly from an anechoic environment.

1. Nexus 4 phone which according to a teardown analysis [13] is equipped with an InvenSense MPU-6050 [12] gyroscope and accelerometer chip.

2. Nexus 7 tablet which according to a teardown analysis [14] is equipped with an InverSense MPU-6050 gyroscope and accelerometer.

3. Samsung Galaxy S III phone which according to a teardown analysis [6] is equipped with an STMicroelectronics LSM330DLC [10] gyroscope and accelerometer chip.

3.5 Sphinx

We first try to recognize digit pronunciations using general-purpose speech recognition software. We used Sphinx-4 [47] – a well-known open-source speech recognizer and trainer developed in Carnegie Mellon University. Our aim for Sphinx is to recognize gyro-recordings of the TIDIGITS corpus. As a first step, in order to test the waters, instead of using actual gyro recordings we downsampled the recordings of the TIDITS corpus to 200 Hz; then we trained Sphinx based on the modified recordings. The aim of this experiment is to understand whether Sphinx detects any useful information from the sub-100 Hz band of human speech. Sphinx had a reasonable success rate, recognizing about 40% of pronunciations.

Encouraged by the above experiment we then recorded the TIDIGITS corpus using a gyro – both for Galaxy S III and Nexus 4. Since Sphinx accepts recording in WAV format we had to convert the raw gyro recordings. Note that at this point for each gyro recording we had 3 WAV files, one for each gyro axis. The final stage is silence removal. Then we trained Sphinx to create a model based on a training subset of the TIDIGITS, and tested it using the complement of this subset.

The recognition rates for either axes and either Nexus 4 or Galaxy S III were rather poor: 14% on average. This presents only marginal improvement over the expected success of a random guess which would be 9%.

This poor result can be explained by the fact that Sphinx's recognition algorithms are geared towards standard speech recognition tasks where most of the voice-band is present and is less suited to speech with very low sampling frequency.

3.6 Custom recognition algorithms

In this section we present the results obtained using our custom algorithm. Based on the TIDIGITS corpus we randomly performed a 10-fold cross-validation. We refer mainly to the results obtained using Nexus 4 gyroscope readings in our discussion. We also included in the tables some results obtained using a Galaxy III device, for comparison.

	SVM	GMM	DTW
Nexus 4	80%	72%	84%
Galaxy S III	82%	68%	58%

Table 3: Speaker's gender identification results

		SVM	GMM	DTW
Nexus 4	Mixed female/male	23%	21%	50%
	Female speakers	33%	32%	45%
	Male speakers	38%	26%	65%
Galaxy S III	Mixed female/male	20%	19%	17%
	Female speakers	30%	20%	29%
	Male speakers	32%	21%	25%

Table 4: Speaker identification results

Results for gender identification are presented in Table 3. As we see, using DTW scoring for STFT features yielded a much better success rate.

Results for speaker identification are presented in Table 4. Since the results for a mixed female-male set of speakers may be partially attributed to successful gender identification, we tested classification for speakers of the same gender. In this setup we have 5 different speakers. The improved classification rate (except for DTW for female speaker set) can be partially attributed to a smaller number of speakers.

The results for speaker-independent isolated word recognition are summarized in Table 5. We had correct classification rate of $\sim 10\%$ using multi-class SVM and GMM trained with MFCC statistical features, which is almost equivalent to a random guess. Using DTW with STFT features we got 23% correct classification for male speakers, 26% for female speakers and 17% for a mixed set of both female and male speakers. The confusion matrix in Figure 6, corresponding to the mixed speaker-set recorded on a Nexus 4, explains the not so high recognition rate, exhibiting many false positives for the words "6" and "9". At the same time the recognition rate for

		SVM	GMM	DTW
Nexus 4	Mixed female/male	10%	9%	17%
	Female speakers	10%	9%	26%
	Male speakers	10%	10%	23%
Galaxy S III	Mixed female/male	7%	12%	7%
	Female speakers	10%	10%	12%
	Male speakers	10%	6%	7%

Table 5: Speaker-independent case – isolated words recognition results

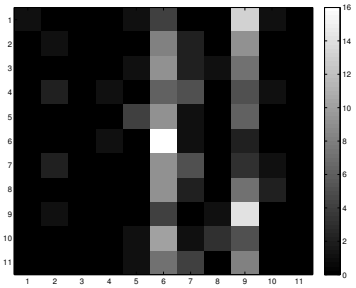

Figure 6: Speaker independent word recognition using DTW: confusion matrix as a heat map. $c_{(i,j)}$ corresponds to the number of samples from group i that were classified as j, where i, j are the row and column indices respectively.

SVM	GMM	DTW
15%	5%	65%

Table 6: Speaker-dependent case – isolated words recognition for a single speaker. Results obtained via "leave-one-out" cross-validation on 44 recorded words pronounced by a single speaker. Recorded using a Nexus 4 device.

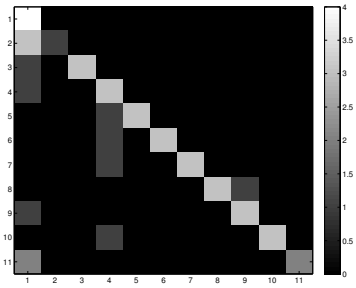

Figure 7: Speaker dependent word recognition using DTW: confusion matrix as a heat map.

these particular words is high, contributing to the correct identification rate.

For a speaker-dependent case one may expect to get better recognition results. We recorded a set of 44 digit pronunciations, where each digit was pronounced 4 times. We tested the performance of our classifiers using "leave-one-out" cross-validation. The results are presented in Table 6, and as we expected exhibit an improvement compared to the speaker independent recognition[10] (except for GMM performance that is equivalent to randomly guessing). The confusion matrix corresponding to the word recognition in a mixed speaker-set using DTW is presented in Figure 7.

DTW method outperforms SVM and GMM in most cases. One would expect that DTW would perform better for word recognition since the changing in time of the spectral features is taken into account. While true for Nexus 4 devices it did not hold for measurements taken with Galaxy III. possible explanation to that is that the low-pass filtering on the Galaxy III device renders all methods quite ineffective resulting in a success rate equivalent to a random guess. For gender and speaker identification, we would expect statistical spectral features based methods (SVM and GMM) to perform at least as good as DTW. It is only true for the Galaxy S III mixed speaker set and gender identification cases, but not for the other experiments. Specifically for gender identification, capturng the temporal development of the spectral feature wouldn't seem like a clear advantage and is therefore somewhat surprising. One comparative study that supports the advantage of DTW over SVM for speaker recognition is [48]. It doesn't explain though why it outperforms GMM which is a well established method for speaker identification. More experimentation is required to confirm whether this phenomenon is consistent and whether it is related to capturing the high frequencies.

3.7 Further improvement

We suggest several possible future improvements on our recognition algorithms. Phoneme recognition instead of whole words, in combination with an HMM could improve the recognition results. This could be more suitable since different pronunciations have different lengths, while an HMM could introduce a better probabilistic recognition of the words. Pre-filtering of the signal could be beneficial and reduce irrelevant noise. It is not clear which frequencies should be filtered and therefore some experimentation is needed to determine it.

[10] It is the place to mention that a larger training set for speaker independent word recognition is likely to yield better results. For our tests we used relatively small training and evaluation sets.

For our experiments, we used samples recorded by the gyroscope for training. For speaker-dependent speech recognition we can imagine it may be easier to obtain regular speech samples for a particular speaker than a transcribed recording of gyroscope samples. Even for speaker independent speech recognition, it would be easier to use existing audio corpora for training a speech recognition engine than to produce gyroscope recordings for a large set of words. For that purpose it would be interesting to test how well the recognition can perform when the training set is based on normal audio recordings, downsampled to 200 Hz to simulate a gyroscope recording.

Another possible improvement is to leverage the 3-axis recordings. It is obvious that the three recordings are correlated while the noise of gyro readings is not. Hence, one may take advantage of this to get a composed signal of the three axes to get a better signal-to-noise ratio.

While we suggested that the signal components related to speech, and those related to motion lie in separate frequency bands, the performance of speech analysis in the presence of such noise is yet to be evaluated.

4 Reconstruction using multiple devices

In this section we suggest that isolated word recognition can be improved if we sample the gyroscopes of multiple devices that are in close proximity, such that they exhibit a similar response to the acoustic signals around them. This can happen for instance in a conference room where two mobile devices are running malicious applications or, having a browser supporting high-rate sampling of the gyroscope, are tricked into browsing to a malicious website.

We do not refer here to the possibility of using several different gyroscope readings to effectively obtain a larger feature vector, or have the classification algorithm take into account the score obtained for all readings. While such methods to exploit the presence of more than one acoustic side-channel may prove very efficient we leave them outside the scope of this study. It also makes sense to look into existing methods for enhancing speech recognition using multiple microphones, covered in signal processing and machine learning literature (e.g., [23]).

Instead, we look at the possibility of obtaining an enhanced signal by using all of the samples for reconstruction, thus effectively obtaining higher sampling rate. Moreover, we hint at the more ambitious task of reconstructing a signal adequate enough to be comprehensible by a human listener, in a case where we gain access to readings from several compromised devices. While there are several practical obstacles to it, we outline the idea, and demonstrate how partial implementation of it facilitates the automatic speech recognition task.

We can look at our system as an array of time-interleaved data converters (interleaved ADCs). Interleaved ADCs are multiple sampling devices where each samples the signal with a sub-Nyquist frequency. While the ADCs should ideally have time offsets corresponding to a uniform sampling grid (which would allow to simply interleave the samples and reconstruct according to the Whittaker-Shannon interpolation formula [44]), usually there will be small time skews. Also, DC offsets and different input gains can affect the result and must all be compensated.

This problem is studied in a context of analog design and motivated by the need to sample high-frequency signals using low-cost and energy-efficient low-frequency A/D converters. While many papers on the subject exist, such as [27], the proposed algorithms are usually very hardware centric, oriented towards real-time processing at high-speed, and mostly capable of compensating for very small skews. Some of them require one ADC that samples the signal above the Nyquist rate, which is not available in our case. At the same time, we do not aim for a very efficient, real-time algorithm. Utilizing recordings from multiple devices implies offline processing of the recordings, and we can afford a long run-time for the task.

The ADCs in our case have the same sampling rate $F_s = 1/T = 200$. We assume the time-skews between them are random in the range $[0, T_Q]$ where for N ADCs $T_Q = \frac{T}{N}$ is the Nyquist sampling period. Being located at different distances from the acoustic source they are likely to exhibit considerably different input gains, and possibly have some DC offset. [26] provides background for understanding the problems arising in this configuration and covers some possible solutions.

4.1 Reconstruction algorithm

4.1.1 Signal offset correction

To correct a constant offset we can take the mean of the Gyro samples and compare it to 0 to get the constant offset. It is essentially a simple DC component removal.

4.1.2 Gain mismatch correction

Gain mismatch correction is crucial for a successful signal reconstruction. We correct the gain by normalizing the signal to have standard deviation equal to 1. In case we are provided with some reference signal with a known peak, we can adjust the gains of the recordings so that the amplitude at this peak is equal for all of them.

4.1.3 Time mismatch correction

While gyroscope motion events are provided with precise timestamps set by the hardware, which theoretically could have been used for aligning the recordings, in practice, we cannot rely on the clocks of the mobile devices to be synchronized. Even if we take the trouble of synchronizing the mobile device clock via NTP, or even better, a GPS clock, the delays introduced by the network, operating system and further clock-drift will stand in the way of having clock accuracy on the order of a millisecond[11]. While not enough by itself, such synchronization is still useful for coarse alignment of the samples.

El-Manar describes foreground and background time-mismatch calibration techniques in his thesis [27]. Foreground calibration means there is a known signal used to synchronized all the ADCs. While for the purpose of testing we can align the recordings by maximizing the cross-correlation with a known signal, played before we start recording, in an actual attack scenario we probably won't be able to use such a marker[12]. Nevertheless, in our tests we attempted aligning using a reference signal as well. It did not exhibit a clear advantage over obtaining coarse alignment by finding the maximum of the cross-correlation between the signals. One can also exhaustively search a certain range of possible offsets, choosing the one that results in a reconstruction of a sensible audio signal.

Since this only yields alignment on the order of a sampling period of a single gyroscope (T), we still need to find the more precise time-skews in the range $[0,T]$. We can scan a range of possible time-skews, choosing the one that yields a sensible audio signal. We can think of an automated evaluation of the result by a speech recognition engine or scoring according to features that would indicate human speech, suggesting a successful reconstruction.

This scanning is obviously time consuming. If we have n sources, we set one of the time skews (arbitrary) to 0, and have $n-1$ degrees of freedom to play with, and the complexity grows exponentially with the number of sources. Nevertheless, in an attack scenario, it is not impossible to manually scan all possibilities looking for the best signal reconstruction, provided the information is valuable to the eavesdropper.

[11] Each device samples with a period of 5 ms, therefore even 1 ms clock accuracy would be quite coarse.

[12] While an attacker may be able to play using one of the phones' speakers a known tone/chirp (no special permissions are needed), it is unlikely to be loud enough to be picked up well by the other device, and definitely depends on many factors such as distance, position etc.

4.1.4 Signal reconstruction from non-uniform samples

Assuming we have compensated for offset, gain mismatch and found the precise time-skews between the sampling devices, we are dealing with the problem of signal reconstruction from periodic, non-uniform samples. A seminal paper on the subject is [28] by Eldar et al. Among other works in the field are [39, 46] and [31]. Sindhi et al. [45] propose a discrete time implementation of [28] using digital filterbanks. The general goal is, given samples on a non-uniform periodic grid, to obtain estimation of the values on a uniform sampling grid, as close as possible to the original signal.

A theoretic feasibility justification lies in Papoulis' Generalized Sampling theorem [38]. Its corollary is that a signal bandlimited to π/T_Q can be recovered from the samples of N filters with sampling periods $T = NT_Q$. [13] We suggest using one of the proposed methods for signal reconstruction from periodic non-uniform samples. With only several devices the reconstructed speech will still be narrow-band. While it won't necessarily be easily understandable by a human listener, it could be used for better automated identification. Applying narrowband to wideband speech extension algorithms [36] might provide audio signals understandable to a human listener.

We suggest using one of the methods for signal reconstruction from periodic non-uniform samples mentioned above. With only several devices the reconstructed speech will still be narrow-band. For example, using readings from two devices operating at 200 Hz and given their relative time-skew we obtain an effective sampling rate of 400 Hz. For four devices we obtain a sampling rate of 800 Hz, and so on. While a signal reconstructed using two devices still won't be easily understandable by a human listener, it could be used to improve automatic identification.

We used [28] as a basis for our reconstruction algorithm. The discussion of *recurrent non-uniform sampling* directly pertains to our task. It proposes a filterbank scheme to interpolate the samples such that an approximation of the values on the uniform grid is obtained. The derivation of the discrete-time interpolation filters is provided in Appendix A.

This method allows us to perform reconstruction with arbitrary time-skews; however we do not have at the time a good method for either a very precise estimation

[13] It is important to note that in our case the signal is not necessarily bandlimited as required. While the base pitch of the speech can lie in the range $[0, 200 \cdot N]$, it can contain higher frequencies that are captured in the recording due to aliasing, and may interfere with the reconstruction. It depends mainly on the low-pass filtering applied by the gyroscope. In InvenSense's MPU-6050, Digital Low-Pass Filtering (DLPF) is configurable through hardware registers [11], so the conditions depend to some extent on the particular driver implementation.

SVM	GMM	DTW
18%	14%	77%

Table 7: Evaluation of the method of reconstruction from multiple devices. Results obtained via "leave-one-out" cross-validation on 44 recorded words pronounced by a single speaker. Recorded using a Nexus 4 device.

of the time-skews or automatic evaluation of the reconstruction outcome (which would enable searching over a range of possible values). For our experiment we applied this method to the same set of samples used for speaker-dependent speech recognition evaluation, which was recorded simultaneously by two devices. We used the same value for τ, the time-skew for all samples, and therefore chose the expected value $\tau = T/2$ which is equivalent to the particular case of sampling on a uniform grid (resulting in all-pass interpolation filters). It is essentially the same as interleaving the samples from the two readings, and we ended up implementing this trivial method as well, in order to avoid the adverse effects of applying finite non-ideal filters.

It is important to note that while we propose a method rooted in signal processing theory, we cannot confidently attribute the improved performance to obtaining a signal that better resembles the original, until we take full advantage of the method by estimating the precise time-skew for each recording, and applying true non-uniform reconstruction. It is currently left as an interesting future improvement, for which the outlined method can serve as a starting point. In this sense, our actual experiment can be seen as taking advantage of better feature vectors, comprised of data from multiple sources.

4.1.5 Evaluation

We evaluated this approach by repeating the speaker-dependent word recognition experiment on signals reconstructed from readings of two Nexus 4 devices. Table 7 summarizes the final results obtained using the sample interleaving method[14].

There was a consistent noticeable improvement compared to the results obtained using readings from a single device, which supports the value of utilizing multiple gyroscopes. We can expect that adding more devices to the setup would further improve the speech recognition.

[14] We also compared the performance of the DTW classifier on samples reconstructed using the filterbank approach. It yielded a slightly lower correct classification rate of 75% which we attribute to the mentioned effects of applying non-ideal finite filters.

5 Further Attacks

In this section we suggest directions for further exploitation of the gyroscopes:

Increasing the gyro's sampling rate. One possible attack is related to the hardware characteristics of the gyro devices. The hardware upper bound on sampling frequency is higher than that imposed by the operating system or by applications[15]. InvenSense MPU-6000/MPU-6050 gyroscopes can provide a sampling rate of up to 8000 Hz. That is the equivalent of a POTS (telephony) line. STMicroelectronics gyroscopes only allow up to 800 Hz sampling rate, which is still considerably higher than the 200 Hz allowed by the operating system (see Appendix C). If the attacker can gain a one-time privileged access to the device, she could patch an application, or a kernel driver, thus increasing this upper bound. The next steps of the attack are similar: obtaining gyroscope measurements using an application or tricking the user into leaving the browser open on some website. Obtaining such a high sampling rate would enable using the gyroscope as a microphone in the full sense of hearing the surrounding sounds.

Source separation. Based on experiments' results presented in Section 2.3.4 it is obvious that the gyro's measurements are sensitive to the relative direction from which the acoustic signal arrives. This may give rise to the possibility to detect the angle of arrival (AoA) at which the audio signal hits the phone. Using AoA detection one may be able to better separate and process multiple sources of audio, e.g. multiple speakers near the phone.

Ambient sound recognition. There are works (e.g. [42]) which aim to identify a user's context and whereabouts based on the ambient noise detected by his smart phone, e.g restaurant, street, office, and so on. Some contexts are loud enough and may have distinct fingerprint in the low frequency range to be able to detect them using a gyroscope, for example railway station, shopping mall, highway, and bus. This may allow an attacker to leak more information on the victim user by gaining indications of the user's whereabouts.

6 Defenses

Let us discuss some ways to mitigate the potential risks. As it is often the case, a secure design would require an

[15] As we have shown, the sampling rate available on certain browsers is much lower than the maximum sampling rate enabled by the OS. However, this is an application level constraint.

overall consideration of the whole system and a clear definition of the power of the attacker against whom we defend. To defend against an attacker that has only user-level access to the device (an application or a website), it might be enough to apply low-pass filtering to the raw samples provided by the gyroscope. Judging by the sampling rate available for Blink and WebKit based browsers, it is enough to pass frequencies in the range 0 – 20 Hz. If this rate is enough for most of the applications, the filtering can be done by the driver or the OS, subverting any attempt to eavesdrop on higher frequencies that reveal information about surrounding sounds. In case a certain application requires an unusually high sampling rate, it should appear in the list of permissions requested by that application, or require an explicit authorization by the user. To defend against attackers who gain root access, this kind of filtering should be performed at the hardware level, not being subject to configuration. Of course, it imposes a restriction on the sample rate available to applications.

Another possible solution is some kind of acoustic masking. It can be applied around the sensor only, or possibly on the case of the mobile device.

7 Conclusion

We show that the acoustic signal measured by the gyroscope can reveal private information about the phone's environment such as who is speaking in the room and, to some extent, what is being said. We use signal processing and machine learning to analyze speech from very low frequency samples. With further work on low-frequency signal processing of this type it should be possible to further increase the quality of the information extracted from the gyro.

This work demonstrates an unexpected threat resulting from the unmitigated access to the gyro: applications and active web content running on the phone can eavesdrop sound signals, including speech, in the vicinity of the phone. We described several mitigation strategies. Some are backwards compatible for all but a very small number of applications and can be adopted by mobile hardware vendors to block this threat.

A general conclusion we suggest following this work is that access to all sensors should be controlled by the permissions framework, possibly differentiating between low and high sampling rates.

Acknowledgements

We would like to thank Nimrod Peleg, from the Signal and Image Processing Lab (SIPL) at the Technion, for providing assistance with the TIDIGITS corpus. We also greatful to Sanjay Kumar Sindhi, from IIT Madras, for providing implementation and testing of several signal reconstruction algorithms. We would also like to thank Prof. Jared Tanner, from UC Davis, and Prof. Yonina Eldar, from the Technion, for advising on reconstruction of non-uniformly sampled signals. We thank Hriso Bojinov for taking part in the initial brainstorming related to this research and finally, Katharina Roesler, for proofreading and advising on writing and formulation.

This work was supported by NSF and the DARPA SAFER program. Any opinions, findings and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of NSF or DARPA.

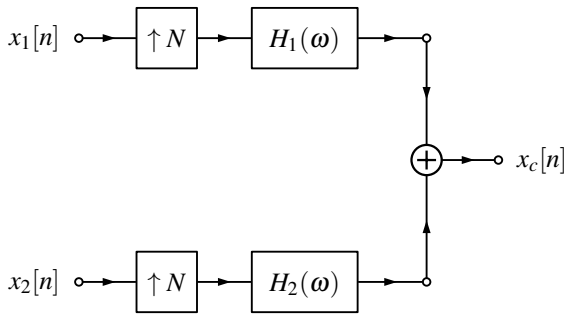

Figure 8: Filterbank reconstruction scheme

A Signal reconstruction from Recurrent Non-Uniform Samples

Here we present the derivation of the discrete-time interpolation filters used in our implementation. The notation in the expressions corresponds to the notation in [28]. The continuous time expression for the interpolation filters according to Eq. 18 in [28] is given by

$$h_p(t) = a_p sinc\left(\frac{t}{T}\right) \prod_{q=0, q\neq p}^{N-1} \sin\left(\frac{\pi\left(t+t_p-t_q\right)}{T}\right)$$

We then sample this expression at times $t = nT_Q - t_p$ and calculate the filter coefficients for 48 taps. Given these filters, the reconstruction process consists of upsampling the input signals by factor N, where $N = T/T_Q$ is the number of ADCs, filtering and summation of the outputs of all filters (as shown in Figure 8).

B Code for sampling a gyroscope via a HTML web-page

For a web page to sample a gyro the DeviceMotion class needs to be utilized. In the following we included a JavaScript snippet that illustrates this:

```
if(window.DeviceMotionEvent) {
  window.addEventListener('devicemotion', function(
      event) {
    var r = event.rotationRate;
    if ( r!=null ) {
      console.log('Rotation at [x,y,z] is: [' +
        r.alpha+','+r.beta+','+r.gamma+']\n');
    }
  }
}
```

Figure 9 depicts measurements of the above code running on Firefox (Android) while sampling an audio chirp 50 – 100 Hz.

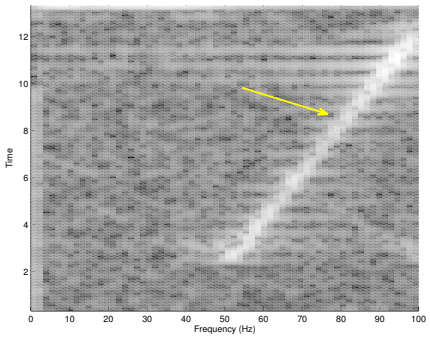

Figure 9: Recording audio at 200 Hz using JavaScript code on a web-page accessed from the Firefox browser for Android.

C Gyroscope rate limitation on Android

Here we see a code snippet from the Invensense driver for Android, taken from *hardware/invensense/65xx/libsensors_iio/MPLSensor.cpp*. The OS is enforcing a rate of 200 Hz.

```
static int hertz_request = 200;
#define DEFAULT_MPL_GYRO_RATE          (20000L)      //us
...
#define DEFAULT_HW_GYRO_RATE           (100)         //Hz
#define DEFAULT_HW_ACCEL_RATE          (20)          //ms
...
/* convert ns to hardware units */
#define HW_GYRO_RATE_NS                (1000000000LL / rate_request) // to Hz
#define HW_ACCEL_RATE_NS               (rate_request / (1000000L))   // to ms
...
/* convert Hz to hardware units */
#define HW_GYRO_RATE_HZ                (hertz_request)
#define HW_ACCEL_RATE_HZ               (1000 / hertz_request)
```

D Code Release

We provide the source code of the Android application we used for recording the sensor measurements, as well as the Matlab code we used for analyzing the data and training and testing of the speech recognition algorithms. We also provide the gyroscope recordings used for the evaluation of our method. The code and data can be downloaded from the project website at `http://crypto.stanford.edu/gyrophone`. In addition, we provide a web page that records gyroscope measurements if accessed from a device that supports it.
