Two mechanisms are used to determine if there is an attack. The first mechanism aims to identify abnormal function returns. It is based on the observation that ROP chains manipulate control-flow to redirect control to arbitrary points in the program, where the attacker-selected gadgets reside. This constitutes a deviation from legitimate behavior, where returns transfer control to instructions immediately following a call. kBouncer checks the targets of all return instructions in the LBR to ensure that they are preceded by a call instruction. In x86 architectures where unaligned instructions are permissible, this call instruction does not necessarily need to be one actually intended by the program and emitted by the compiler. Any executable byte with the value of *0xE8*, one of the opcodes for the `call` instruction, can be actually considered as an *unintended* call instruction and attackers can use the gadget following it.

Recently, even just using gadgets following *intended* calls was shown to be sufficient to compose ROP payloads [16]. In anticipation of the possibility of such attacks, kBouncer introduced a second mechanism, based on gadget-chain length, to detect and prevent attacks. First, all potential gadgets are identified through offline analysis of an application. Every uninterrupted sequence of at most *20 instructions* ending in an indirect branch is treated as a potential gadget. At run time, kBouncer checks that there is no uninterrupted chain of *eight* or more such gadgets as targets in the LBR. In this case, the maximum gadget length of $T_G = 20$ was selected arbitrarily [25, Sec. 3.2], while through experimentation with a set of Windows applications, it was determined that a safe choice for the gadget-chain length threshold is $T_C = 8$ [25, Sec. 3.2, Fig. 7].

2.2.2 ROPecker

Similarly to kBouncer, ROPecker [8] utilizes LBR to detect ROP attacks. However, instead of only checking LBR registers upon entry to sensitive API calls, it introduces a new mechanism for triggering checks more often. It maintains a sliding window of code that is executable, while all other code pages are marked as non-executable. Checks are made each time a permission fault is triggered because control flow is transferred outside the sliding window. The intuition behind this approach is that due to code locality page faults are not triggered very often and ROP attacks are unlikely to use only gadgets contained within the sliding window (between 8 and 16 KB), so a check will be triggered before the attack completes.

Attack detection occurs primarily by checking gadget-chain length, like in kBouncer. However, ROPecker also checks for attacks in future returns by inspecting the return addresses stored in the stack. Potential gadgets are collected offline by statically analyzing applications, but they are defined differently from kBouncer. In particular, a gadget is a sequence of no more than *six instructions* that ends with an indirect branch, but does *not* contain any direct branches. Experiments were conducted with various Linux applications and benchmarks to determine a safe choice for the gadget-chain length threshold that will indicate an attack. The results varied, but a chain of *at least 11* gadgets was determined to be a safe choice. However, using a per-application threshold, if possible, is recommended. To summarize, the maximum length of a gadget is set to $T_G = 6$ and is selected arbitrarily [8, Sec. VII.B], while the safe choice for the gadget-chain length threshold is $T_C = 11$ [8, Sec. VII.A].

In the presence of multiple smaller gadget chains, intentionally created by mixing long and short gadgets to evade the mechanism, ROPecker also proposes accumulating the lengths of the smaller chains across multiple windows and using that instead, to gain a certain degree of tolerance to such attacks. Accumulation is done every three windows, and experimental results showed that an acceptable threshold for cumulative gadget-chain length is $T_{CC} = 14$.

3 The Problem

Both systems we study in this paper heavily depend on two parameters, namely T_C (the chain length) and T_G (the gadget length). In this section, we discuss the problem of picking the right values for T_C and T_G, and the way attackers can bypass the defenses proposed by kBouncer, ROPecker, and similar approaches.

What Is the Right Size? Mechanisms like kBouncer and ROPecker rely on defining gadgets based on the size of instruction sequences ending in indirect branches, and detect attacks based on the size of gadget chains. The problem with such measures is that while they do raise the bar, they are also their own Achilles' heel. By interspersing their ROP code with an occasional longer sequence of instructions (ending with an indirect branch) that will not be registered as a gadget, an attacker can reduce the length of gadget chains, as observed by these systems, and avoid detection.

Figure 3 shows a high-level overview of such an attack. After receiving control through an exploit, an attacker first uses up to $T_C - 1$ *detectable gadgets* (DG). Then, he employs at least one longer *undetectable gadget* (UG), that is, a sequence of more than T_G instructions. To be precise, an attacker may need to use an UG earlier for the first time because a chain of T_C legitimate application gadgets may already exist before he receives control, leading to a longer chain of DGs. If a check is triggered while this chain is still visible in the LBR, the attack will be detected. kBouncer only conducts checks on certain API calls, so an attacker needs to only worry about the number of DGs in the LBR when performing such calls. On the other hand, ROPecker triggers checks more frequently, but, exactly due to this fact, uses less restrictive T_C and T_G parameters. In the worst case, an attacker needs to use an UG first in his ROP chain.

Weak Control-Flow Enforcement kBouncer performs an additional check to ensure that the targets of all return instructions in the LBR point to instructions preceded by calls. However, recent work [16] has shown that it is possible to build a ROP payload using such call-preceded (CP) gadgets and evade even stricter control-flow restrictions. As a result, the effectiveness of defenses like kBouncer depends entirely on the T_C and T_G parameters. In the example shown in Fig. 2, the attacker would not be able to link gadgets that are not preceded by calls using function returns.

Accumulating Gadget-Chain Lengths ROPecker proposes an extension to tackle exactly the problem of mixing long and short gadgets. They define another parameter, T_{CC}, which is the threshold for the cumulative length of gadget chains in three successive windows and, hence, checks. This extension aims to prevent attacks following the pattern shown in Fig. 3. However, ROPecker does not consider instruction sequences including direct branches as gadgets, so an attacker can employ those as alternative shorter UGs. Furthermore, attackers can carefully construct attacks that consist of a small number of gadgets and then inject code, as it was

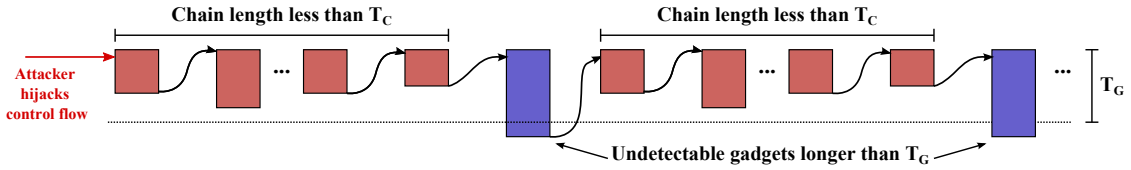

Figure 3: Mixing shorter and longer gadgets to avoid detection. Gadgets larger than T_G instructions are not considered as gadgets by both kBouncer and ROPecker. The latter also ignores gadgets that contain direct branch instructions.

done in previous work [16]. Details follow in the next section.

4 Proof-of-Concept Attack

In this section, we describe the construction of a proof-of-concept (PoC) exploit, which can compromise a vulnerable binary running under kBouncer. We have selected kBouncer, since we consider it the hardest to evade of the two systems examined in this paper. Recall that kBouncer is based on restricting ret instructions, so that they can only redirect control flow to gadgets preceded by an intended or unintended call instruction, and on a heuristic that scans for long chains of consecutive gadgets, as they are defined by kBouncer. The constructed exploit is generic, because it uses gadgets solely from the `shell32.dll` library which is shared among many widely used applications in Windows, and it is also effective against similar approaches, like ROPecker [8].

Previous work [16] has already shown that it is possible to compose attacks using an even more limited set of gadgets, that is, only gadgets following intended call instructions and starting at function entry points. We build on this prior knowledge to collect the gadgets that are available under kBouncer and show that we can build an exploit that remains undetectable. More importantly, we show that we can construct a very short payload that could not be easily detected unless T_C and T_G are set to considerably more restrictive values.

4.1 Preparation

The vulnerability we use to build our exploit is based on a real heap overflow in Internet Explorer [27] and has been also used in multiple other works [16,34] in the past. The first part of the exploit deals with disclosing information to bypass ASLR and then controlling the target address of an indirect jump instruction. Details of the preparation phase can also be found in previous work [16]. Here, we summarize the initial steps that are common with previous work and introduce new actions that are necessary for completing this exploit.

The vulnerability is triggered by accessing the `span` and `width` attributes of an HTML table's column through JavaScript. A great feature of the vulnerability is that it can be triggered repeatedly to achieve different tasks. First, it can be triggered to overwrite the size attribute of a string object, which consequently allows the `substring()` method of the string class to read data beyond the boundary of the string object, as long as we know the relative offset of that data from the string object. The `substring()` method serves as a memory disclosure interface for us. Second, it can be triggered to overwrite the virtual function table (VFT) pointer within a button object. Later, when we access the button object from within carefully prepared JavaScript code, the program will operate on the overwritten data and will eventually grant us control over an indirect jump instruction.

Due to ASLR being in use, we need to exploit the string object to "learn" where `shell32.dll` is loaded at run time, i.e., its base address. Before anything else, we use heap Feng Shui [35] to position the vulnerable buffer, and the string and button objects in the right order, so that we can overflow in the string object without concurrently receiving control of the indirect jump. The following steps are taken to locate `shell32.dll`, the first two steps have been also part of prior work, while the latter was added to achieve our end goal:

1. This vulnerability allows us to easily locate `mshtml.dll`. The button object's VFT contains a pointer to a fixed offset within the DLL. After heap Feng Shui, the button object follows the string object in memory at a fixed distance, so we use the controlled string object to read that pointer and reveal the location of the DLL. `mshtml.dll` contains pointers directly to `shell32.dll`, however, they are located in its *Delayed Import Address Table* (IAT), so they are not available at the time of exploitation.

2. In contrast to `mshtml.dll`, `ieframe.dll` do contain pointers to `shell32.dll` in its normal IAT, which gets loaded during the initiation of libraries. So `ieframe.dll` has the pointers to `shell32.dll` we are looking for available at the time of exploitation. As a result, by learning the base address of `ieframe.dll`, we can achieve our end goal. `mshtml.dll` has pointers

to `ieframe.dll` available in its Delayed IAT, but to read that, we first need to calculate its relative offset from the string. Since we already know the base address of `mshtml.dll`, we just need to find out the address of the string object, so we can calculate offsets within the DLL. Fortunately, the button object contains an address that has a constant distance from the beginning of the string object, so by first exfiltrating that, we can calculate the base address of `ieframe.dll`.

3. Since we now know the base address of `ieframe.dll`, we exploit the string object once more to read a pointer to `shell32.dll`, thus revealing its base address. `shell32.dll` also allows us to locate `VirtualProtect()` through its own IAT.

Finally, we need to also determine the location of a buffer we control, which we use to store the ROP payload, shellcode, etc. We use heap spraying [11] to create many copies of such a buffer in the process' memory, which has the effect of placing one of the copies at an address that can be reliably determined. Heap spraying is not foolproof, however, it works consistently in this particular case.

4.2 Collecting Gadgets

When kBouncer and friends are active the `ret` instruction can only target gadgets that are preceded by a call instruction. Previous work has referred to such gadgets as call-site (CS) gadgets [16], we will use this term to refer to them. CS gadgets are a subset of all the gadgets available in traditional ROP and JOP attacks, and include gadgets defined by intended and unintended call instructions. So any bytes in the program that could be interpreted as a call instruction, subsequently introduce a CS gadget. Note that the entire set of gadgets is still present in the application, but it can now only be targeted by indirect jump and call instructions. Generally, we will use the CS prefix with gadgets that are call preceded and the type of indirect branch ending the gadget as suffix (e.g., `RET` or `CALL *`).

To find usable gadgets, we disassemble the target binary multiple times. We start disassembling from each individual byte in the code segment of each image, until we encounter a stop condition, which can be an indirect control flow transfer, or an invalid or privileged instruction. This is similar to the static analysis phase of kBouncer that determines the locations of gadgets. Like kBouncer, we follow direct branches and calculate the length of a gadget using the shortest number of instructions that can execute from the beginning of the gadget till an indirect branch. This means that in the presence of conditional branches, we follow both paths and use the shortest one as the length of the gadget.

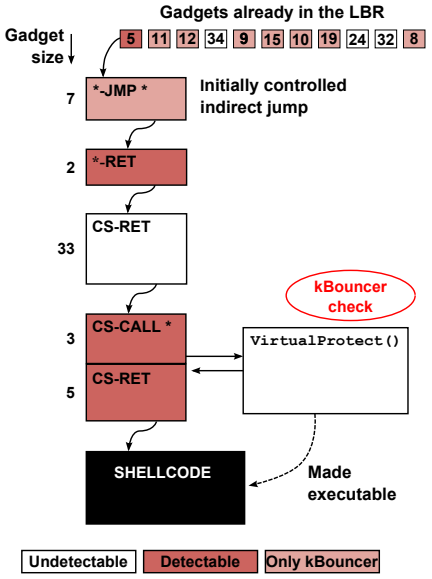

Figure 4: PoC exploit that bypasses both kBouncer and ROPecker. This figure focuses more on the details related with kBouncer, since it uses stricter detection thresholds. Gadgets receiving control through a return are all call-preceded, depicted using the *CS* prefix in the figure. The exploit uses one heuristic breaking gadget to keep the chain of detectable gadgets small and calls `VirtualProtect()` which triggers a kBouncer check. Note that kBouncer and ROPecker fail to detect gadgets longer than 20 and 6 instructions, respectively.

4.3 Heuristic Breakers

Since our exploit should fly under kBouncer's defensive radar, we have to ensure that we do not use sequences of more than seven short gadgets at any time (i.e., kBouncer-gadgets with 20 instructions or less). We avoid doing so by using a long gadget that performs minimal work (i.e., only sets a single register) as part of the exploit. Generally, to avoid the detection an attacker needs to intersperse the ROP chain with long gadgets. We call such gadgets *heuristic breakers* (HBs). The best properties for heuristic breaker gadgets are:

- **Use a small number of registers.** Such gadgets that preserve the values of registers allow us to chain multiple gadgets to carefully set the CPU and memory state to perform an operation like a call.

- **Used registers are loaded from memory or assigned constant values.** Long gadgets can have various side effects like loading and writing to

memory, etc.. When the registers used in such operations are set within the gadget, it is easier to prepare the gadgets so that the gadget does not cause a fatal fault.

- **Registers are loaded from memory.** Gadgets including the epilogue of functions frequently restore the values of various registers from the stack, allowing us to set multiple registers from the controlled stack.

- **Intended gadgets.** Long sequences of unintended gadgets tend to translate to unusual sequences of instructions. As a result, they are not as useful as intended gadgets. Our exploit, uses only a single small unintended gadget of two instructions, while another one only uses an unintended call instruction so it is call preceded.

Finally, we have to be flexible when a HBs cannot be included at a desired position in the gadget-chain. Consider for example a chain of seven gadgets. Ideally, we would insert a HB after the first five gadgets to break the sequence in two smaller ones, of five and two gadgets respectively. Since this is not always possible, due to the exploit's semantics, we may need to insert a HB sooner, for example *after* the first three gadgets.

4.4 Putting It All Together

Figure 4 provides a high-level graphical representation of our PoC exploit. We obtain control by exploiting the button object's VFT pointer, which grants us control of an indirect jump instruction. This instruction is actually part of a gadget (Appendix A, listing 1), as far as kBouncer is concerned, however it is not a gadget for ROPecker because it contains a conditional branch. The end goal is to invoke `VirtualProtect()` to mark the buffer we control and contains shellcode as executable. We can then transfer control to it, effectively bypassing DEP and performing a code-injection attack.

Our first task is to point the stack pointer (i.e., `ESP`) to the buffer we control, so we can perform ROP, a process commonly referred to as stack pivoting. After receiving control, `eax` points to our buffer, so we use an unintended gadget that exchanges the values of `eax` and `esp`, and terminates with a `ret`, to achieve this (Appendix A, listing 2).

Next, we want to prepare for calling `VirtualProtect()`. Before doing so, we need to interpose a HB gadget, so that the kBouncer check, triggered by entering the API function, will not detect our exploit. At this point, we know that the LBR contains two gadget addresses, the one for the stack pivoting gadget and the one before that, which is part of the program's legitimate control flow. We know that these two gadgets are not enough to cause detection, but there may be other entries in the LBR preceding these that could trigger kBouncer. Using a HB at this point ensures that the gadget-chain length in the LBR is reset. Moreover, using a HB at this point makes the payload generic, allowing us to use it with other vulnerabilities, as it will always break the gadget chain in the LBR, as long as T_G is less than its length. We use a HB gadget of 33 instructions that sets the `ESI` and `EDI` registers, which we use later on, and most importantly does not depend on any register being set up on entry (Appendix A, listing 3).

We perform the call to `VirtualProtect()` using a gadget that includes an indirect call (Appendix A, listing 4). This gadget only requires the `ESI` register to be prepared, which we set with the previous gadget. Also, it does not push any arguments to the stack, so the arguments to the call can be prepared in our buffer in advance. This is also the point where kBouncer kicks in and checks the LBR for an attack. By consulting Fig. 4, we notice that kBouncer cannot detect the attack at this point. When `VirtualProtect()` returns, control is transferred where it is expected to, that is, the instruction following the call. The next gadget executing is essentially the code following the indirect call (Appendix A, listing 5). The `ret` at the end of it transfers control to our shellcode, which is now executable. To ensure that we do not trigger any alarms in the future, we make sure that the first instruction in our shellcode is preceded by a fake, unused, call instruction.

Having managed to inject code into the process, we can now execute code without the risk of triggering kBouncer. Notice that this exploit will keep working even if T_G is raised to 31 and T_C reduced to 6.

5 Countermeasures

In this section, we discuss countermeasures, as well as fundamental boundaries in the use of gadget-chain length for preventing code-reuse attacks. While we mainly focus on kBouncer and ROPecker, we are confident that our analysis of their weaknesses and the proposed countermeasures will be of use to future works that plan to explore comparable methodologies.

5.1 Tweaking the T_G and T_C Parameters

An obvious improvement to both these techniques involves increasing T_G, i.e., the parameter that determines whether a sequence of instructions ending with an indirect branch is a gadget or not. Looking back at Fig. 4, it is clear that, in the case of kBouncer, increasing T_G to 33

instructions would neutralize our exploit. However, increasing the length of gadgets is not straightforward, as it has various side effects.

Increasing T_G will unavoidably lead to longer gadget chains that belong to legitimate, innocuous code. As we consider longer code sequence as potential gadgets, inevitably more application execution paths will be identified as gadgets, leading to observing longer gadget chains at run time. Consequently, to avoid false positives, T_C also needs to be increased to avoid misclassifying legitimate control flows as attacks. Unfortunately, raising T_C presents opportunities to attackers for using more gadgets. Both kBouncer and ROPecker assume that attackers cannot use longer gadgets due to the side effects that such gadgets have, something that both this paper and previous work [16] disproves. Defenders also face an asymmetry, as usual, because attackers need only find a handful of long gadgets to masquerade their payload. To maximize the effect of the parameters, what needs to be optimized is the fraction $\frac{T_G}{T_C}$. While this is probably an oversimplification, it provides a useful rule of thumb.

5.1.1 Per-Application Parameters

Acceptable settings for T_G and T_C vary depending on the application being examined [8]. The nature of the application itself, the compiler it was built with, and the shared libraries it uses, influence the generated binary code and what parameter values can be used to avoid FPs and concurrently detect attacks consistently.

We can exploit this observation to use different values based on the application. This would ensure that the strictest rules are applied every time. However, doing so is also not without difficulty because both the defense and the attack depend greatly on the application in question. For example, after analyzing an application, we can determine that a very strict set of T_C and T_G can be used without FPs. However, the application may contain gadgets much larger than T_G that can be directly chained together, so no gadget chains are identified. This scenario is obviously ideal for the attacker. Further research is required to establish a metric that quantifies the effect of selecting a particular set of parameters. Using per-application parameters can be also challenging in the presence of dynamically loaded (DL) libraries (i.e., libraries loaded at times other than program start up), as new, potentially unknown code is introduced in the application.

5.1.2 Per-Call Parameters

A novel idea to further customize the parameters is to use different gadget-chain thresholds (T_C) based on the part of the code executing. kBouncer that triggers check on certain API calls, would greatly benefit from this approach. Certain APIs may be normally called through limited executions paths that exhibit very particular characteristics. For instance, a Windows native API call (win32) is frequently called by higher-level frameworks. This approach has the benefit of both avoiding FPs, hence providing better stability, and improving security guarantees.

5.1.3 Cumulative Chain-Length Calculation

ROPecker also accumulates the lengths of smaller gadget-chain segments and uses a different parameter T_{CC} to detect attacks. While this heuristic is not effective with our exploit, it would be interesting to explore whether incorporating it in kBouncer, which checks for attacks less frequently and in a more controlled manner, would further raise the bar for attackers.

5.1.4 Obstacles

Recursive functions can cause significant problems with techniques based on counting gadget chains. Due to their nature, they can generate a large number of consecutive returns when they reach their end condition (e.g., when their computation has finished). If the returns within the recursive function lead to gadgets, then it is extremely hard to find any value of T_C that would not cause FPs, unless the recursion is very shallow (relative to the value of T_C). kBouncer seems to avoid such conditions because it only checks the LBR when an API call is made. In a sense, it performs checks at the boundary between application and kernel, and the intuition is that the checks are made "far" away from the algorithms in the core of applications. However, it is not an uncommon scenario that a recursive algorithm requires to allocate memory or write into a file. In such cases, lowering the maximum gadget length (T_G) is the only option for avoiding FPs. On the other hand, ROPecker performs checks far more frequently and whenever execution is transferred to new pages, so we expect that it is even more fragile in the presence of recursive algorithms.

5.2 Combining with CFI

CFI [1] enforces control-flow integrity and can prevent the exploit we describe in Sec. 4. In particular, recent CFI approaches like CCFIR [39] and binCFI [40] prevent the use of unintended gadgets, such as the two-instruction gadget we use for stack pivoting (Appendix A, listing 2). CCFIR, in particular, also disallows indirect calls to certain API calls like `VirtualProtect()`, so it prevents two gadgets used by our exploit. These CFI approaches also incur low performance overhead, making them a good candidate for

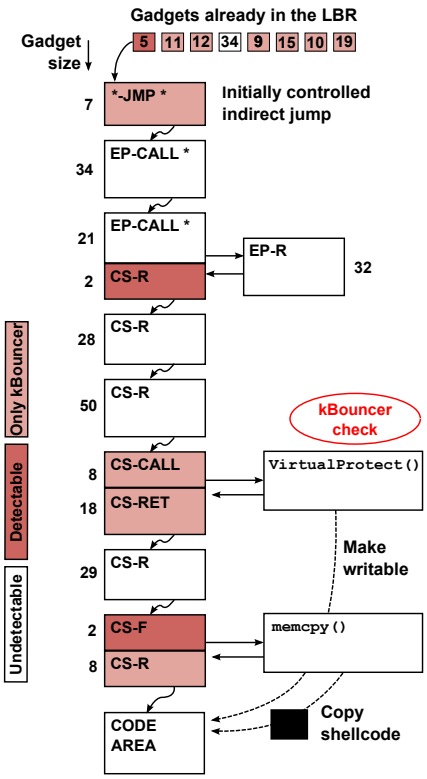

Figure 5: PoC exploit that bypasses kBouncer, ROPecker, and CCFIR. All the gadgets used are intended call-site (CS) or entry-point (EP) gadgets.

coupling with kBouncer. Unfortunately, recent work [16] has shown that they are still vulnerable to attack. *So is a combination of CFI and kBouncer still vulnerable?*

To answer the above question, we begin from the exploit used to bypass CFI in previous work [16, Sec. IV] and replace the smaller gadgets with longer HB gadgets that are also allowable by CFI. Similarly to prior work, we assume that CCFIR is in place, as it is stricter than binCFI. Because CFI does not allow transfers to new code, the goal of this payload is to mark existing code as writable and overwrite it with our shellcode. Before proceeding to describe the exploit, we summarize the additional restrictions imposed by CCFIR below.

Under CCFIR, return instructions can no longer transfer control to unintended gadgets, so only CS gadgets that were originally emitted by the compiler can be used when constructing a payload. Indirect call and jump instructions are also restricted and can only transfer control to function entry points, defining a new type of entry-point (EP) gadget. Indirect calls to sensitive API calls are prohibited, so any such calls need to be made using direct call instructions, contained within otherwise allowable gadgets. Finally, CCFIR introduces a new level of randomization through the use of springboard sections that proxy indirect control transfers. The location of these sections is randomized at load time and all indirect branches can only proceed through them.

To prepare the new payload, we need to replicate the steps described in Sec. 4, as well as a couple of additional steps required for bypassing CCFIR. Because of the randomized springboard sections, we need to reveal the sections that hold call and return stubs to the gadgets we plan to use. Fortunately, this can be achieved by exploiting the string object to leak code and meta-data from the DLLs of interest [16, Sec. IV.C]. `VirtualProtect()` and `memcpy()` are now called through gadgets that contain a direct call to these functions, so we do not need to explicitly locate them in the target process.

Figure 5 depicts a high-level overview of our second PoC exploit that overcomes the restrictions imposed by both kBouncer and CCFIR. We notice that because of CCFIR, we cannot use the same gadget to perform stack pivoting and, furthermore, we can only jump to an EP gadget. We resort to using a series of five gadgets to achieve the same goal (Appendix B, listings 6-10). Specifically, we first use three EP gadgets to corrupt the stack, so we can control a return instruction. This is similar to [16], however we use different, longer gadgets that are not detected by kBouncer. The fourth gadget loads `EBP` with our data and completes the switch to chaining through returns. We then use the fifth gadget, consisting of 28 instructions, to perform stack pivoting by copying `EBP` to `ESP` through the `leave` instruction.

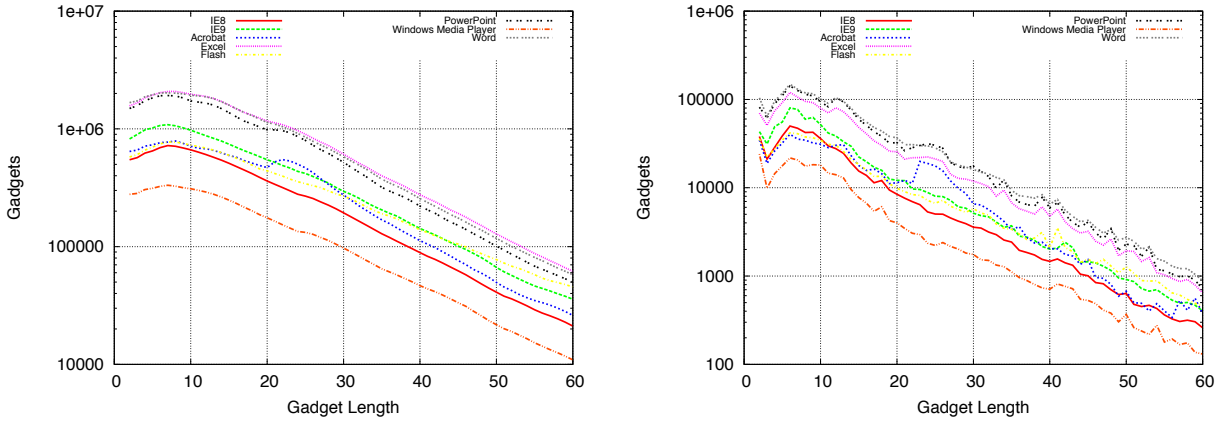
For calling `VirtualProtect()` and `memcpy()`, we reuse the same gadgets used against CFI (Appendix B, listings 12-13 and 15-16 respectively). The last gadget's `ret` transfers control to our shellcode that has been copied to the code section of the binary and has been preceded by a call to also foil future kBouncer checks. However, we replace the gadgets used to prepare the function-calling gadgets with the ones shown in listings 11 and 14 respectively, in Appendix B.

The exploit depicted in Fig. 5 demonstrates that even if we combine kBouncer and a loose CFI defense, it is still possible to devise attacks that can go undetected. Moreover, it shows that even if T_C and T_G are significantly tweaked, gadgets much larger than 21 instructions are available to partition an exploit to smaller, possibly undetectable, chains. In the particular exploit, setting T_G to 33 and T_C to 5 would still not have any effect.

6 Evaluation

6.1 Gadget Availability

The existence of long gadgets determines the potential to find HB gadgets that can be used to break long gadget chains. It is also an indicator on whether, we can poten-



(a) All gadgets.

(b) Call-preceded gadgets available to link using a `ret`.

Figure 6: Distribution of gadgets available to attackers under kBouncer based on their length, as recorded for multiple popular applications. We notice that there are numerous gadgets, even for gadgets of 60 instructions.

Application	**Workload**
Windows Media Player	Music playback for approximately 30 secs
Internet Explorer 9	Surf to google.com
Adobe Flash Player	Watch a YouTube video
Microsoft Word	Browse a Word document
Microsoft PowerPoint	Browse a PowerPoint presentation
Adobe Reader XI	Browse a PDF file

Table 1: Applications used in the evaluation.

tially use many different HB gadgets with varying functionality. We analyze the applications listed in Tab. 1, along with all their DLLs, to determine how many gadgets of different sizes they contain. In addition, we analyze Internet Explorer 8, which we used in our PoC. We follow the same methodology we used for collecting gadgets for the PoC exploit (Sec. 4.2). Specifically, we developed a gadget extraction tool in Python, using the popular *distorm* disassembler [15].

The process begins by disassembling from each byte in the code segment of each target binary, recursively following conditional branches, direct calls and jumps to locate instruction paths that end with a return or an indirect call or jump. That is, potential gadgets. As we disassemble, we count the number of instructions on each of the traversed paths, while we also keep track of the nodes we visit to avoid counting the same instructions more than once, due to loops. If we find more than one path starting from a particular byte and ending in an indirect branch, we keep the shortest path, and consider its length to be the length of the gadget at that byte. This is in accordance to how kBouncer identifies gadgets.

Figure 6 draws our results. We notice that even for relatively large gadget sizes, there are tens of thousands of gadgets. While we cannot make any assumptions on how usable they are, these results are an indication that there is a significant pool of gadgets to choose from. We attribute their large number to the fact that unintended gadgets are basically allowed by kBouncer.

6.2 Per-Application Parameters

In this section, we evaluate the feasibility of our per-application parameter scheme described in Sec. 5.1.1. To determine if, indeed, different applications can benefit from using tighter parameters, we run the six applications listed in Tab. 1 performing simple tasks, such as browsing. These applications were also used to perform a similar evaluation in kBouncer. We follow the same methodology to measure gadget-chain length.

We use a run-time monitoring tool based on Intel's Pin [22] to emulate the operation of LBR. We monitor every indirect branch instruction, including returns, jumps, and calls, and log the running thread ID, the address of the branch, and its target. To locate kBouncer gadgets, we borrowed the scripts used by kBouncer to disassemble the application images and their DLLs and, at the same time, locate the sensitive API calls where checks are injected by kBouncer [25, Appendix]. We combine the statically and dynamically collected information to match gadgets with control transfers observed at run time and calculate the length of gadget chains that would be checked by kBouncer.

Figure 7 shows the size of gadget chains (for $T_G = 20$), as they would be stored in LBR when entering a sensitive API call and for different applications. We observe that among the tested applications, only Adobe Reader

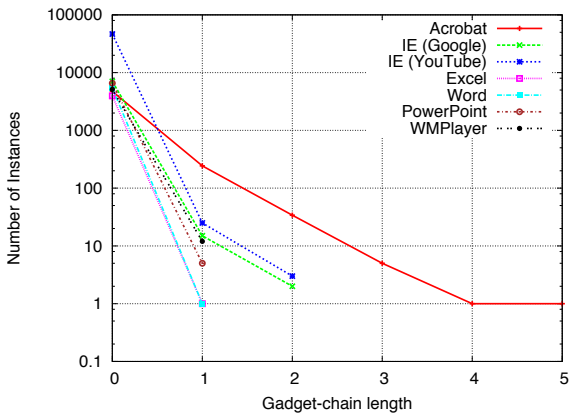


Figure 7: Length of chains for $T_G = 20$ for different applications, when entering a protected API function call. We run seven workloads using six applications, replicating the experiment in kBouncer [25, Sec. 3.2].

exhibits relatively long chains of five gadgets. This is in accordance with previously reported results [25]. All other tested applications include chains of up to two gadgets. In principle, this implies that we could use very strict values of T_C for all these applications. For example, using T_C = 3 with Internet Explorer would detect our long five-gadget sequence preceding the call to `VirtualProtect()` (Fig. 4).

This experiment shows that application-specific parameters can make it very hard for attackers to evade detection, at least with the methodology followed by our PoC exploit. However, we remain cautious, as run-time analysis can have limited coverage, even when divergent workloads are used, so using such strict values for T_C could cause FPs. In fact, recent works [12,29] report FPs with applications other than the ones originally tested in kBouncer [25], and when more restrictive parameters are employed. Nonetheless, establishing viable values for these parameters through dynamic and static analysis calls for additional research. The above serve as an indicator that per-application parameter fitting is necessary.

7 Related Work

Code reuse is the dominant form of exploitation since the wide adoption of stack canaries [9] and data execution prevention [2], which provide protection against stack smashing and code injections respectively. Return-to-libc attacks [37] is one of the simplest types of code reuse, involving the redirection of control to a `libc` function after setting up its arguments in the stack. Usually, this involves invoking functions like `system()` or `exec()` to launch another program (e.g., to spawn a shell). Short gadgets were also used in register springs [10] to load a register with the address of the attacker-controlled buffer located in the randomized stack or heap.

Return-Oriented Programming [31] generalizes the task of leveraging existing code to compromise a program. Short snippets of code, called gadgets, are chained together to introduce a new, not initially intended, control flow. ROP is particularly effective on instruction sets like CISC, where there are no instruction alignment requirements and the instruction number is high, because any sequence of executable bytes in memory can potentially become a gadget. Nevertheless, RISC architectures are also vulnerable to ROP [5].

Diversification approaches like Address-Space Layout Randomization (ASLR) [26] can be effective against ROP attacks and are already present in most OSs. ASLR randomizes the layout of a program when it is executed by loading the binary and its dynamic libraries on different base addresses each time. ASLR can be brute-forced [32], but the difficulty of doing so increases as more entropy becomes available, like in 64-bit systems. Recent attacks bypassing ASLR [30] rely on memory disclosure bugs that leak enough data from the targeted process to infer where the binary and/or its libraries are loaded at run time.

Finer-grained randomization approaches [17, 24, 38] have been proposed to further diversify programs and limit the effectiveness memory leaks. In-place randomization [24] relies on randomizing the sequence of instructions and replacing instructions with others of equivalent effect to further diversify the image of a running process. ILR [17] attempts to break the linearity of the address space, and binary stirring [38] randomizes a binary in the basic block level. However, recent research [34] has demonstrated that bugs that allow an attacker to read almost arbitrary memory locations can be used to bypass the above solutions as well.

CFI [1] enforces control-flow integrity preventing the malicious control flows that are part of ROP attacks, and it is not affected by memory leaks. CFI requires an accurate control-flow graph of the target program, which usually implies access to source code, but recent works [39, 40] have made steps towards addressing this limitation by applying a loose version of CFI on binaries. However, it has been recently shown [16] that these loose-CFI approaches are still vulnerable to attack in the presence of memory leaks. This work builds on the latter, borrowing the notion of call-site and entry-point gadgets, which are also the only kind of accessible gadgets under kBouncer and friends, and uses the same IE vulnerability as a starting point. However, the attack described in [16] is not effective against kBouncer. In this work we build an attack that is again effective. We also show that using the LBR and a set of heuristics is not sufficient to

prevent ROP attacks and reveal the inherent limitations of solutions based on gadget and chain length for detection. Finally, we propose various extensions that could alleviate the situation.

Compile-time solutions have been also proposed to alter the produced binary, so it is impervious to code reuse attacks. For example, producing a kernel that does not include any return instructions [21] cannot be exploited using ROP. However, variations of ROP that use indirect jumps instead of returns [3, 6] can be used to circumvent the above. G-Free [23] attempts to restrict control flow by using function cookies saved in a shadow stack at run time and inserts NOPs to destroy unintended gadgets. Because it is only loosely enforcing control flow, it is potentially vulnerable to the same attacks as CFI [16]. Additionally, compile-time approaches require that a binary and all of its libraries are recompiled.

Concurrently with our work, other efforts have also dealt with evaluating kBouncer and related approaches. Schuster et al. [29] take a slightly different approach and focus on finding gadgets that could be used to flush the LBR before performing any API call. The presence of such gadgets in the application nullifies any LBR-based defense, however, it leads to the same value being repeated in the LBR, which could potentially be used to detect such attacks. Moreover, the addition of CFI could restore the effectiveness of kBouncer.

On the other hand, Davi et al. [12] take an approach closer to ours. First, they show that there are enough small gadgets under loose CFI to perform any computation. Then, they introduce a long gadget of 23 instructions that does not perform any useful functionality and has limited side effects. They use this as a NOP gadget for breaking long gadget chains. Registers are not preserved, so additional gadgets need to be introduced to save any registers that need to be preserved. Larger NOP gadgets are not investigated, so unlike our approach their approach is more prone to detection when choosing stricter thresholds. Interestingly enough, both approaches test kBouncer, albeit with a different set of applications, and report false positives with the current, as well as with stricter thresholds.

8 Conclusion

In this paper we explored the feasibility of bypassing state-of-the-art ROP defenses based on monitoring processes (by means of Intel's new Last Branch Record) to detect control flows that resemble the execution of ROP chains [8, 25]. Essentially, these defenses check whether a sensitive API call was reached via a sequence of indirect branches to short, gadget-like, instruction sequences. Evading such detection is perceived as a hard task. First, all exploitation should be carried out using call-preceded gadgets, since otherwise the ROP chain will be easily detectable. Second, exploitation should find and then carefully insert long gadgets, in the middle of a series of shorter gadgets, in order to fly under the defense's ROP radar. The long gadgets should be long enough to make the ROP chain look like a legitimate control flow of the running process. Finding such long gadgets and gluing them in the actual ROP chain is not trivial, since it is possible that these long series of instructions interfere with the state of the exploit (e.g., modify a valuable register). Nevertheless, in this paper, we successfully constructed two real exploits, which utilizes the long gadgets to evade detection. With this work we stress that the selection of critical parameters, such as the length of a series of instructions that should be considered a gadget, as well as the gadget-chain length is not trivial. Until we solve these problems, the defenses are prone to false negatives and false positives. Finally, we discuss various countermeasures and provide evidence, through an experimental evaluation, that defining parameters on a per-application basis, can alleviate these concerns.

Acknowledgment

We want to express our thanks to the anonymous reviewers for their valuable comments. In particular, we want to thank our shepherd, Kevin Fu, who helped us give this paper its final form. A PoC Exploit Gadgets

```
; library: mshtml.dll
; offset:  0x001BC907
; type:    intended, *-JMP *
1 mov   eax, [ecx+1Ch]
2 test  al,  al
3 js    loc1
```

```
loc1:
4 mov   ecx, dword ptr [ecx+24h]
5 mov   eax, dword ptr [ecx]
6 mov   edx, dword ptr [eax+24h]
7 jmp   edx                 ; edx points to 1st gadget
```

Listing 1: The exploitation of the vulnerability in Internet Explorer 8 gives us control of an indirect jump. The target address of the indirect jump is loaded from the sprayed buffer, by dereferencing values in the overwritten button object. After this code sequence, `ecx` contains a pointer to the overwritten button object, `eax` contains a pointer to our sprayed buffer, and `edx` contains the address of the first gadget.

```
; library: shell32.dll
; offset:  0x00146FB2
; type:    unintended, *-RET
1 xchg  esp, eax
2 retn
```

Listing 2: This is the first executed gadget after the control of the indirect jmp instruction. The gadget performs the stack pivoting operation. Essentially, the values in the `eax` and the `esp` registers are swapped. On entry, `eax` points to the sprayed buffer, which contains the rest of the ROP chain.

```
; library: shell32.dll
; offset:  0x0007AACD
; sort:    intended instructions, unintended CS-RET
 1 mov     esi, 738AD720h
 2 mov     edi, 73BCC3C0h
 3 movsd
   ...
 7 mov     esi, 738AD710h
 8 mov     edi, 73BCC3D4h
 9 movsd
   ...
13 mov     esi, 738AD730h
14 mov     edi, 73BCC3E8h
15 movsd
   ...
19 mov     esi, 738AD700h
20 mov     edi, 73BCC3FCh
21 movsd
   ...
25 mov     esi, 7387A2CCh
26 mov     edi, 73BCC410h
27 movsd
   ...
31 pop     edi
32 pop     esi
33 retn
```

Listing 3: This is a heuristic-breaker gadget, i.e., an undetectable long gadget. First, it is used to reset the chain of detectable gadgets in the ROP chain. Second, it will prepare the `esi` register, which is required by the next gadget that will call `VirtualProtect()`. Upon entry, it does not require any registers to be already set up, but it alters two registers: `esi` and `edi`, loading them with values from our buffer.

```
; library: shell32.dll
; offset:  0x0039C0E5
; type:    intended, CS-CALL *
1 lea     ecx, [esi+28h]
2 mov     edi, eax
3 mov     eax, [ecx]
4 call    dword ptr [eax+44h]
```

Listing 4: An indirect function call that we use to call `VirtualProtect()` and change the memory permissions of the region occupied by the injected shellcode, which also resides in the sprayed buffer. The gadget does not push values, so the arguments for the called function can be prepared in advance in the ROP chain, and it also saves `EAX` in `EDI` before calling.

```
; library: shell32.dll
; offset:  0x0039C0EF
; type:    intended, CS-RET
1 mov     eax, edi
2 pop     edi
3 pop     esi
4 pop     ebp
5 retn    0Ch
```

Listing 5: The instructions following the indirect call in listing 4 also constitute a gadget. This gadget restores `EAX` from `EDI`, thus restoring to the value it had before entering the previous gadget, and returns using the next value in our ROP chain transferring control to our shellcode.

B CFI-resistant PoC Exploit Gadgets

```
; library: ieframe.dll
; offset:  0x00216C0E
; type:    EP
 1 mov     edi, edi
 2 push    ebp
 3 mov     ebp, esp
 4 sub     esp, 2C8h
 5 mov     eax, ___security_cookie
 6 xor     eax, ebp
 7 mov     [ebp-4], eax
 8 mov     eax, [ebp+0Ch]
 9 push    ebx
10 push    esi
11 push    edi
12 mov     edi, [ebp+8]
13 mov     [ebp-290h], eax
14 xor     eax, eax
15 push    3
16 mov     [ebp-280h], eax
17 mov     [ebp-284h], eax
18 mov     [ebp-288h], eax
19 mov     [ebp-2A0h], eax
20 mov     [ebp-2A4h], eax
21 pop     eax
22 mov     esi, ecx
23 mov     [ebp-2B8h], ax
24 mov     eax, [esi+24h]
25 lea     edx, [ebp-2C8h]
26 push    edx
27 mov     [ebp-2B0h], eax
28 mov     eax, [esi+1Ch]
29 mov     ecx, [eax]
30 lea     edx, [ebp-2B8h]
31 push    edx
32 push    eax
33 mov     [ebp-294h], edi
34 call    dword ptr [ecx+1Ch]
```

Listing 6: By pushing a pointer to the sprayed buffer as an argument (see Line 32), this gadget prepares the gadget (see Listing 7) that will call the stack smasher (see Listing 8).

```
; library: mshtml.dll
; offset:  0x004A959F
; type:    EP
 1 mov     edi, edi
 2 push    ebp
 3 mov     ebp, esp
 4 push    dword ptr [ebp+30h]
 5 mov     eax, [ebp+8]
 6 push    dword ptr [ebp+2Ch]
 7 mov     ecx, [eax+4]
 8 push    dword ptr [ebp+28h]
 9 mov     ecx, [ecx]
10 push    dword ptr [ebp+24h]
11 push    dword ptr [ebp+20h]
12 push    dword ptr [ebp+1Ch]
13 push    dword ptr [ebp+18h]
14 push    dword ptr [ebp+14h]
15 push    dword ptr [eax+0Ch]
16 push    dword ptr [eax+8]
17 push    dword ptr [ebp+10h]
18 push    dword ptr [ebp+0Ch]
19 push    eax
20 push    dword ptr [ecx]
21 call    dword ptr [ecx+10h]
```

Listing 7: This gadget will push the address of the call site gadget (see Line 15) we want to be executed later in the chain (see Listing 10). Once we get to this desired call site gadget, the switch from Entry Point to Call Site gadgets is complete.

```
; library: ieframe.dll
; offset:  0x000A98B5
; type:    EP
 1 mov     edi, edi
 2 push    ebp
 3 mov     ebp, esp
 4 mov     eax, [ebp+8]
 5 mov     ecx, [eax+140h]
 6 push    ebx
 7 mov     ebx, [ebp+14h]
 8 push    esi
 9 mov     esi, [ebp+0Ch]
10 mov     [esi], ecx
11 lea     ecx, [eax+144h]
12 mov     edx, [ecx]
13 push    edi
14 mov     edi, [ebp+10h]
15 mov     [edi], edx
16 lea     edx, [eax+148h]
17 mov     edi, [edx]
18 mov     [ebx], edi
19 xor     edi, edi
20 mov     [eax+140h], edi
21 mov     [ecx], edi
22 mov     [edx], edi
23 mov     eax, [esi]
24 neg     eax
25 sbb     eax, eax
26 pop     edi
27 and     eax, 7FFFBFFBh
28 pop     esi
29 add     eax, 80004005h
30 pop     ebx
31 pop     ebp
32 retn    10h
```

Listing 8: This is a long gadget that moves data and does not harm the status of our ROP chain. Also, it will break the calling assumptions of the caller gadget (see Listing 7).

```
; library: mshtml.dll
; offset:  0x004A95D6
; type:    EP
 1 pop     ebp
 2 retn    2Ch
```

Listing 9: The instructions following the indirect call in listing 7 also constitute a gadget. The return instruction in this gadget will use the address of the call site gadget that was pushed before (see Listing 7). Also, in this gadget `ebp` is prepared with a pointer to our sprayed buffer. The value in this register will be moved to the `esp` register in the stack pivoting gadget (see Listing 10).

```
; library: mshtml.dll
; offset:  0x00305202
; type:    CS
 1 mov     ecx, [ebp+30h]
 2 mov     edx, [ebp+40h]
 3 mov     [ecx], eax
 4 mov     eax, [ebp+34h]
 5 mov     ecx, [ebp+3Ch]
 6 shr     esi, 6
 7 and     esi, 1
 8 and     dword ptr [ebp+8], 0
 9 mov     [eax], esi
10 mov     eax, [ebp-0Ch]
11 mov     [ecx], eax
12 mov     eax, [ebp-4]
13 mov     ecx, [eax]
14 mov     ecx, [ecx+88h]
15 mov     [edx], ecx
16 mov     ecx, [eax]
17 mov     ecx, [ecx+30h]
18 mov     edx, [ebp+44h]
19 mov     [edx], ecx
20 mov     ecx, [ebp+38h]
21 mov     [ecx], eax
22 jmp     next_ins
23 mov     eax, [ebp+8]
24 pop     edi
25 pop     esi
26 pop     ebx
27 leave
28 retn    40h
```

Listing 10: This is a stack pivoting gadget. This gadget will load `esp` with a pointer to our sprayed buffer at Line 27.

```
; library: mshtml.dll
; offset:  0x0021FDF4
; type:    CS
 1 mov     eax, [ebp+0Ch]
 2 mov     [ebx], eax
 3 push    7
 4 pop     ecx
 5 lea     esi, [eax+228h]
 6 rep movsd
 7 mov     ecx, [eax+244h]
 8 mov     [ebx+20h], ecx
 9 mov     ecx, [eax+260h]
10 mov     [ebx+24h], ecx
11 mov     ecx, [eax+264h]
12 mov     [ebx+28h], ecx
13 mov     ecx, [eax+268h]
14 mov     [ebx+2Ch], ecx
15 mov     ecx, [eax+26Ch]
16 mov     [ebx+30h], ecx
17 mov     ecx, [eax+270h]
18 mov     [ebx+34h], ecx
19 mov     ecx, [eax+274h]
20 mov     [ebx+38h], ecx
21 mov     ecx, [eax+278h]

Oxymoron
Making Fine-Grained Memory Randomization Practical by Allowing Code Sharing

Abstract

The latest effective defense against code reuse attacks is fine-grained, per-process memory randomization. However, such process randomization prevents code sharing since there is no longer any identical code to share between processes. Without shared libraries, however, tremendous memory savings are forfeit. This drawback may hinder the adoption of fine-grained memory randomization.

We present Oxymoron, a secure fine-grained memory randomization technique on a per-process level that does not interfere with code sharing. Executables and libraries built with Oxymoron feature *'memory-layout-agnostic code'*, which runs on a commodity Linux. Our theoretical and practical evaluations show that Oxymoron is the first solution to be secure against just-in-time code reuse attacks and demonstrate that fine-grained memory randomization is feasible without forfeiting the enormous memory savings of shared libraries.

1 Introduction

Code reuse attacks manage to re-direct control flow through a program with the intent of imposing malicious behavior on an otherwise benign program. Despite being introduced more than 20 years ago, code reuse is still one of the three most prevalent attack vectors [1, 28], e.g., through vulnerable PDF viewers, browsers, or operating system services. Several code reuse mitigations have been proposed. They either detect the redirection of control flow [7, 12], or randomize a process's address space. Randomizations jumble the whole address space, with the intent of preventing code reuse attacks by making it impossible to predict where specific code resides.

Especially *Address Space Layout Randomization* (ASLR [23, 22]) has become widespread, but meanwhile has been shown to be ineffective [24, 25]. A promising avenue is the use of even finer randomization techniques that randomize at the granularity of functions, basic blocks or even instructions [18, 10, 16, 19, 17].

To be effective, fine-grained memory randomization must prevent an attacker from using information about the memory layout of one process to infer the layout of another process. This is a particular threat in the light of shared code originating from shared libraries. Hence, most recent fine-grained memory randomization solutions also randomize shared libraries for every single process [13, 21, 29]. As a result, there is no identical code in any two processes, which makes sharing impossible. A dysfunctional code sharing, however, increases the memory footprint of the entire system, likely on the order of Gigabytes, as we elaborate in Section 2.

To summarize: fine-grained randomization solutions presented so far come at the expense of tremendous memory overhead, which renders them impractical.

Oxymoron /ˌɒk.sɪ'mɔː.rɒn/ (noun)
Greek. A figure of speech that combines contradictory terms.

We present Oxymoron, which combines two seemingly contradictory methods: a secure fine-grained memory randomization with the ability to share the entire code among other processes. At the heart of Oxymoron is a new x86 calling convention we propose: *Position-and-Layout-Agnostic CodE (PALACE)*. This code uses no instructions that reference other code or data directly, but instead the instructions use a layer of indirection referred to by an index. This index uniquely identifies a target and hence remains identical when targets are randomized in memory. Consequently, the memory in which those instructions are stored does not change, thereby making it available to be shared with other processes.

Oxymoron cuts program code into the smallest sharable piece: a memory page. We randomize those pages and share them individually among processes. Each shared page appears at a different, random address in each process. We use the x86 processor's segmentation feature to disable access to the unique indices, which we organized in a translation table. This unique property of Oxymoron makes our solution more secure than fine-grained memory randomization solutions published so far.

To demonstrate the effectiveness and efficiency of Oxymoron, we implemented and evaluated a static binary rewriter for the Intel x86 architecture that emits PALACE executables and libraries with a very low run-time overhead of only 2.7%. By re-enabling code sharing, Oxymoron is the first memory randomization technique that reduces the total system memory overhead back to levels it was before fine-grained memory randomization, while simultaneously being the first solution that is secure against the just-in-time code reuse attacks recently proposed by Snow et al [26].

2 Problem Description

Before we describe our idea, we want to explain in more detail why any traditional fine-grained memory randomization necessarily makes sharing libraries impossible. The goal of fine-grained randomization is for every process to feature a memory layout that is as varied as possible from any other process. If we treat program code, which usually is en bloc, as a puzzle and shuffle the puzzle pieces throughout the entire address space, their combinatorial possibilities provide a high entropy. It is only possible to share those puzzle pieces individually as a memory page with other processes if the content of each piece is identical in each process. With traditional code, the content of those piece necessarily changes when their order in memory is rearranged, as we explain in the following:

Code references other code or other data using either absolute memory addresses, e.g., `call 0x804bd32`, or relative addresses, e.g., `call +42`. For absolute addresses it is obvious that different randomizations necessarily lead to different code and data addresses. As a result, the encoding of instructions that hold such addresses changes as well, thereby forfeiting the sharing with other processes. Relative addresses, in turn, make code independent of its load address in memory. However, in case of using code pieces that are randomized, the relative distances change as well. Here, for the same reason, those pieces cannot be shared across processes as they feature different relative addresses. Consequently, fine-grained memory randomization impedes common code sharing, which is a fundamental concept of *all* modern OSes.

Severity. Modern operating systems use code sharing automatically, and it is in effect because the running programs use the same libraries (C library, threading library etc.), i.e. their address spaces have identical code loaded.

To verify this claim, we conducted a simple experiment that shows the impact of code sharing and lack thereof. We used an unmodified Ubuntu 13.10 x86 operating system on a machine with 4 GB of RAM and evaluated how much RAM is saved due to code sharing. After booting to an idle desktop, the 234 running processes consumed a total 679 MB. Our analysis of memory page mappings in each process obtained from `/proc/<PID>/maps` revealed that most of the processes used the same set of shared libraries. As expected, most frequently the standard C-library `libc.2.17.so` was shared between all of the 234 processes. All mapped portions of `libc` sum up to 207,028 KB while only 885 KB of real memory are consumed. This is a savings of 206 MB for `libc` alone.

Figure 1 illustrates the top ten savings by library. In total, sharing instead of duplicating saved 1,388 MB of RAM on the idle Ubuntu desktop. When additionally starting the Firefox browser, the memory consumption was increased from 679 MB to 817 MB. The total amount of savings by sharing summed up to 1,435 MB of RAM, which is an additional savings of 47 MB.

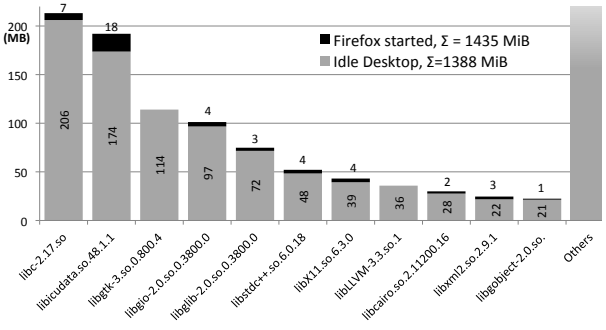

Figure 1: *Savings due to sharing of libraries. Idle desktop saves 1388 MB, with Firefox 47 MB more is saved.*

2.1 Threat Model

We assume a Linux operating system that runs a user mode process, which contains a memory corruption vulnerability. The attacker's goal is to exploit this vulnerability in order to divert the control flow and execute arbitrary code on her behalf. To this end, the attacker knows the process' binary executable and can precompute potential gadget chains in advance. The attacker can control the input of all communication channels to the process, especially including file content, network traffic, and user input. However, we assume that the attacker

has not gained prior access to the operating system's kernel and that the program's binary is not modified. Apart from that, the computational power of the attacker is not limited.

Moreover, for JIT-ROP attacks [26] to work, we assume that the process has at least one memory disclosure vulnerability, which makes the process read from an arbitrary memory location chosen by the attacker and report the value at that location. This vulnerability can be exploited any number of times during the runtime of the process. Note that the process itself performs the read attempt: both address space and permissions are implied to belong to the process.

3 High-Level Design of Oxymoron

To benefit from the best of both worlds – fine-grained memory randomization and code sharing – the challenge is to create a form of code that does not incorporate absolute or relative addresses, as we have already shown that both addressing schemes by definition suffer from being dependent on their randomization. An additional layer of indirection that translates unique labels to current randomized addresses allows the byte representation of code to remain the same, which enables code page sharing. However, this approach is difficult to realize as it is accompanied by four key challenges:

1. keeping the size of the translation table small in order not to increase the memory that we saved,
2. developing an efficient layer of indirection so that it is practical,
3. making the translation inaccessible by adversaries,
4. making the solution run on a commodity, unmodified Linux OS.

Overall Procedure. Oxymoron prevents code reuse attacks by shuffling every instruction of a program to a completely different position in memory so that no instruction stays at a known address, thereby making it infeasible for an adversary to guess or brute-force addresses. We use a three-step procedure (cf. Figure 2):

A) **Code Transformation**: The executable E is transformed to Position-and-Layout-Agnostic CodE (PALACE). The result is a PALACE-code executable P_E. The same applies to shared libraries, which can be treated like executables.

B) **Splitting**: The P_E code is then split into the smallest possible piece that can be shared among processes: a memory page. The code of P_E now consists of code pieces $P_E = p_1|p_2|\ldots|p_n$.

C) **Randomization**: At program load time, the pieces $p_1|p_2|\ldots|p_n$ are shuffled by the ASLR part of the operating system loader. In memory, their order is completely random and the pieces may have empty gaps of arbitrary size between them.

The first two steps only have to be done once, while the third step is performed at load-time of the executable P_E.

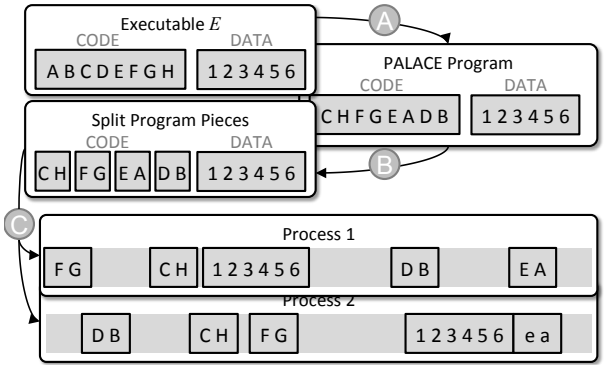

Figure 2: *The program is transformed and split once (A and B), then randomized at every process start-up (C).*

3.1 Code Transformation

To enable layout-agnostic code, all references to code and data are replaced with a unique label. Such a unique label is an assigned index into a translation table. This *Randomization-agnostic Translation Table* (RaTTle) in turn refers to the actual target (see Figure 3). This is the key to code sharing among processes, since the byte representation of the PALACE code does not change in the next step, when it is split and individual pieces are shuffled in memory.

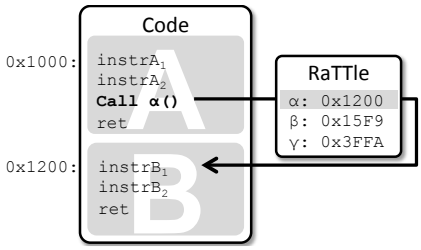

Figure 3: *Control-flow is redirected through the RaTTle rather than jumping to addresses directly.*

3.2 Splitting

Splitting ensures that the resulting pieces can be mapped into different processes at different addresses. As PALACE code references every target through a unique label in the RaTTle, it can be split without the need for traditional relocation, which rewrites addresses that hence have changed.

The PALACE code is split into page-sized pieces. If those pieces are later shuffled, it must be assured that the original semantics of the program are kept intact. This is essential when control flows from the end of one piece to the piece that was adjacent to it in the original program code. Thus, we need to insert explicit control flows between consecutive code pieces that might be moved away in a later stage of randomization. These explicit links only need to be inserted as the last instruction of a piece to ensure that control indeed flows to the intended successor (see Figure 4). After the links have been inserted, the code pieces can be randomized in memory without violating the original program semantics.

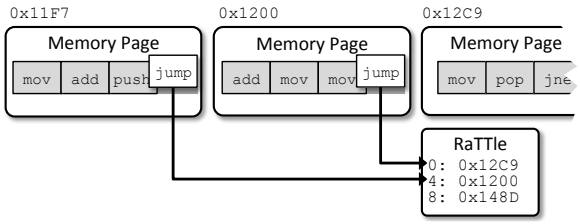

Figure 4: *Filling a page with instructions and linking them with explicit control flow transfers.*

3.3 Randomization

Modern OS loaders for shared libraries already support Address Space Layout Randomization (ASLR), i.e. they load the code, data, and stack segments at random base addresses. We leverage this fact by putting every memory page in its own loadable segment of the executable file or of the shared library. As the page-sized code pieces are already transformed to PALACE code, no relocation of addresses is needed. An ASLR-enabled commodity loader can blindly load all pieces at random addresses. Consequently, each process can have its own permutation of the randomization. Only the RaTTle needs to be kept up to date with a per-process randomization (see *"Populating the RaTTle"*).

3.4 Addressing the RaTTle

At first glance, it might seem we have only shifted the problem of addressing functions in code to securely addressing the RaTTle. However, our approach enables secure access to the RaTTle without access for adversaries. We first explain why we chose the more involved realization of the RaTTle and not existing approaches, such as a fixed address, a fixed register or the Global Offset Table (GOT). As already alluded to by Shacham et al. [25], the following techniques have drawbacks:

Fixed. Storing the RaTTle at a fixed address in memory allows for its address to be hard-coded in the instructions themselves. Unfortunately, a hard-coded address restricts the table to a fixed position. This fact can be exploited by an attacker.

GOT. Accessing the GOT is realized by using relative addresses, which forfeits sharing as discussed earlier. Moreover, several attacks are known that dereference the GOT [5].

Register. A dynamic address that is randomly chosen for every process could be stored in a dedicated machine register. However, this register would need to be sacrificed and every original use of that register must then be simulated with other registers or the stack. Moreover, a leakage vulnerability could reveal the address of the RaTTle.

Our Approach. Our RaTTle does not suffer from the aforementioned drawbacks. We use the x86 feature of memory *segmentation* to address and at the same time hide the RaTTle from adversaries. X86's segmentation is disused today because it has been superseded by memory paging. Memory paging, also called virtual memory, allows a fine-grained mapping of memory on a per-process basis and is much more versatile than segmentation. However, segmentation is still available in modern processors and in combination with paging allows for the security we need for the RaTTle. Additionally, as segmentation is a hardware feature and we can use it to implement the translation table, it is very efficient. Segmentation allows the memory to be divided in user-defined segments that may overlap. Segmentation is realized in the processor by adding a user-defined offset to all addresses the code handles (see Figure 5).

Segmentation allows different so-called *segment descriptors* to be created, each with their own *base address* and *limit*, i.e. the start and length of that segment. The list of these segment descriptors is kept in the *Global Descriptor Table* (GDT, see Figure 5). *Segment selectors* must then point to exactly one segment entry in that GDT. Segment selection is done using dedicated segment selector registers such as `CS` (Code Segment), `DS` (Data Segment),

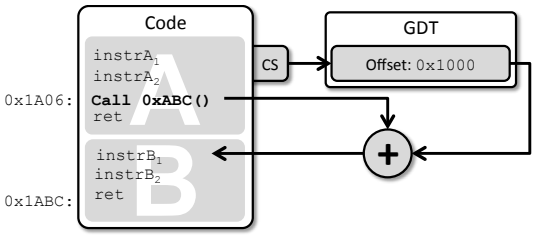

Figure 5: *Code using segments as offsets for addresses.*

SS (Stack Segment) and three general purpose segment selectors ES, FS and GS.

Position-and-Layout-Agnostic CodE (PALACE). The trick we use is the fact that segments can be selectively overridden on a per-instruction basis. In this way, a single instruction may use an addressing that is relative to the RaTTle, thereby indexing the RaTTle to change control flow or to access data. For example, `call *%fs:0x4` dereferences the double-word stored at `%fs:4` and calls the function stored at that double-word. If we let the segment selector FS point to the randomly chosen address of the RaTTle, we effectively index the RaTTle by an offset of 4 (see Figure 6).

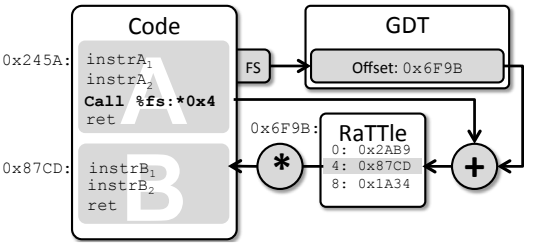

Figure 6: *The RaTTle in Action: Indexed through the GDT and dereferenced using an indirect call; all in* one instruction.

In PALACE code, we substitute each branch and jump instruction with an `%fs` segment override and a unique index. When not using the FS segment override, code does not have access to the RaTTle because it uses a different segment. The address of a segment, and hence of the RaTTle, cannot be read from user space because the local and global descriptor tables point to kernel space memory which is inaccessible from user space. This makes the address of the RaTTle inaccessible.

As a segment selector for the RaTTle, we chose the general purpose segment selector register FS, as already used in the example above. To the best of our knowledge, this register is unused. The only use we found is in the Windows emulator Wine that uses segmentation for its 16-bit Windows emulation.

Efficient Data Access. Data can be accessed in a similar way, but through the Global Offset Table (GOT). The GOT is used in position-independent code such as libraries anyway. We just need to substitute the way the address of the GOT is calculated with an indirection through the RaTTle. Further access is done through the GOT as in traditional position-independent code. This is explained in more detail in Section 4.5.

Populating the RaTTle. The RaTTle is the only part of the code that needs rewriting at load time. The RaTTle is empty in the ELF executable file on disk and its memory gets initialized by the loader with the help of relocation information. This relocation information points to the actual symbols that each RaTTle index refers to. The Linux loader automatically takes the relocation information to rewrite the RaTTle at program load [6].

4 Design Details

With the ingredients described earlier, we can put together our mitigation against code reuse attacks that is efficient, lightweight and shares code and data between processes.

4.1 Design Decisions

There are several ways to implement PALACE. A PALACE executable can be produced by a compiler, or it can be transformed from a traditional executable using static or load-time translation.

Compiler Support. The same way contemporary compilers support PIC, they can be augmented to emit PALACE code. Based on the principles of PALACE code introduced in the previous *Idea* section, the compiler needs to generate PALACE code and put it in subsequent memory-page-sized chunks. It is then ready to be loaded by a traditional loader that permutes the chunks prior to execution of the code.

Static Translation. If the source is not available, an existing executable can be transformed to PALACE by means of static translation [14, 15]. Static translation reads an executable or shared library file from disk, disassembles it, transforms the instructions, and writes a modified executable file back to disk. In our scenario, static translation keeps most of the instructions untouched while only replacing code and data references with the appropriate indirection through the RaTTle.

Load-time Translation. Load-time Translation can be regarded as a static translation that happens automatically at very load-time, after the executable or library has been read from disk into memory but before it starts execution. This method is often referred to as *binary rewrit-*

ing. Its advantage is that a process can be randomized at every startup. In our scenario, however, we do not need load-time translation as we can achieve a randomization at load-time with the specially crafted PALACE chunks in the executable file.

Our Choice. We want to stress that Oxymoron can be implemented by a compiler that simply emits PALACE code in the first place instead of traditional code. We could have implemented Oxymoron as a compiler solution. However, this would have required us to modify existing compilers. Instead, we built a legacy-compatible solution that uses static translation and can be built on an existing fine-grained memory randomization framework, which already uses static translation. We built Oxymoron on the existing framework Xifer provided by Davi et al. [13].

In theory, a static translation approach may seem fragile because it needs a perfect disassembly. However, static translation can be tuned to reliably disassemble code generated by a particular compiler with known and carefully chosen parameters. Besides, in this paper we use the translation from traditional x86 code to PALACE code as a comprehensible running example that demonstrates how PALACE code looks in contrast to traditional x86 code.

In both cases, compiler and static translation, the generated PALACE code of the executables and libraries can be read by a commodity Linux. The Linux OS loader will detect the executable as being ASLR-enabled and will randomize its base address. Unfortunately the commodity loader does not randomize the program segments individually but keeps their relative distances. For traditional position-independent code that was necessary so that code in the `.text` section can still reference objects in the `.data` section by their relative distance to the current instruction pointer. However, for PALACE this limitation is not required. We want to achieve a more fine-grained randomization by allowing an individual randomization of each program segment, which could be as small as a memory page. This can be achieved by requesting a special linker in the program header, which randomizes the segments individually.

4.2 Setting up the RaTTle

The RaTTle needs to be populated with all references in the executable and the table needs to be loaded at a random address. Moreover, one table does not suffice for the interaction of several shared libraries. Before we can use PALACE code, we need to set up the RaTTle as follows:

1. Assign every reference in code a unique number that will act as an index into the RaTTle,
2. Fill the RaTTle with the actual, current, random addresses of the original targets, and
3. Set up segmentation so that a free segment selector points to the RaTTle and we can index the RaTTle.

In step 1, the absolute addresses of the original program are saved in a hash set. Then, every address is assigned an ascending index. This ensures that the table does not grow unnecessarily large. Because the final, random addresses are unknown before the process is started, the RaTTle cannot be filled until start-up of the process. As we want to avoid modification of the operating system loader, we chose a method that is able to fill the RaTTle using only traditional features of the loader. Such a feature is relocation. Relocation information tells the loader which objects in the executable file or in the library must be overwritten with current addresses at load time. Therefore, we add relocation information for each RaTTle index to the final executable/library file. This ensures that the loader rewrites each index so that it points to the corresponding position of code or data that this index represents. As a result, the randomized addresses of the code pieces are automatically written into the RaTTle by the operating system loader.

4.3 Setting up Segmentation

In order to find the RaTTle in memory, we need to set up segmentation so that a pre-defined segment points to the beginning of the table. Unfortunately, we cannot use relocation information for this purpose, because neither setting up segmentation nor setting segment selectors is supported by relocation information. Setting up segmentation via the Global Descriptor Table (GDT) would require kernel modifications. Since the goal is to avoid operating system modifications in order to stay legacy compatible, this is not an option. Luckily, the x86 architecture additionally supports a so-called *Local Descriptor Table* (LDT). The LDT can be switched for every address space, so that Linux emulates a per-process LDT. This is a perfect feature for enabling Oxymoron on a per-process basis.

The set-up of the LDT and the segment selector that points into the LDT is done in initialization code. To this end, we leverage the ELF executable format's initialization code that resides in the `.init` section. Code in this section is ensures to be executed before any other code. This init code figures out the address at which the RaTTle has been randomly loaded by the loader and sets up the LDT accordingly. After the initialization code has run, the segment selector `FS` points to the random address

of the RaTTle. The PALACE code can now work as intended.

4.4 Control Flow and Data

Code. Control flow branches or function calls that target another memory page need to be replaced with an indirection through the RaTTle. The simplest case is a direct `call` or an unconditional `jmp` to a different place in code:

Address	Before	After
8050512:	`call 0x8050c08`	`call %fs:4`
RaTTle:		[0] ..... [4] `0x8050c08`

Only branches that reference code outside of the current memory page must go through the RaTTle. Code and data access within one memory page may be encoded position-relative (e.g., `call +90`).

If the to-be-replaced instruction is an indirect jump, the translation is slightly larger due to the fact that x86 does not support two levels of indirection. It is either possible to use the RaTTle to get the address of the second indirection and then dereference that using an indirect jump or to use a trampoline. We use a trampoline because it is slightly faster:

Address	Before	After
8050512:	`jmp *0x80a00012`	`jmp %fs:4`
80a00012:	`8050c08`	`8050c08`
RaTTle:		[0] ..... [4] `jmp *80a00012`

A slightly more involved case is a conditional jump because there is no equivalent conditional indirect jump. Our solution is a bit more involved:

Address	Before	After
8050512:	`cmp %eax, %ebx`	`cmp %eax, %ebx`
8050514:	`jne 0x8050590`	`jne 0x8050518`
8050516:		`jmp 0x805051a`
8050518:		`jmp *%fs:4`
RaTTle:		[0] ..... [4] `0x8050590`

An indirect jump, such as `jmp *%eax` does not need to be replaced at all. However, the used register (in this example `%eax`) must point to the correct randomized position in memory. This is either ensured by the compiler that generated PALACE code or by the translation from traditional code. In either case, a register is loaded with a code address. Optionally, this address is modified to mimic jump tables or C++ vTables, and then the indirect jump transfers control flow to the address stored in the register. To load a code address to the register before it is modified, a fixed address is copied to the register. This is similar to `mov $0x8402dbc, %eax`. In the case of PALACE, this step needs an indirection to conceal the actual address and to make the address exchangeable by the RaTTle. In PALACE code this register loading looks like this: `mov %fs:$0x4, %eax`. This copies an address stored as an entry in the RaTTle to the register `%eax`. Then, some mathematical operations can be performed, such as adding the offset into C++ vTables and finally the indirect jump is performed as in traditional x86: `jmp *%eax`.

Data Access. Accessing data through the RaTTle is done in exactly the same way. An indirect memory operation is used to read or write data from or to an address stored in the RaTTle. `mov %fs:$0x4, %ebx` is used to read the first entry (4 bytes) of the RaTTle into register `%ebx` and vice versa the operation `mov %ebx, %fs:$0x8` copies the register `%ebx` to the second entry (8 bytes) of the RaTTle.

4.5 Inter-Library Calls and Data

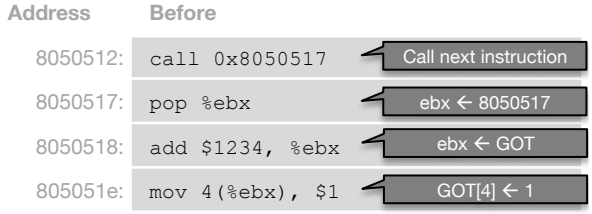
Control flow and access to data is not restricted to one library or executable. Naturally, these code elements frequently use each other's functions and data. Some operating systems, like Windows, use relocation information to directly patch the control flow so that it points into a library after it has been loaded. Linux, on the other hand, uses the procedure linkage table (PLT) to link calls to libraries with the advantage of lazy loading.[1] In contrast, we use an indirection through the RaTTle for every library call or access to global library data because this approach conceals the actual address of the loaded library and has only minor performance impact.

Inter-Library Data. Libraries can export data to be used by the executable main process or other shared libraries. Since it is known a priori which data is accessed in another library, each reference gets a place-holder in the GOT which can be accessed as described above. When the appropriate library is loaded by the loader, it automatically updates the GOT thanks to the relocation info pointing to this entry in the GOT.

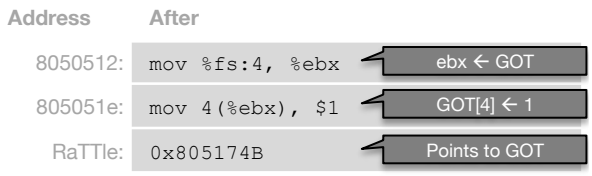
The following is an example of typical position-independent code that uses a GOT to access data: The code is first calling the next instruction, thereby pushing its own address as a return address to the stack. Following, this very address is popped off the stack to get the

[1] First, the PLT entries do not point to the actual procedure inside a library because it has not been loaded yet. Instead, they point to code that loads the library and then rewrites the PLT to link the call to the actual target procedure.

absolute address of the currently running code. The address of the GOT is calculated by adding a known offset.



When transforming this piece of code to PALACE, only the calculation of the GOT needs to be substituted. In this case, the three former instructions get compressed to a single instruction with segment override. Interestingly, this is a faster method of accessing the GOT than the currently used PC-relative addressing.



Inter-Library Calls. Inter-library calls are calls from one loaded library to another or from the main executable to a library. In theory, these calls are no different from a call within the same library or executable because the RaTTle can simply point to code in another library. However, in practice, this would require the RaTTle to reflect all possible combinations of loaded libraries. Therefore, we resort to a solution in which every loaded library brings its own RaTTle and an inter-library call acts as a trampoline that changes the segment selector `FS` to point to the corresponding RaTTle of another library prior to jumping into that library (see in Figure 7).

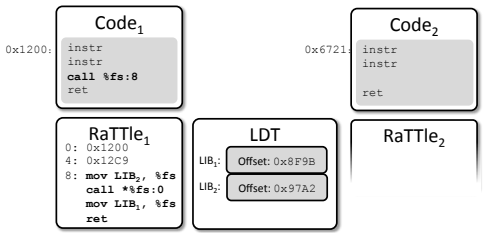


Figure 7: *Inter-Library Calls: Because the indices overlap, a new RaTTle needs to be set up before those calls.*

Please note the missing "*" in the `call %fs:8` of Figure 7, which means the RaTTle is not de-referenced rather than used as a trampoline. This trampoline then lets `FS` point to the index of the other library's RaTTle without the need to know the exact address. Suppose the function that we want to call is stored at index 0 in RaTTle_2, but RaTTle_1 is currently active. The code in Figure 7 first sets `FS` to point to RaTTle_2. RaTTle_2 is the second selector in the LDT. Hence, the trampoline code in RaTTle_1 assigns $10111_{bin} = 23$ to `FS`, which corresponds to a segment selector of "2" (see Appendix A). The trampoline code then jumps to index 0, which now corresponds to currently active RaTTle_2. Because the trampoline uses a `call` instruction to finally call into the other library, control flow returns to the trampoline where `FS` is restored to its former value.

4.6 Debugging

Debugging information augments the executable or library file with annotations describing which memory addresses correspond to which variables or lines of code. These stored addresses must be compatible with Oxymoron randomized addresses. Since Oxymoron is implemented as a static translation tool, the original debugging information needs to be translated as well. Currently Oxymoron supports the common DWARF [3] file format which can be read by the `gdb` or other debuggers. This way, it is possible to teach `gdb` the randomized addresses so that `gdb` can still step through the code, inspect variables etc. like for the non-randomized executable.

5 Evaluation

In this section, we evaluate the effectiveness of Oxymoron empirically as well as theoretically. In order to demonstrate the efficiency, we used the de-facto standard performance benchmark SPEC CPU2006 as well as micro benchmarks to measure cache hit/miss effects.

First, we inspect the security of the RaTTle itself to verify that it did not open the flood gates for other attack vectors. Then, we compare the slightly different randomization of memory pages that this solution entails to the more classical memory randomization solutions in order to get an understanding of the implied security.

5.1 Practical Security Evaluation

We tested our randomization solution against real-life vulnerabilities and exploits. The documented vulnerabilities `CVE-2013-0249` and `CVE-2008-2950` both allow arbitrary code execution by means of return-oriented programming [2]. `CVE-2013-0249` targets the `libcurl` library which handles web requests and is used in dozens of popular programs, including ClamAntiVirus, LibreOffice, and the Git versioning system. The exploit for this vulnerability is crafted in such a way that it triggers a buffer overflow in `libcurl` with the ability to overwrite a return address and ultimately execute a chain of ROP gadgets. The severity of this bug lies in the fact that it can be triggered remotely when `libcurl` accesses

a prepared resource that is under the control of the adversary. In order to test the exploit, we used the 'curl' downloader executable in version 7.28.1, which internally uses `libcurl`. We could successfully run arbitrary code by assembling ROP gadgets at our discretion. After curl had been rewritten to use Oxymoron, the exploit was no longer possible as the addresses that are needed to successfully mount the attack are unknown due to the randomization at every program start.

Similarly, the vulnerability `CVE-2008-2950` allows for arbitrary code reuse in the PDF library `poppler`, which is used by many popular programs such as LibreOffice, Evince and Inkscape. A specially prepared PDF file can trigger an arbitrary memory reference in the `poppler` library, ultimately leading to a code reuse attack. After our attacks against `pdftotext` using `libpoppler` 0.8.4 were successful, we applied Oxymoron. Since the memory address of the PALACE-protected process were no longer known, the exploit was rendered unsuccessful after applying Oxymoron to the pdftotext executable.

5.2 Security of the RaTTle

Because processes are protected by $W \oplus X$ (stack execution prevention), no code can be injected by an attacker. Hence, the only possibility is to reuse existing code. This existing (PALACE) code is littered with `%fs`-prefixed instructions that implicitly point to the RaTTle due to the sheer fact they incorporate a reference to `%fs`. However, the situation is identical to finding ROP gadgets in a classical program, as an attacker needs to know their randomized position in memory in order to chain them together. The fact that this address is not known to an attacker prevents the reuse of code. In fact, the probability of guessing a correct address is negligible (see subsection *"Theoretical Security Evaluation"*).

The RaTTle holds lots of random addresses and, at first glance, seems like a valuable target for an attacker. The security of the RaTTle originates from the fact that its address is unknown and that its content cannot be accessed. All `%fs`-instructions are mere replacements for control flow branches and as such only use the RaTTle as a layer of indirection without ever knowing the actual address of the landing position. If an `%fs`-instruction is a replacement for data access, the same holds true: The RaTTle is only used for indirect access of the actual data. In general, the x86 architecture does not support revealing addresses that segments point to. The only way to read the address is to parse the GDT or LDT which both reside in kernel space. To access the LDT, a user mode program needs to issue a special syscall. Even if a program would consist of ROP gadgets to issue this syscall, he would still need to know the addresses of the required ROP gadgets. So this can be reduced to finding special instructions that can be used as ROP gadgets. This has a negligible probability as explained in *"Theoretical Security Evaluation"*.

5.3 Enhanced Security of the RaTTle

It is possible to further enhance the security of the RaTTle by making it completely inaccessible. The segmentation principle of the x86 architecture allows to distinguish code access from data access. This way, it is possible to set up two different RaTTles, one for code going through `%fs` and one for data going through `%gs`. First of all, in a program without self-modifying code, there should be no instructions that read data using the `%fs` code segment selector. Even if there were, the processor would prohibit such access. Further, it is possible to move the RaTTle completely outside of the normal, otherwise flat[2] data segment (`%ds`). This results in the inability for code to ever access the RaTTle without using proper segment selectors, because it no longer resides in the accessible segment. This is an effective protection against leakage and disclosure attacks (see subsection *"Disclosure Attacks"*). Also, the call stack could be protected using this method. If return addresses are not saved on the regular stack, but rather on a side stack in a reserved area inside the RaTTle, there is no way for memory disclosure vulnerabilities to ever read return addresses and thus they cannot gain information about function addresses.

5.4 Theoretical Security Evaluation

In this subsection we elaborate on why the entropy of memory page granularity randomization is still sufficient for fine-grained randomization and why it is much higher than traditional ASLR.

First, we show that the entropy induced by a page-granular randomization is high enough in the sense that the adversary has only negligible probability of successfully guessing an address. We model the adversary's goal as mounting a code reuse attack against a running program consisting of the executable and its loaded libraries. Hence, his goal is to know the address of either a particular function f of interest (return-into-libc attack) or of several particular instructions $i_1 \dots i_k$ to build gadgets from (ROP attack). Since the contents of a memory page can be extracted from the executable file, the attacker can determine in which memory page the instruction in question resides. Therefore, the success of the adversary re-

[2] A flat segment is a segment that covers the entire address space, i.e. `0x00000000` to `0xFFFFFFFF` on a 32-bit system. This is the default for Windows, Linux and MacOS.

lies on the probability of knowing the address of a particular memory page.

Every memory page is assigned a random address at load-time. Thus, the first page can choose 1 out of n possible page-aligned address slots. The second 1 out of $n-1$ and so forth. For p total process pages to lay out in memory, this yields a total of $\frac{n!}{(n-p)!}$ combinations. The adversary's probability of correctly guessing one address is hence the reciprocal $\frac{(n-p)!}{n!}$. In a 32 bit address space, we have $n = 2^{19} = 524,288$ possible page addresses. The probability of guessing one page correctly therefore is 2^{-19}. That scenario is intuitively identical to ASLR which only randomizes the base address of the code. However, when finding ROP gadget chains, the page granularity drastically lowers the chance of success compared to ASLR because several pages have to be guessed correctly. For a 128 kB ($p = 32$ pages) executable to lay out in memory, the adversary's probability of guessing the correct memory layout therefore is:

$$Pr\left[Adv_{layout}\right] = \frac{(n-p)!}{n!} = \frac{(2^{19}-2^5)!}{2^{19}!} = 2^{-608}$$

Leakage Attacks in ASLR. A leakage vulnerability inadvertently reveals a valid, current address inside the running program. If the adversary additionally knows which object or function has been leaked, he knows the address of that object/function. In the case of ASLR, he can then infer the current addresses of all other objects or functions because ASLR has shifted the entire code segment in memory by changing its base address. Consequently, the relative distances between functions stay exactly the same.

To model the leakage attack, we assume the adversary exploits an existing leakage vulnerability thereby learning a valid address. We assume that this address depicts the beginning of a particular function that the adversary knows. That such a leaked address actually constitutes a function pointer is not very likely but here it models the best-case scenario for the adversary. Hence, the following calculations give a upper bound of success for an adversary.

More formally, the adversary has access to an oracle that can tell which function f has leaked and the adversary can use the leakage vulnerability to learn the current address of A_f of the function f. The adversary can then calculate their difference in memory by calculating their difference in the executable file. As their relative positions did not change in ASLR, the adversary can infer the current address of f' by calculating the difference to the leaked function f. In the case of traditional ASLR, the address of any function f' can be calculated with probability 1. Ultimately, the success probability of the adversary entirely depends on the likelihood of finding such a leakage vulnerability.

Leakage Attacks in Oxymoron. In our case of memory page granularity shuffling, the relative distance between functions varies in general since the code segment is not just shifted en bloc. For any leaked pointer f, there is a chance that it resides in the same memory pages as the desired function f'. For an equal distribution of f' in p pages, the likelihood of f' being in the same page as f is $\frac{1}{p}$. For a program of a total size of only one memory page (4kB), both functions f and f' must reside in the same memory page. Under the assumption that both functions are uniformly distributed, the probability for both to appear in the same memory page is $\frac{1}{p}$ for a program size of p pages. Hence

$$Pr[Adv^{PALACE}_{ret2libc}] \leq \frac{1}{p} \quad \text{and} \quad Pr[Adv^{PALACE}_{ROP}] \leq \frac{1}{p^k}$$

Disclosure Attack. We distinguish between a leakage and a disclosure vulnerability. A disclosure vulnerability allows an attacker to read arbitrary memory content given its address. Snow et al. proposed just-in-time code reuse, which showed that a disclosure vulnerability can significantly reduce the security of fine-grained memory randomization [26]. Just-in-time code reuse repeatedly exploits a memory disclosure vulnerability to map portions of a process' address space with the objective of reusing the so-discovered code in a malicious way. In a fine-grained randomization, the memory pages are scattered across the address space and scanning with arbitrary memory addresses is very likely to end up in unmapped memory. In order not to trap into unmapped memory, they rely on a leakage attack to learn a valid address and then start from this address by disassembling the code in order to follow control flow instructions. Even fine-grained randomization can be reversed using their technique by transitively following the control flow.

However, in our setting of PALACE code, no control flow branch can be followed by reading memory as such a branch only constitutes an offsets into the RaTTle. In order to resolve branches such as `call *%fs:4`, the attacker would need to know the address of the RaTTle or `%fs`, which is not possible, as alluded to earlier. The only chance an attacker has is to rely on a leakage vulnerability to get a valid address. If that address points to data it is useless to the attacker. If it points to code, the attacker can only use a disclosure vulnerability to get the contents of up to a whole memory page (4KB). Otherwise, he is likely to overrun the page and end up in unmapped memory which triggers a page fault that kills the program.

5.5 Effectiveness of Memory Page Sharing

To have a set basic programs one would typically find on a Linux machine, we used the *busybox* project, which incorporates 298 standard Linux commands. Those command line programs were started and their memory footprint was measured using `/proc/<PID>/maps`. On average, they mapped 14.9% more code pages than their unmodified original. Their data pages were unmodified. Only the RaTTle consumes memory (see Subsection 6.1). Compared to fine-grained memory randomization solutions that impede code page sharing, Oxymoron on average saves about 85% of program memory.

6 Performance Evaluation

To evaluate the efficiency of Oxymoron, we did not only use standard command line tools from busybox but conducted CPU benchmarks with PALACE-enabled programs using the de facto standard SPEC CPU2006 integer benchmark suite. All benchmarks were performed on an Intel Core i7-2600 CPU running at 3.4 GHz with 8 GB of RAM.

Static Translation Overhead. Before the executable and libraries can be shuffled in memory, they either need to be compiled with an PALACE-enabled compiler or they must be converted using static translation (cf. section 3). Even though the translation only needs to be performed once, it must be efficient. We measured the rewriting time for all benchmark programs of the Spec CPU suite. The rewriting process is not exactly linear, but on average achieves between 35,000 and 700,000 instructions per second. An overview of the timings of several programs is given in Table 1.

Benchmark	Total # of Instructions	Rewriting Time (s)
483.xalancbmk	1,111,779	4.321
403.gcc	942,244	3.667
471.omnetpp	238,978	0.316
400.perlbench	322,084	1.084
445.gobmk	226,661	6.744
464.h264ref	170,942	0.396
456.hmmer	54,582	0.116
458.sjeng	40,438	0.101
473.astar	32,502	0.032
401.bzip2	28,087	0.056
462.libquantum	15,788	0.024
429.mcf	12,268	0.024

Table 1: *Timings for static rewriting that needs to be done at least once. The total # of instructions include the executable and all its shared libraries.*

The number of instructions per benchmark reflect the total number of instructions from the executable file itself plus its dependent libraries. Note, that this measurement rewrites the entire C-library and other dependent libraries again for each benchmark and is hence slower than just translating the main executable.

Run-Time Overhead. The run-time overhead introduced by the translation through the RaTTle as well as the introduction of `jmp` instructions to connect pages (cf. section 3) is measured in Figure 8. The average run-time overhead of all benchmarks is only 2.7% for the PALACE code and 0.1% for the additionally needed chunking in memory page-sized pieces (4096 bytes).

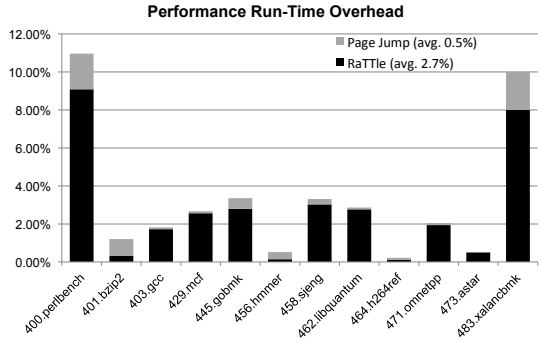

Figure 8: *SPEC CPU2006 integer benchmark results.*

Cache Miss Penalty. We also evaluated the cache effects of our randomization. This is important, since modern processors assume locality of code, which might be thwarted by wild jumping in the code due to the randomization. Keeping cache effects in mind, our implementation optimizes jumping behavior in order to optimize performance under real-life conditions. Our cache experiments showed that PALACE and the randomization have no measurable cache effect.

For this impact to be measured, we handcrafted code consisting of interdependent `add` instructions with a total length of one L1 cache line. These instructions are aligned in memory in such a way that they start at the beginning of a cache line and re-occur such that every cache set and every cache line is filled after execution. We inserted equidistant `jmp` instructions and measured the overhead of 100,000 runs on an Intel Core i7-2600 (32 KB L1 cache, 64 bytes per line). Our results show that the performance impact is not measurable up to every seventh instruction being a `jmp`. If every sixth instruction is a `jmp`, a negligible overhead of 0.4% is introduced. Our analysis of the `busybox` code showed that after translating it to PALACE, on average indeed every 6^{th} instruction was a branch or jump.

6.1 Memory and Instruction Overhead

Compared to a traditional program, the introduction of PALACE code replaced control flow branches with other, `%fs`-relative, instructions. For all SPEC2006 benchmark executables, on average 9% +-1.7% of all instructions are calls that needed to be replaced by indirections through the RaTTle. GOT indirect calls through the RaTTle are only 0.03% of all instructions.

Additionally, a PALACE binary executable file is slightly larger than a traditional executable file because each code page (4 KB) is a separate ASLR-enabled section in the executable file.

During run-time, the memory footprint also slightly increases because the RaTTle has to be kept in memory. Of course, this run-time memory usage is accompanied with the achieved goal of memory savings due to the sharing of code pages with other processes.

Encapsulating each memory page in a separate segment in the ELF file requires the allocation of one section header and one program header per page. A section header is 40 bytes and the ELF program header is 32 bytes which leads to an overhead of 72 bytes per 4096 byte memory page, or $\approx 1.76\%$. Figure 9 depicts both the increase of instructions due the static translation as well as the increase of the ELF section and program headers.

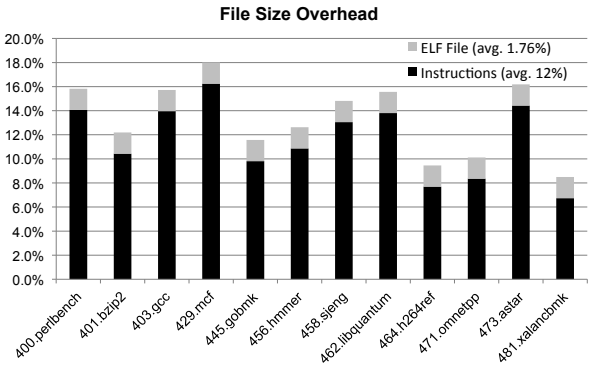

Figure 9: *Memory overhead after static translation.*

Run-Time. The size of the RaTTle depends on how many references the code has. If a target is referenced more then once, e.g., the GOT, only one index is saved in the RaTTle. For all files that belong to the SPECint CPU2006 benchmark, on average 19% of the code segment had to be added in the form of a RaTTle.

7 Related Work

Over the course of the last several years, code reuse attacks and their mitigation has been an ongoing cat and mouse game. Some of the code reuse mitigation techniques address the problem at its roots by preventing buffer overruns or by confining the control flow to the destined control-flow graph. Other mitigation techniques make it hard for the adversary to guess or brute-force addresses that are necessary for successful execution of malicious code.

In this section, we focus on approaches that use fine-grained memory randomization as a means to mitigate code reuse attacks and work that nullifies memory randomization or even fine-grained memory randomization.

One way to categorize fine-grained memory randomization solutions is by their implementation: There exist compiler-based solutions, static or load-time translations, and dynamic translations. Another category dimension is whether they randomize only once, every time the program starts, or even continuously during program execution.

Compiler-Based Solutions. If a program is not randomized, an adversary can learn the layout, i.e. addresses, of all functions and gadgets and hence use them in a ret2libc or ROP attack. The idea of compiler-based approaches is to randomize the layout of a program and to install differently randomized copies on different computers so that the program layout is not predictable for an adversary.

Cohen et al. [10] suggested compiling different versions of the same program. In a modern setting this technique can be applied within an AppStore to distribute individually randomized software. Similarly, Franz et al. [16, 19] have suggested automating this compiler process and generate a different version of a program for every customer. The authors suggest that app store providers integrate a multicompiler in the code production process. However, those approaches have several shortcomings: First, app store providers have no access to the app source code. This requires the multicompiler to be deployed on the developer side, who has to deliver possibly millions[3] of app copies to the app store. Second, the proposed scheme requires software update processes to correctly patch app instances that in turn differ from each other. Finally, the most severe drawback of compiler-based solutions is the fact that the diversified program remains unchanged until an update is provided, which increases the chance of an adversary compromising this particular instance over time.

[3] According to Gartner [4], the number of app downloads is about 102 billion in 2013.

Similar to Oxymoron is the idea of using a compiler-based solution to divide a shared library into even more fragments. Code Islands [30] follows this path and compiles groups of functions to several shared libraries instead of one shared library containing all the functions. These (potentially thousands of shared library files) are then put in a container whose format is understood by a modified loader which maps the libraries in the particular process. However, their solution needs a modified loader to support the proprietary format. Executables then need to load literally thousands of shared libraries, while each library constitutes a single function.

In contrast, Bhatkar et al. [8] presented a source code transformer and its implementation for x86/Linux. The main idea is to augment any source code with the capability of self-diversification for each run. In particular, features are added to the source code that allow the program to re-order its functions in memory in order to mitigate code reuse attacks. Their tool can also be applied to shared libraries if their source code is available. However, their solution induces a run-time overhead of 11% and apparently needs access to the source code.

Static Translation. Static translation reads an executable or shared library file from disk, disassembles it and transforms the instructions according to a predefined pattern within the executable file itself. Kil et al. [20] use static translation for their Address Space Layout Permutation (ASLP). ASLP performs function permutation without requiring access to source code. The proposed scheme statically rewrites ELF executables to permute all functions and data objects of an application. The presented scheme is efficient and also supports re-diversification for each run. However, only the functions themselves are permuted, not their content.

Pappas et al. proposed randomizing instructions and registers within a basic block to mitigate return-oriented programming attacks [21]. However, the proposed solution cannot prevent return-into-libc attacks (which have been shown to be Turing-complete [27]), since all functions remain at their original position.

Load-Time Translation. Load-time translation solutions are similar to static translation but apply the translation at load time in order for the processes to benefit from a re-randomization at each run. This can be achieved by several means, such as rewriting the binary file after it has been loaded but before execution [29, 13]. Such solutions usually suffer from the fact that each execution either needs a translation/rewriting phase each time a process is started or they need a prior static analysis phase [29].

Dynamic Translation. Dynamic translation leaves the original file untouched and does not apply binary rewriting but the program undergoes a *dynamic translation*, i.e. the instructions are transformed as they are executed. Dynamic translation is very similar to Just-in-Time (JIT) compilation but usually translates from and to the same instruction set architecture. For example, Bruening proposed the DynamoRIO framework in his PhD thesis [9]. DynamoRIO is able to perform run-time code manipulation. ILR (instruction location randomization) [18] randomizes the location of each single instruction in the virtual address space. For this, a program needs to be analyzed and re-assembled during a static analysis phase. This is why ILR induces a significant performance overhead (on average 13%), and suffers from a high space overhead, i.e., the rewriting rules reserve on average 104 MB for only one benchmark of the SPEC CPU benchmark suite. For direct calls, ILR can only randomize the return address in 58% of the calls, meaning that for a large number of return instructions, ILR needs to do a live translation for un-randomized return addresses to runtime addresses.

Constant Re-Randomization. To the best of our knowledge, there are only two papers that actually implemented and benchmarked re-randomization. Curtsinger et al. [11] have implemented an LLVM compiler modification that injects code, which adds the functionality to re-randomize the address of functions every 500 ms. According to [11], their overhead of code, heap and stack (re-)randomization is 7%.

Giuffrida et al. [17] changed the Minix microkernel to re-randomize itself every x seconds. This is achieved by maintaining the intermediate language of the LLVM compiler for the compiled kernel modules. However, this procedure has a significant run-time overhead of 10% for a randomization every $x = 5$ seconds or even 50% overhead when applied every second.

Common Shortcomings and Nullification. All the related work on fine-grained memory randomization has in common that they either do not randomize shared libraries, or if they do, the difference introduced in the shared libraries prohibits code sharing.

Furthermore, it is unclear whether fine-grained memory randomization alone is enough to protect against code reuse attacks. Recently, Snow et al. [26] showed that given a memory disclosure vulnerability it is possible to assemble ROP gadgets on-demand without knowing the layout or randomization of a process. They explore the address space of the vulnerable process step by step by following the control flow from an arbitrary start position. After they have discovered enough ROP gadgets

they compile the payload so that it incorporates the actual current addresses that were discovered on-site.

Snow et al. also proposed potential mitigations of their own attack. However, the proposed solutions are either very specific to their heap spraying exploitation or are as general and slow as frequent re-randomization of a whole process. The latter is not even secure if the attack takes place between two randomization phases.

To the best of our knowledge, in this paper we present the first solution that addresses both problems: (1) It is secure against the new just-in-time ROP by Snow et al. (2) It profits from code sharing despite secure randomization.

8 Discussion

In this section we would like to discuss the general applicability of Oxymoron but also its limitations.

The PALACE code presented in this paper only relies on segmentation as an additional hardware feature. Hence, Oxymoron also works in virtualized environments. We successfully tested Oxymoron in software and hardware virtual machines as well as on a para-virtualized Linux using the Xen hypervisor.

The solution presented herein was implemented for the 32 bit x86 architecture. While its 64 bit successor has limited supported for segmentation, the necessary offset functionality of `%fs` segment registers is still available. However, in 64 bit mode, segments do no longer support to set a limit, which makes the RaTTle accessible as data if its address is known.

Another interesting avenue that we did not investigate is just-in-time (JIT) compiled code, such as the Java runtime environment. Those JIT-compilers would need to be adapted in order to emit PALACE-enabled code, otherwise the traditional code they emit is not protected.

9 Conclusion

We presented a novel technique for fine-grained memory randomization that still allows sharing of code among processes. This makes fine-grained memory randomization practical as the memory overhead is significantly reduced in contrast to other randomization solutions. Oxymoron is effective, i.e., code reuse attacks can be mitigated, memory leakage vulnerabilities can no longer be used to revert the randomization, and we presented the first solution to be secure against just-in-time code reuse attacks. The randomized addresses are protected by hardware means, which is an unprecedented security level with a run-time overhead of only 2.7%.

An interesting side effect of our PALACE code is that accessing the Global Offset Table (GOT) uses fewer instructions than the state-of-the-art technique of using PC-relative addressing. Maybe our method could be a slightly faster alternative for accessing the GOT.

A LDT Selector Bits

The actual value that a segment selector must hold is not merely an index to the GDT/LDT, but is defined by the architecture set as follows:

Bits 15 - 3	Bit 2	Bit 1 - 0
Number of the entry	0=GDT, 1=LDT	Privilege Level

As user mode is in Ring 3, bits 0 and 1 must be set to 11_{bin}. The use of the LDT forces us to set bit 2 to 1_{bin}. The index "0" of the LDT yields a valid value for the segment selector of 111_{bin} or 7 in decimal.

Password Managers: Attacks and Defenses

Abstract

We study the security of popular password managers and their policies on automatically filling in Web passwords. We examine browser built-in password managers, mobile password managers, and 3rd party managers. We observe significant differences in autofill policies among password managers. Several autofill policies can lead to disastrous consequences where a remote network attacker can extract multiple passwords from the user's password manager without any interaction with the user. We experiment with these attacks and with techniques to enhance the security of password managers. We show that our enhancements can be adopted by existing managers.

1 Introduction

With the proliferation of Web services, ordinary users are setting up authentication credentials with a large number of sites. As a result, users who want to setup different passwords at different sites are driven to use a password manager. Many password managers are available: some are provided by browser vendors as part of the browser, some are provided by third parties, and many are network based where passwords are backed up to the cloud and synced across the user's devices (such as Apple's iCloud Keychain). Given the sensitivity of the data they manage, it is natural to study their security.

All the password managers (PMs) we examined do not expect users to manually enter managed passwords on login pages. Instead they automatically fill-in the username and password fields when the user visits a login page. Third party password managers use browser extensions to support autofill.

In this paper we study the autofill policies of ten popular password managers across four platforms and show that all are too loose in their autofill policies: they autofill the user's password in situations where they should not thereby exposing the user's password to potential attackers. The results can be disastrous: an attacker can extract many passwords from the user's password manager without the user's knowledge or consent as soon as the user connects to a rogue WiFi network such as a rogue router at a coffee shop. Cloud-based password syncing further exacerbates the problem because the attacker can potentially extract user passwords that were never used on the device being attacked.

Our results. We study the security of password managers and propose ways to improve their security.

- We begin with a survey of how ten popular password managers decide when to autofill passwords. Different password managers employ very different autofill policies, exposing their users to different risks.

- Next, we show that many corner cases in autofill policies can lead to significant attacks that enable remote password extraction without the user's knowledge, simply by having the user connect to a rogue router at a coffee shop.

- We believe that password managers can help strengthen credential security rather than harm it. In Section 5 we propose ways to strengthen password managers so that users who use them are more secure than users who type in passwords manually. We implemented the modifications in the Chrome browser and report on their effectiveness.

We conclude with a discussion of related work on password managers.

An example. We give many examples of password extraction in the paper, but as a warm-up we present one example here. Consider web sites that serve a login page over HTTP, but submit the user's password over HTTPS (a setup intended to prevent an eavesdropper from reading the password but actually leaves the site vulnerable). As we show in Section 4, about 17% of the Alexa Top 500 websites use this setup. Suppose a user, Alice, uses a password manager to save her passwords for these sites

At some point later, Alice connects to a rogue WiFi router at a coffee shop. Her browser is directed to a landing page that asks her to agree to the terms of service, as is common in free WiFi hotspots. Unbeknownst to Alice, the landing page (as shown in Figure 1) contains multiple invisible iFrames pointing to the login pages of the websites for which Alice has saved passwords. When the browser loads these iFrames, the rogue router injects JavaScript into each page and extracts the passwords autofilled by the password manager.

This simple attack, without any interaction with the user, can automatically extract passwords from the password manager at a rate of about ten passwords per second. Six of the ten password managers we examined were vulnerable to this attack. From the user's point of view, she simply visited the landing page of a free WiFi hotspot. There is no visual indication that password extraction is taking place.

Figure 1: A sample landing page of a rogue WiFi hotspot containing invisible iFrames to the target sites. Note that the iFrames are actually invisible to the user and shown here only for clarity.

2 Password managers: a survey

We begin with a detailed survey of the autofill policies implemented in widely deployed password managers. The password managers we survey include:

- **Desktop Browser PMs**: Google Chrome 34, Microsoft Internet Explorer 11, Mozilla Firefox 29, and Apple Safari 7.
- **3rd Party PMs**: 1Password [1], LastPass [5], Keeper [7], Norton IdentitySafe [6], and KeePass [4]. All of these besides KeePass provide browser extensions that support password field autofill.
- **iOS PMs**: Mobile Safari's password manager syncs with the desktop version of Safari through Apple's iCloud Keychain synchronization service. Since mobile Safari does not support extensions, 3rd Party PMs are separate applications with their own built-in web browser. In addition to Mobile Safari, we survey password managers in Google Chrome, 1Password, and LastPass Tab.
- **Android PMs**: the default Android browser and Chrome.

All these password managers offer an "autofill" functionality, wherein the password manager automatically populates the username and password fields within the user's web browser. We divide autofill strategies into two broad categories:

- **Automatic autofill:** populate username and password fields as soon as the login page is loaded without requiring any user interaction. Password managers that support automatic autofill include Chrome (all platforms), Firefox, Safari, LastPass, Norton IdentitySafe, and LastPass Tab.
- **Manual autofill:** require some user interaction before autofilling. Types of interaction include clicking on or typing into the username field, pressing a keyboard shortcut, or pressing a button in the browser. Password managers that always require manual interaction include 1Password, Keeper, and KeePass.

Internet Explorer 11 uses a hybrid approach: it automatically autofills passwords on pages loaded over HTTPS, but requires user interaction on pages loaded over HTTP. We show in Section 4 that even this conservative behavior still enables some attacks.

Some password managers require manual interaction for autofill in specific situations:

- Chrome requires manual interaction if the password field is in an iFrame.
- Chrome can read passwords stored in Mac OS X's system-wide keychain, but will not automatically autofill them until they have been manually selected by the user at least once.
- The first time Safari or Chrome on Mac OS X access a password in the system keychain, a system dialog requests permission from the user. If the user chooses "Always Allow", this dialog will not be shown again and the password will automatically autofill in the future. This dialog does not appear if the password was synchronized from another device using iCloud Keychain.
- LastPass and Norton IdentitySafe provide non-default configuration options to disable automatic autofill. In this paper we only discuss the default configurations for these password managers.

Platform	Password manager	Same protocol and action	Different protocol	Different form action on load	Different form action on submit	auto-complete = "off"	Broken HTTPS
Mac OS X 10.9.3	Chrome 34.0.1847.137	Auto	No Fill	Manual	Auto	Auto	No Fill
	Firefox 29.0.1	Auto	No Fill	None	Auto	No Fill	Auto
	Safari 7.0.3	Auto	No Fill	Auto	Auto	Auto	Auto
Safari ext.	1Password 4.4	Manual	Manual	Manual	Manual	Manual	Manual
Safari ext.	LastPass 3.1.21	Auto	Manual	Warning	Auto	Auto	Auto
Safari ext.	Keeper 7.5.26	Manual	Manual	Manual	Manual	Manual	Manual
Windows 8.1 Pro	IE 11.0.9600.16531	Auto/Man	No Fill	Auto/Man	Auto/Man	Auto/Man	Manual
	KeePass 2.24	Manual	Manual	Manual	Manual	Manual	Manual
IE addon	IdentitySafe 2014.7.0.43	Auto	Auto	Auto	Auto	Auto	Auto
iOS 7.1.1	Mobile Safari	Auto	No Fill	Auto	Auto	No Fill	Auto
	1Password 4.5.1	Manual	Manual	Manual	Manual	Manual	Manual
	LastPass Tab 2.0.7	Auto	Manual	Auto	Auto	Auto	Auto
	Chrome 34.0.1847.18	Auto	No Fill	No Fill	Auto	No Fill	Auto
Android 4.3	Chrome 34.0.1847.114	Auto	No Fill	No Fill	Auto	Auto	No Fill
	Android Browser	Auto	No Fill	Auto	Auto	No Fill	Auto

Table 1: Password Manager autofill behavior (automatic autofill, manual autofill, or no fill), depending on the protocol (http/https), autocomplete attribute, form action used on the current page relative to the protocol, and form action used when the password was saved. *Manual autofilling* refers to autofilling a password after some user interaction, such as a click or tap on one of the form fields. *No fill* means that no autofilling of passwords takes place. The second to last column refers to autofill behavior when the password field's autocomplete attribute is set to "off". The last column refers to autofill behavior for a login page loaded over a bad HTTPS connection.

2.1 Autofill policies

Next, we ask what happens when the PM is presented with a login page that is slightly different from the login page at the time the password was saved. Should the PM apply autofill or not? Different PMs behave differently and we survey the different policies we found. Table 1 summarizes some of our findings.

The domain and path. All password managers we tested allow passwords to be autofilled on any page within the same domain as the page from which the password was originally saved. For example, a password originally saved on `https://www.example.com/aaa.php` would be filled on `https://www.example.com/bbb.php`. This allows autofill to function on sites that display the login form on multiple pages, such as in a page header visible on all pages. It also allows autofill after a site redesign that moves the login form.

This feature means that an attacker can attack the password manager (as in Section 4) on the *least-secure* page within the domain. It also means that two sites hosted on the same domain (ie, `example.edu/~jdoe` and `example.edu/~jsmith`) are treated as a single site by the password manager.

Protocol: HTTP vs. HTTPS. Suppose the password was saved on a login page loaded over one protocol (say, HTTPS), but the current login page is loaded over a different protocol (say, HTTP)? All other elements of the URL are the same, including the domain and path. Should the password manager autofill the password on the current login page?

Chrome, Safari, Firefox, and Internet Explorer all refuse to autofill if the protocol on the current login page is different from the protocol at the time the password was saved. However, 1Password, Keeper, and LastPass all allow autofill after user interaction in this case. Note that LastPass normally uses automatic autofill, so this downgrade to manual autofill on a different protocol was implemented as a conscious security measure. Norton IdentitySafe does not pay attention to the protocol. It automatically autofills a password saved under HTTPS on a page served by HTTP. As we show later on, any form of autofilling, manual or not, is dangerous on a protocol change.

Modified form action. A form's action attribute specifies where the form's contents will be sent to upon submission.

```
<form action="example.com" method="post">
```

One way an attacker can steal a user's password is to change the action on the login form to a URL under the

attacker's control. Therefore, one would expect password managers to not autofill a login form if the form's action differs from the action when the password was first saved.

We consider two different cases. First, suppose that at the time the login page is loaded the form's action field points to a different URL than when the password was first saved. Safari, Norton IdentitySafe and IE (on HTTPS pages) nevertheless automatically autofill the password field. Desktop Chrome and IE (on HTTP pages) autofill after some manual interaction with the user. LastPass asks for user confirmation before filling a form whose action points to a different origin than the current page.

Second, suppose that at the time the login page is loaded the form's action field points to the correct URL. However, JavaScript on the page modifies the form action field so that when the form is submitted the data is sent to a different URL. All of the password managers we tested allow an autofilled form to be submitted in this case even though the password is being sent to the wrong location. We discuss the implications of this in Section 4 and discuss mitigations in Section 5.

Password managers without automatic autofill require user interaction before filling the form, but none give any indication to the user that the form's action does not match the action when the credentials were first saved. Since a form's action is normally not visible to the user, there is no way for the user to be sure that the form was submitting to the place the user intended.

The effects of the action attribute on autofill behavior is captured in the third and fourth columns of Table 1.

Autocomplete attribute A website can use the *autocomplete* attribute to suggest that autocompletion be disabled for a form input [3]:

```
<input autocomplete="off" ... >
```

We find that Firefox, Mobile Safari, the default Android Browser, and the iOS version of Chrome respect the autocomplete attribute when it is applied to a password input. If a password field has its autocomplete attribute set to "off", these password managers will neither fill it nor offer to save new passwords entered into it. All of the other password managers we tested fill the password anyway, ignoring the value of the autocomplete attribute. LastPass ignores the attribute by default, but provides an option to respect it.

Once the password manager contains a password for a site, the autocomplete attribute does not affect its vulnerability to the attacks presented in this paper. As described in Section 4, in our setting, the attacker controls the network and can modify the login form to turn the password input's autocomplete attribute on even if the victim website turns it off.

In supporting browsers, the autocomplete attribute can be used to prevent the password from being saved at all. This trivially defends against our attacks, as they require a saved password. However, it is not a suitable defense in general due to usability concerns. A password manager that doesn't save or fill passwords will not be popular amongst users.

Broken HTTPS behavior. Suppose the password was saved on a login page loaded over a valid HTTPS connection, but when visiting this login page at a later time the resulting HTTPS session is broken, say due to a bad certificate. The user may choose to ignore the certificate warning and visit the login page regardless. Should the password manager automatically autofill passwords in this case? The desktop and Android versions of Chrome refuse to autofill passwords in this situation. IE downgrades from automatic to manual autofill. All other password managers we tested autofill passwords as normal when the user clicks through HTTPS warnings. As we will see, this can lead to significant attacks.

Modified password field name. All autofilling password managers, except for LastPass, autofill passwords even when the password element on the login page has a `name` that differs from the name present when the password was first saved. Autofilling in such situations can lead to "self-exfiltration" attacks, as discussed in Section 5.2.1. LastPass requires manual interaction before autofilling a password in a field whose name is different from when the password was saved.

2.2 Additional PM Features

Several password managers have the following security features worth mentioning:

iFrame autofill. Norton IdentitySafe, Mobile Safari and LastPass Tab do not autofill a form in an iFrame that is not same-origin to its parent page. Desktop Chrome requires manual interaction to autofill a form in an iFrame regardless of origin. Chrome for iOS and the Android browser will never autofill an iFrame. Firefox, Safari, and Chrome for Android automatically autofill forms in iFrames regardless of origin.

Safari and Mobile Safari will only autofill a single login form per top-level page load. If a page, combined with all of its iFrames, has more than one login form, only the first will be autofilled.

We discuss the impact of these policies on security in Section 4.

Visibility. Norton IdentitySafe does not automatically autofill a form that is invisible because its CSS display attribute is set to "none" (either directly or inherited from a parent). However, it *will* automatically autofill a form with an opacity of 0. Therefore, this defense does not enhance security.

Autofill method. KeePass is unique amongst desktop password managers in that it does not integrate directly with the browser. Instead, it can "autotype" a sequence of keystrokes into whatever text field is active. For most login forms, this means it will type the username, the Tab key, the password, then the Enter key to populate and submit the form.

Autofill and Submit. 1Password, LastPass, Norton IdentitySafe, and KeePass provide variants of "autofill and submit" functionality, in which the password managers not only autofills a login form but also automatically submits it. This frees the user from interacting with the submit button of a login form and thus makes autofill more convenient for the user.

3 Threat Model

In the next section we present a number of attacks against password managers that extract passwords from all the managers we examined. First, we define the attackers capabilities and goals. We only consider active man-in-the-middle network attackers i.e. we assume that the adversary can interpose and modify arbitrary network traffic originating from or destined to the user's machine. However, unlike standard man-in-the-middle attacks, we do not require the user to log into any target websites in the presence of the attacker. Instead, the setup consists of two phases:

First, the user logs in to a number of sites and the attacker cannot observe or interfere with these logins. The user's password manager records the passwords used for these logins. For password managers that support syncing of stored passwords across multiple machines (e.g., Apple's iCloud KeyChain), users may even carry out this step on an altogether different device from the eventual victim device.

At a later time the user connects to a malicious network controlled by the attacker, such as a rogue WiFi router in a coffee shop. The attacker can inject, block, and modify packets and its goal is to extract the passwords stored in the user's password manager without any action from the user.

We call this type of attacker the evil coffee shop attacker. These attacks require only temporary control of a network router and are much easier and thus more likely to happen in practice. We show that even such weak man in the middle attackers can leverage design flaws in password managers to remotely extract stored passwords without the user logging into any website.

The attacker has no software (malware) installed on the user's machine. We only assume the presence of a password manager acting in the context of a web browser.

4 Remote extraction of passwords from password managers

We show that an evil coffee shop attacker can extract passwords stored in the user's password manager. In many of our attacks the user need not interact with the victim web site and is unaware that password extraction is taking place. We discuss defenses in Section 5.

4.1 Sweep attacks

Sweep attacks take advantage of automatic password autofill to steal the credentials for multiple sites at once without the user visiting any of the victim sites. For password managers backed by a syncing service (such as Apple's iCloud Keychain) the attacker can extract site passwords even if the user never visited the site on that device. These attacks work in password managers that support automatic autofill, highlighting the fundamental danger of this feature.

Sweep attacks consist of three steps. First, the attacker makes the user's browser visit an arbitrary vulnerable webpage at the target site without the user's knowledge. Next, by tampering with network traffic the attacker injects JavaScript code into the vulnerable webpage as it is fetched over the network using one of the methods described in Section 4.2. Finally, the JavaScript code exfiltrates passwords to the attacker using the techniques in Section 4.3.

In the sweep attacks we implemented, the user connects to a WiFi hotspot controlled by the attacker. When the user launches the browser, the browser is redirected to a standard hotspot landing page asking for user consent to standard terms of use. This is common behavior for public hotspots. Unbeknownst to the user, however, the landing page contains invisible elements that implement the attack.

iFrame sweep attack. Here the innocuous hotspot landing page contains invisible iFrames pointing to the arbitrary pages at multiple target sites. When the browser loads these iFrames, the attacker uses his control of the router to inject a login form and JavaScript into each iFrame using the methods described in Section 4.2. As we will see, injecting a login form and JavaScript is not

difficult and can be done in several different ways. All that is needed is *some* vulnerable page on the target site. It is especially easy for sites that serve their login page over HTTP (but submit passwords over HTTPS), which is a common setup discussed in the next section.

As each iFrame loads, the password manager will automatically populate the corresponding password field with the user's password. The injected JavaScript in each iFrame can then steal and exfiltrate these credentials.

Our experiments show that this method can extract passwords, unbeknownst to the user, at a rate of about ten passwords per second. To prevent the user from clicking through the landing page before the attacks are done, the landing page includes a JavaScript animated progress bar that forces the user to wait until the attacks complete.

We also find that the password extraction process can be made more efficient by arranging the iFrames in a hierarchical structure instead of adding one iFrame to the top-level page for each target website. Adding all the iFrames to the top-level page would create large increases in both the amount of traffic on the network and the amount of memory used by the victim's browser. Hierarchical arrangement of the iFrames can avoid such issues. The top-level iFrame contains most of the code for the attack and dynamically spawns child frames and navigates them to the target pages. This technique allows the iFrames to load asynchronously and thus ensures that network and memory usage remain reasonable for the duration of the attack.

Chrome (all platforms) is the only automatic autofill password manager that is not vulnerable to the iFrame-based attack, because they never automatically autofill passwords in iFrames. All the other automatic autofill password managers are vulnerable to this attack. Even though the autofill policies of Norton IdentitySafe, Safari, Mobile Safari, and LastPass Tab described in Section 2.2 restrict the number of passwords that can be stolen in a single sweep to 1, they remain vulnerable.

Window sweep attack. A variant of the sweep attack uses windows instead of invisible iFrames. If the attacker can trick users into disabling their popup blocker (e.g., by requiring a window to open before the user can gain access to the WiFi network), the landing page can open each of the victim pages in a separate window. This is more noticeable than the iFrame-based approach, but the JavaScript injected into each victim page can disguise these windows to minimize the chances of detection. Techniques for disguising the windows include minimizing their size, moving them to the edge of the screen, hiding the pages' contents so that they appear to the user as blank windows, and closing them as soon as the password has been stolen.

Nearly all automatic autofill password managers, including desktop Chrome, are vulnerable to the window-based attack. Only LastPass Tab is not vulnerable, as it does not support popup windows at all. Hence, although iFrames make the sweep attack easier, they are not required.

Redirect sweep attack. A redirect sweep attack enables password extraction without any iFrames or separate windows. In our implementation, once the user connects to a network controlled by the attacker and requests an arbitrary page (say, a.com), the network attacker responds with an HTTP redirect to some vulnerable page on the target site (say, b.com). The user's browser receives the redirect and issues a request for the page at b.com. The attacker allows the page to load, but injects a login form and JavaScript into the page, as described in Section 4.2. The injected JavaScript disguises the page (for example, by hiding its body) so that the user does not see that b.com is being visited.

When the user's browser loads the page from b.com, the vulnerable password manager will automatically autofill the login form with the credentials for b.com, which the injected JavaScript can then exfiltrate. Once done, the injected JavaScript redirects the user's browser to the next victim site, (say c.com) and exfiltrates the user's password at c.com in the same way. When sufficiently many passwords have been exfiltrated the attacker redirects the user's browser to the original page requested by the user (a.com).

This attack leaves small indications that password extraction took place. While the attack is underway the user's address bar will display the address of the attacked site, and the attacked site will remain in the user's history. However, as long as the body of the page itself is disguised, most users will not notice these small visual clues.

All of the automatic autofill password managers we tested were vulnerable to this attack.

Summary. Table 2 describes which password managers are vulnerable to these sweep attacks.

Attack amplification via password sync. Most password managers offer services that synchronize users' passwords between different devices. These password synchronization services can potentially result in password extraction from devices without them ever having visited the victim site.

Suppose the user's password manager syncs between their desktop and tablet, and will automatically autofill a password synced from another device without user in-

Platform	Password Manager	iFrame sweep	Window sweep	Redirect sweep

Table 2: Vulnerability to sweep attacks. **+** indicates vulnerability without restriction. **HTTPS** indicates vulnerability only on pages served over HTTPS. **Single** indicates a single site is vulnerable per top-level page load. **SO** indicates vulnerability when the page containing the iFrame is same-origin with the target page in the iFrame.

teraction. Suppose further that the site c.com is vulnerable to network attacks and thus to the attacks described above. The user is careful and only ever visits c.com on their desktop, which never leaves the user's safe home network. However, when the user connects their tablet to the attacker's WiFi network at a coffee shop, the attacker can launch a sweep attack on the user's tablet and extract the user's password for c.com even though the user has never visited c.com on their tablet.

We tested Apple's iCloud Keychain, Google Chrome Sync, Firefox Sync, and LastPass Tab, and found all of them to be vulnerable to this attack. In general, any password manager that automatically autofills a password synced from another device will be vulnerable to this type of attack amplification. Therefore, the security of any password manager is only as strong as the security of the weakest password manager it syncs with.

4.2 Injection Techniques

Sweep attacks rely on the attacker's ability to modify a page on the victim site by tampering with network traffic. The attacks are simplest when the vulnerable page is the login page itself. However, any page that is same-origin with login page is sufficient, as all password managers associate saved passwords with domains and ignore the login page's path. The attacker can inject a login form into any page in the origin of the actual login page and launch a password extraction attack against that page. We list a few viable injections techniques.

HTTP login page. Consider a web site that serves its login page over HTTP, but submits the login form over HTTPS. While this setup protects the user's password from eavesdropping when the form is submitted, a coffee shop attacker can easily inject the required JavaScript into the login form at the router and mount all the sweep attacks discussed in the previous section.

Clearly serving a login form over HTTP is bad practice because it exposes the site to SSLstrip attacks [33]. However extracting passwords via SSLstrip requires users to actively enter their passwords while connected to the attacker's network and visiting the victim page. In contrast, the sweep attacks in the previous section extract passwords without any user interaction.

To test the prevalence of this setup — a login page loaded over HTTP, but login form submitted over HTTPS — we surveyed Alexa Top 500 sites (as of October 2013) by manually visiting them and examining their login procedures. Of the 500 sites surveyed, 408 had login forms. 71 of these 408 sites, or 17.40%, use HTTP for loading the login page, but HTTPS for submitting it. Some well known names are on this list of 71 sites, including `ask.com`, `godaddy.com`, `reddit.com`, `huffingtonpost.com`, and `att.com`.

Additionally, 123 (or 30.15%) of the sites used HTTP both for loading the login page and for submitting it. This setup is trivially vulnerable to eavesdropping, but a vulnerable password manager increases this vulnerability by removing the need for a human to enter their password. For the purposes of our attacks, these sites can be thought of as an especially vulnerable subclass of sites with a login form served over HTTP.

Passwords for all these vulnerable websites can be easily extracted from an autofilling password manager using the sweep attacks in the previous section. One could argue that all these sites need to be redesigned to load and submit the login page over HTTPS. However, until that is done there is a need to strengthen password managers to prevent these attacks. We discuss defenses in Section 5.

Embedded devices I. Many embedded devices serve their login pages over HTTP by default because the channel is assumed to be protected by a WiFi encryption protocol such as WPA2. Indeed, Gourdin et al. report that the majority of the embedded web interfaces still use HTTP [26]. Similarly, internal servers in a corporate network may also serve web login pages over HTTP because access to these servers can only be done over a Virtual Private Network (VPN).

Sweep attacks are very effective against these devices: the password manager autofills the password even when the underlying network connection is insecure. By injecting JavaScript into the HTTP login page as above, a coffee shop attacker can extract passwords for embedded devices and corporate servers that the user has previously interacted with.

Embedded Devices II. Some home routers serve their login pages over HTTPS, but use are self-signed certificates. An attacker can purchase a valid certificate for the same common name as the router's [38] or generate its own self signed certificate. When the user's machine connects to the attacker's network, the attacker can spoof the user's home router by presenting a valid certificate for the router's web site. This allows the attacker to mount the sweep attack and extract the user's home router password.

Broken HTTPS. Consider a public site whose login page is served over HTTPS. In Section 2 we noted that many password managers that autofill passwords automatically do so even when the login page is loaded over a broken HTTPS connection, say due to a bad certificate. This can be exploited in our redirect sweep attack: when the browser is redirected to the victim site, the attacker serves the modified login page using a self signed cert for that site. This modified login page contains a login form and the JavaScript needed to exfiltrate the user's password once it is autofilled by the password manager.

These self signed certs will generate HTTPS warning in the browser, but if the redirect sweep attack happens as part of the process of logging on to the hotspot, the user is motivated to click through the resulting HTTPS warning messages. As a result the attacker can extract user passwords from the password manager, even for sites where the login page is served over HTTPS.

Indeed, several prior works have found that users often tend to click through HTTPS warnings [43, 8]. The user may decide to click through the warning and visit the site anyway, but not enter any sensitive information. Nevertheless, the user's password manager autofills the password resulting in password extraction by the attacker, regardless of the user's caution. All of the password managers we tested fill passwords even when the user has clicked through an SSL warning, with the exception of the desktop and Android versions of Chrome.

Active Mixed Content. Any HTTPS webpage containing active content (e.g., scripts) that is fetched over HTTP is also a potential vector. If rendering active mixed content is enabled in the user's browser, any HTTPS page containing active mixed content is vulnerable to injection. Chrome, Firefox, and IE block active mixed content by default but provide a user option to enable it. Safari, Mobile Safari, and the Android stock browser allow active mixed content to be fetched and executed without any warnings. Several types of active mixed content, especially those processed by browser plugins, are harder to block. For example, embedding a Shockwave Flash (SWF) file over HTTP if not blocked correctly can be used by a network attacker to inject arbitrary scripts [30].

XSS Injection. A cross-site scripting vulnerability in a page allows the attacker to inject JavaScript to modify the page as needed [24]. XSS vulnerabilities are listed as one of the most common web vulnerabilities in 2013 internet security threat report by Symantec [20]. If an XSS vulnerability is present on *any* page of the victim site, the sweep attacks will work even if the site's login page is served over HTTPS. For example, the attacker simply includes an iFrame or a redirect on the malicious hotspot landing page that links to the XSS page. The link uses the XSS vulnerability to inject the required login form and JavaScript into the page.

Furthermore, an XSS vulnerability allows for a weaker threat model than our coffee shop attacker. An ordinary web attacker can trick the user into visiting his site, then launch the attack through the XSS vulnerability. This style of attack requires no access to the user's network and has been suggested previously by RSnake [37] and Saltzman et al. [40].

Leftover Passwords. The user's password manager may contain leftover passwords from older, less secure versions of a site. An attacker could spoof the old site to steal the leftover password. Unless the user is proactive about removing older passwords, updating the security of the site does not protect the domain from this type of

attack. For example, if a user's password manager contained a password for Facebook from before its switch to HTTPS, an attacker could spoof an HTTP Facebook login page to steal the password.

4.3 Password Exfiltration

In the previous section we referred to JavaScript that exfiltrates the user's password once it is autofilled by the password manager. Once the password manager has autofilled the login form, the attacker must be able to access the filled-in credentials and send them to a server under its control. We briefly describe two methods for accomplishing this.

4.3.1 Method #1: Stealth

Using stealth exfiltration, the attacker waits until the login form is populated with the user's credentials automatically by a password manager, then steals the password by loading an attacker controlled page in an invisible iFrame and passing the credentials as parameters. The following simple JavaScript does just that and works with all password managers we tested:

```
function testPassword() {
 var password =
        document.forms[0].password.value;
 if(password != "") {
  var temp = document.createElement("div");
  temp.innerHTML +=
        "<iFrame src=\""+ attacker_addr +
        "?password=" + password +
        "\" style=\"display:none;\" />";
  document.body.appendChild(temp);
  clearInterval(interval);
}}
interval = setInterval(testPassword, 50);
```

4.3.2 Method #2: Action

An HTML form's "action" is the URL to which the form's data will be submitted. The attacker can modify a login form's action attribute so that it submits to an attacker-controlled site, thereby leaking the user's credentials to the attacker. If the attacker redirects the user's browser back to the real action, the user will not notice the change.

Automatic autofill password managers populate password forms when the page first loads. The attacker can then use injected JavaScript to change the action, submit the form and steal the password. If the login page is loaded in an iFrame or if it is rendered invisible, the users will not even realize that a login form was submitted. The following simple code does just that:

```
changer = function() {
  document.forms[0].action = attacker_addr;
  document.forms[0].submit();   }
setTimeout(changer, 1000);
```

In section 2.1 we showed that password managers that automatically autofill passwords do so on page load and show no warning to the user when the submitted form action differs from the action when the password was first saved. Thus, all password managers with automatic autofill are vulnerable to this exfiltration method.

4.4 Attacks that need user interaction

All of the attacks described thus far take advantage of automatic autofill password managers to work when the user does not interact with the login form. However, the exfiltration techniques we described work regardless of how the login form was filled. If the user's password manager requires user input to fill passwords and an attacker can trick the user to interact with the login form without them realizing it, the same exfiltration techniques can be used to steal the password as soon as the password form is filled.

We created a simple "clickjacking" attack [29, 39, 31]. The attacker presents the user with a benign form seemingly unrelated to the target site. Overlaying the benign form is an invisible iFrame pointing to the target site's login page. The iFrame is positioned such that when a user interacts with the benign form, they actually interact with the invisible iFrame — in this case, when the user thinks they are filling a form on a benign site, they are actually filling the password in the target site. Once filled, any of the exfiltration techniques described previously can be used to steal the password. This attack steals a password for one site at a time, but could be repeated to steal passwords for multiple sites.

We confirmed this attack works against both Chrome and Internet Explorer 11, as both required manual interaction before filling in at least some situations.

5 Strengthening password managers

In this section we present two complementary solutions to the attacks presented earlier. Before describing the details of our solutions, we first describe why some of the obvious solutions do not work. For example, as all our attacks require JavaScript injection, a potential solution is to prevent password managers from autofilling passwords on a page that is vulnerable to JavaScript injection. This solution is hard to implement in practice as some JavaScript injection vectors (e.g., XSS bugs) are extremely hard for the browser to detect. Another possible solution is to completely block autofill inside iFrames. However, this solution does not prevent the window or redirect sweep attacks described in Section 4.

Moreover, blocking autofill inside iFrames will inconvenience users of benign websites that include login forms inside iFrames.

5.1 Forcing user interaction

Our ultimate goal is to ensure that using a password manager results in better security than when users manually enter passwords in a password field. This is certainly not the case with password managers today, as the attacks of the previous section demonstrate. We begin with the simplest defense that makes password managers no worse than manual user entry.

Our most powerful attacks exploit the automatic autofill of the password field. An obvious defense is to *always* require some user interaction before autofilling a form. This will prevent sweep attacks where multiple passwords are extracted without any user interaction. Interaction can come in the form of a keyboard shortcut, clicking a button, selecting an entry from a menu, or typing into the username field. Regardless of the type of interaction, it must be protected against clickjacking attacks as described in Section 4.4. The user interaction should occur through trusted browser UI that JavaScript cannot interact with, preventing malicious JavaScript from spoofing user interaction and triggering an autofill.

Furthermore, the password manager should show the domain name being autofilled before the filling occurs, so that users know which site is being autofilled. This reduces the chances of the user filling a form without meaning to. For example, if a login page for one site contains an invisible iFrame pointing to the login page of another site, the user must explicitly choose which domain they want filled.

In some settings, such as broken HTTPS, the password manager should simply refuse to autofill passwords.

Implementation. Always forcing user interaction was easy to prototype in Chrome[1] because Chrome already requires user input in certain situations, such as when the action on the current page is different from the action when the password was saved. Since the UI implementation already existed we simply had to always trigger it. We did so by hardcoding the `wait_for_username` variable to `true` in the constructor of the `PasswordFormFillData` object. Note that this does not protect against the clickjacking attacks described in Section 4.4 but can be extended to do so.

Minimizing user inconvenience. As always forcing user interaction before autofilling may cause inconvenience to the user, password managers could provide a "autofill-and-submit" functionality that once triggered by user interaction will autofill the login form and submit it. We found that variants of autofill-and-submit are already supported by 1Password, LastPass, Norton IdentitySafe, and KeePass.

With this feature, the user's total interaction will remain similar to the current manual autofill password managers. Instead of interacting with the submit button after the password managers autofill the login form, the user will interact with the password manager to trigger autofill-and-submit. As long as the conditions stated earlier in this section are satisfied, the use of such a feature will be as secure as manually entering a password.

5.2 Secure Filling

Our main defense, called *secure filling*, is intended to make the use of password managers more secure than typing in passwords manually. Simply requiring user interaction is not sufficient. Indeed, if a login page is loaded over HTTP but submitted over HTTPS, no browser or password manager implementation provides security once the login form has been filled with the user's password: JavaScript can read the password directly from the form or change the form's action so that it submits to a password stealing page hosted by the attacker.

The goal of secure filling is that even if an attacker injects malicious JavaScript into the login page, passwords autofilled by the password manager will remain secure so long as the form is submitted over HTTPS. This defense is somewhat akin to `HttpOnly` cookies [10], but applied to autofilled passwords: they can be submitted to the web server, but cannot be accessed by JavaScript. We discuss compatibility issues at the end of the section.

Our proposed defense works as follows:

1. Along with the username and password, the password manager stores the action present in the login form when the username and password were first saved.

2. When a login form is autofilled by the password manager, the password field becomes unreadable by JavaScript. We say that the autofill is now "in progress".

3. If the username or password fields are modified (by the user or by JavaScript) while an autofill is in progress, the autofill aborts. The password is cleared from the password field, and password field becomes readable by JavaScript once more.

4. Once a form with an autofill in progress is submitted, and *after* all JavaScript code that is going to be

[1] Chromium build 231333

run has run, the browser checks that the form's action matches the domain of the action it has stored. If the domains do not match, the password field is erased and the form submission fails. If the domains do match, the form is allowed to submit as normal.

Making the password field unreadable by JavaScript prevents stealth exfiltration, as the malicious JavaScript is unable to read the password field and thus unable to steal the password. Checking the action before allowing the form to submit ensures that the action has not been changed to point to a potentially malicious site. The password is guaranteed to only be filled into a form that submits to the same place as when the password was originally saved. For this to work, it is essential that the check be performed after JavaScript's (and thus the attacker's) last opportunity to modify the form's action.

In the case where the form's action does not match what is stored, it may be desirable to give the user the option to submit the form (and password) anyway. However, the browser should allow the user to make an educated decision by showing the user both the new and original actions and explaining how their password may be leaked. This will weaken security, as the user may chose to submit the form when they should not, but it would improve compatibility when sites undergo a redesign and the login page changes.

Implementation. We implemented a prototype of this defense in Chrome[2] by modifying the `PasswordAutofillAgent` class. In the `FillUserNameAndPassword` method, we fill the password field with a dummy value (a sequence of unprintable characters), then store the real password and the form's action in a `PasswordInfo` object associated with the form. In the `WillSendSubmitEvent` method, we check if the dummy value is still present in the password field; if it is, and if the form's action matches the action we had stored, we replace the dummy value with the real password and allow the form to submit. While our implementation is only a prototype, it shows that implementing this defense is reasonably straightforward, at least in Chrome.

Although browsers vendors will need to implement this functionality in their own password managers, they may consider providing a mechanism for external password manager extensions to implement the same functionality. An API could allow the password manager extension to fill a form and designate it as autofilled, as well as designate the expected action on the form. The behavior would then be the same as with the internal password manager: the password field would become unreadable by JavaScript, and the browser checks that the action has not changed before submitting the form.

[2]Chromium build 231333

5.2.1 Limitations of secure filling

The secure filling approach will cause compatibility issues with existing sites whose login process relies on the ability to read the password field using JavaScript.

AJAX-based login. Some sites submit their login forms using AJAX instead of standard form submission. When the login form's submit button is pressed, these sites use JavaScript to read the form fields, then construct and submit an XMLHttpRequest object. This approach is not compatible with our solution, as JavaScript would not be able to read the filled password field and therefore be unable to construct the XMLHttpRequest. Furthermore, this does not use the form's action field, and therefore the password manager cannot detect when the password is being submitted to a different site than when it was first saved.

To study the impact our proposal would have on existing popular sites, we looked for the use of AJAX for login on the Alexa Top 50 sites, as of October 26, 2013. 10 of the these 50 sites used AJAX to submit logins. 8 of 10 sites were based in China, with only one Chinese site on the list not using AJAX. The remaining two sites were based in Russia and the U.S., with other sites from both countries using ordinary form submission. This suggests the use of AJAX to submit passwords is popular in China but not common elsewhere in the world, and overall AJAX is used by a significant minority of popular sites.

We propose two workarounds that will allow our solution to work with AJAX. First, sites could place the login form in an iFrame instead of using XMLHttpRequest. The iFrame would submit using standard form submission. Using this approach, there is no need for JavaScript to read the form fields and the form's action behaves normally. Therefore, it is fully compatible with our secure filling recommendation, but still allows the user to login asynchronously.

Second, for sites that must use XMLHttpRequest, the browser could provide an additional API that allows JavaScript to submit the password without being able to read it. The existing XMLHttpRequest API uses a send() method to send data. We propose an additional method, sendPassword(). The sendPassword() method accepts a form as a parameter, and sends the contents of the form's password fields without ever making them readable to other JavaScript. To prevent an attacker from exfiltrating a password using AJAX, the password manager should check that whenever a filled password is sent using send-

Password(), the destination URL matches the destination URL from the first time the filled password was sent.

Although these workarounds will require modifications to a few existing sites, the security benefits are well worth the effort. The only downside for sites that do not make the required modifications is that their users will not be able to use some password managers.

Preventing self exfiltration attacks. Chen et al. [17] point out that in some cases an attacker can extract data using what they call "self-exfiltration." In our setting this translates to the following potential attack: if any page on the victim site supports a public discussion forum, an attacker can cause the secure filling mechanism to submit the password to the forum page and have the password posted publicly. The attacker can later visit the public forum and retrieve the posted passwords. Since the attacker is changing the login form's action to another page in the *same domain* our secure filling mechanism will allow the password to be sent. In this discussion, the public forum can be replaced by any public form-posted data on the victim site

For this attack to work, the `name` of the password field on the login page must be the same as the name of the text field on the public forum page. An attacker can easily accomplish this by sending to the browser a login page with the desired name.

Fortunately, it is straight forward to defend against this issue: our secure filling mechanism should only fill a password field whose `name` matches the `name` of the field when the password was saved. Furthermore, dynamically changing the `name` attribute using JavaScript should cause a fill to abort. This defense prevents the attacker from submitting the password using any field with a name`name` other than the one chosen by the site itself for the login page. This prevents the self exfiltration attack, except for the extremely unlikely event where a public forum page on the victim site has a text field whose `name` happens to be identical to the password field `name` on the login page.

User registration pages. An additional limitation of our secure filling proposal is that it cannot improve the security of manually entered passwords. HTML does not provide a way to distinguish between password fields on user registration pages and password fields in login forms. Registration pages frequently use JavaScript to evaluate passwords before submission — for example, to check password strength or to verify two passwords match. Therefore, JavaScript on registration pages must have access to the password.

There are two solutions to this problem. One option is to forbid JavaScript from reading any password field, and require that registration pages use regular text fields programmatically made to behave like password fields. On every key stroke JavaScript on the page replaces the character with an asterisk, as in a password field. To the user the text field will behave as a password field, yet JavaScript on the registration page will be able to access the password.

Alternatively, HTML can be slightly extended to support two types of password fields, one for login and one for registration. For login, the Password field allows no JavaScript access to its contents as needed for *secure fill*. The PasswordRegistration field used for registration allows JavaScript access to its contents but is never autofilled with a saved password (separate password manager features such as a password generator can continue to work).

5.3 Server-side defenses

How can a site defend itself without support from password managers? As the attacks rely on decisions made client-side by the user's password manager, a complete server-side defense is not possible. However, a few existing best-practices can be used to greatly reduce the attack area:

1. Use HTTPS on both the login page and page it submits to. Ideally, use HTTPS everywhere on the site and enable HSTS (HTTP Strict Transport Security) to prevent pages from ever loading under HTTP.

2. Use CSP (Content Security Policy) to prevent the execution of inline scripts, making the injection of JavaScript directly into the login page ineffective.

3. Host the login page in a different subdomain that the rest of the site (i.e., login.site.com instead of site.com). This limits the number of pages considered same-origin with the login page, reducing the attack surface.

None of these defenses are unique to the attacks we described, but are best-practices that will make our attacks more difficult. Even with these defenses, attacks are still possible — attacks that take advantage of broken HTTPS, for example, will still be feasible. Therefore, it remains important that password managers implement the fixes we described to fully defend against the attacks.

6 Related work

There have been several prior works about finding vulnerabilities in existing password managers as well as building stronger password authentication systems. We summarize them below.

Vulnerabilities in password managers: Belekno et al. [11] and Gasti et al. [25] surveyed several password managers and found that most of them save passwords to device storage in an insecure manner. However, these attacks have a very different threat model than the attacks described in this paper. They require the attacker to have physical access to a user's device. By contrast, for our attacks we only consider network attackers which is a weaker threat model than the ones requiring physical access.

Besides autofilling of passwords, several password managers also support autofilling of forms with information like name, phone no etc. Prior works [21, 35, 27] have shown that an attacker can steal autofilled information by using specially crafted forms. This is a different class of attack than the attacks on login forms as unlike login passwords, information filled into these forms is not tied to any particular origin. However, for completeness, we summarize our findings about attacks against autofilling of regular forms in Appendix A.

Some existing works [23, 2] have demonstrated how an attacker can use injected JavaScript to steal user's stored passwords in a password manager for login pages that are either vulnerable to XSS attacks or are fetched over HTTP. However, unlike our attacks, these attacks require that users willingly visit the vulnerable website at the presence of the attacker. Reverse Cross-Site Request (RCSR) [13] vulnerabilities perform phishing attacks by leveraging the fact that several password managers will fill in passwords to login forms even if the form's action differs from the action when the password was first saved. These attacks require that the user clicks the submit button. By contrast, our attacks are completely automated and transparent to the user.

The most closely related works to the attacks we present in this paper are by RSnake [37] and Saltzman et al. [40]. RSnake [37] speculated that an attacker can exploit form autofilling tools that fills forms without any user input in sites vulnerable to XSS attacks to extract the autofillable information without users' notice. The basic idea is to inject JavaScript using the XSS attack and exfiltrate the autofilled information. Saltzman et al. [40] suggested that active network attackers can inject iFrames to login forms of websites vulnerable to script injection either through XSS attacks or through pages loaded over HTTP, make the password managers fill those login forms, and steal those passwords without users noticing anything wrong. However, none of these works tested the attacks. We performed a comprehensive study of vulnerabilities and presented several new and different attack vectors (mixed content, broken SSL, embedded device admin pages etc.) and attack techniques (such as the redirect attack).

Using XSS attacks for stealing autofilled passwords has also been explored by Stock et al. [42]. They suggested that the password managers can prevent such attacks by using a placeholder dummy password for autofilling and replacing it with the original one just before submitting the login form to the remote server. In this work, unlike Stock at al., we explore several different vectors for stealing autofilled passwords besides XSS attacks. We also investigate several different third-party password managers together with the builtin password managers that were analyzed by Stock et al.

Blanchou et al. [12] describe several weaknesses of password manager browser extensions and implement a phishing attack that demonstrates the danger of automatic autofill. They do not examine any built-in browser password managers or consider how passwords from multiple sites could be stolen in one attack. They suggest that password managers prevent the cross-domain submission of passwords (what we called action exfiltration in this paper), but do not consider stealth exfiltration.

Fahl et al. [22] demonstrate attacks against Android password managers. However, their attacks were specific to the Android operating system, and most relied upon a malicious Android app, not a network attacker.

Li et al. [32] survey a variety of vulnerabilities specific to third-party web-based password managers and a web attacker, then discuss mitigation strategies. They do not discuss browser or native code password managers, nor a network attacker.

Both the Chromium and Firefox bug databases have bugs filed to prevent autofilling of login information inside an iFrame [18, 16]. However, preventing autofilling of passwords inside iFrames will not prevent the window sweep or the redirect attacks described in Section 4. At the time of this writing, only the Chromium bug has been fixed.

Another Chromium bug [19] seeks to only autofill forms after the user interacts with the login page, but not necessarily the login form. This is not yet implemented, however, increasing the scope of interaction to the entire page will make it easier for the attackers to launch clickjacking attacks. In contrast, autofilling only after explicit user interaction with the login form as suggested in Section 5 is robust against such attacks.

A Firefox bug [14] discusses man-in-the-middle attacks against the password manager similar to our redirect attack. Another bug [15] suggests that filled passwords should not be readable by JavaScript. Their approach is similar to our secure filling, but remains vulner-

able to exfiltration using the action attribute. Although both bugs are several years old, neither has been acted upon.

Password manager features: Aris [9] discusses the autocomplete attribute and why setting autocomplete=off results in poor security in addition to a bad user experience.

Secure password authentication systems: Another related line of research investigated designing secure password authentication systems that can choose strong domain-specific passwords with minimal user intervention [36, 28]. The main motivation behind these works is to minimize the damage caused by users mistakenly revealing their passwords through phishing websites or social engineering These solutions also protect against an attacker leveraging reused passwords that were stolen from a low security website on a high security website. None of these works focus on autofilling of passwords and thus do not help in preventing against the attacks we presented in this paper.

There are also several research works that built password authentication systems that supported autofilling [45, 44]. However, their primary goal was to prevent phishing attacks. In this paper, we focus on existing password managers and thus do not evaluate how vulnerable these systems are against our attacks.

Sandler et al. proposed the 'password booth', a new secure browser-controlled mechanism to let users securely enter passwords that are not unaccessible from JavaScript running as part of the host page's origin [41]. Their solution is similar to our secure filling defense, but does not take password managers into account. Secure filling takes advantage of password managers to provide guarantees the password booth cannot, namely that an autofilled password is submitted to the same origin it was saved from. Furthermore, their proposal requires a dramatic UI change for all users, whereas ours requires only a very minimal UI change from automatic to manual autofill. They suggest that a dramatic change is a feature because it makes security more visible to the user, yet at the same time a dramatic change will reduce adoption from browser developers unwilling to upset their users with change. Ultimately, our two ideas are compatible as the password booth could be extended to work with password managers as we describe in this paper.

An early unpublished version of this paper, containing only a subset of the results, appears as a technical report in [34].

7 Conclusions

In this paper we surveyed a wide variety of password managers and found that they follow very different and inconsistent autofill policies. We showed how an evil coffee shop attacker can leverage these policies to steal the user's stored passwords without any user interaction. We also demonstrated that password managers can prevent these attacks by simply following two steps - never autofilling under certain conditions like in the presence of HTTPS certificate validation errors and requiring user interaction through some form of trusted browser UI, that untrusted JavaScript cannot affect, before autofilling any passwords. Finally, we presented *secure filling*, a defense that makes autofilling password managers more secure than manually entering a password under certain circumstances (e.g., a login page fetched over HTTP but submitted over HTTPS). We hope that this work will improve the security of password managers and encourage developers to adopt our enhancements.

We disclosed our results to the password manager vendors, prompting several changes to autofill policies. Due to our findings, LastPass will no longer automatically autofill password fields in iFrames, and 1Password will no longer offer to fill passwords from HTTPS pages on HTTP pages.

A Autofilling of forms

Several password managers (Chrome, Safari, LastPass and 1Password) that we studied in this paper also supported autofilling forms with different pieces of information like name, email address, phone no, credit card no, expiry date etc. Even though this is not directly related to autofilling of passwords we summarize our findings in this section for completeness.

Unlike login information, autofill information for forms is not tied to any origin. Therefore, forms from any domain can be autofilled with the same information. To make autofilling secure all the password managers we studied required user interaction to start autofilling of forms. However, several prior works have noticed that a malicious attacker can create specially crafted forms that only have certain innocuous fields visible (e.g. name) while other more sensitive fields (e.g. phone number) invisible to the user and once the user triggers autofilling, both the invisible and visible fields get filled and thus become accessible by the attacker [21, 35].

We found that while all the autofilling password managers we studied are to some extent vulnerable to this attack, the type of sensitive information that can be extracted depends on the nature of user interaction required to trigger autofill. Unlike the rest of the paper in this section we consider web attackers only as the autofill information is not tied by any origin.

- **Chrome & Safari:** Both Chrome and Safari separate the autofillable information into two categories - personal information (e.g., name, email address, phone no., physical address) and credit card information (e.g., credit card no, expiry date). To trigger autofill for each category the user needs to click a field in each category and select an entry from the available ones. Thus, even if an attacker makes a user click a visible field in the personal information category none of the hidden credit card fields will get autofilled. This makes stealing credit information much harder in these password managers without the users noticing it.

- **LastPass:** Unlike Chrome and Safari, for triggering autofilling, LastPass only requires that user click a button shown on top of the page. Once this button is clicked all fields in the form (both hidden and visible) gets filled. This makes it very easy for an attacker to create a crafted form showing only fields like name and email address while stealing additional information, such as credit cards, or a Social Security Number, through hidden fields.

- **1Password:** Unlike LastPass, 1Password requires that the users click different buttons depending on what information they want to fill. Thus, it is not possible to steal credit card information from 1Password by making all credit cards hidden. However, if a legitimate page that a user wants to fill credit card information into also contains an iFrame with hidden credit card fields from a third-party domain (e.g., advertisement), 1Password will fill the credit card information inside the iFrame as well as in the main page with a single click and no notification to the user.

The Emperor's New Password Manager: Security Analysis of Web-based Password Managers

Zhiwei Li, Warren He, Devdatta Akhawe, Dawn Song
University of California, Berkeley

Abstract

We conduct a security analysis of five popular web-based password managers. Unlike "local" password managers, web-based password managers run in the browser. We identify four key security concerns for web-based password managers and, for each, identify representative vulnerabilities through our case studies. Our attacks are severe: in four out of the five password managers we studied, an attacker can learn a user's credentials for arbitrary websites. We find vulnerabilities in diverse features like one-time passwords, bookmarklets, and shared passwords. The root-causes of the vulnerabilities are also diverse: ranging from logic and authorization mistakes to misunderstandings about the web security model, in addition to the typical vulnerabilities like CSRF and XSS. Our study suggests that it remains to be a challenge for the password managers to be secure. To guide future development of password managers, we provide guidance for password managers. Given the diversity of vulnerabilities we identified, we advocate a defense-in-depth approach to ensure security of password managers.

1 Introduction

It is a truth universally acknowledged, that password-based authentication on the web is insecure. One primary, if not *the* primary, concern with password authentication is the cognitive burden of choosing secure, random passwords across all the sites that rely on password authentication. A large body of evidence suggests users have—possibly, rationally [20]—given up, choosing simple passwords and reusing them across sites.

Password managers aim to provide a way out of this dire scenario. A secure password manager could automatically generate and fill-in passwords on websites, freeing users from the cognitive burden of remembering them. Additionally, since password managers automatically fill in passwords based on the current location of the page, they also provide some protection against phishing attacks. Add cloud-based synchronization across devices, and password managers promise tremendous security and usability benefits at minimal deployability costs [10].

Given these advantages, the popular media often extols the security advantages of modern password managers (e.g., CNET [11], PC Magazine [29], and New York Times [32]). Even technical publications, from books [12, 34] to papers [19], recommend password managers. A recent US-CERT publication [21] notes:

> [A Password Manager] is one of the best ways to keep track of each unique password or passphrase that you have created for your various online accounts without writing them down on a piece of paper and risking that others will see them.

Unsurprisingly, users are increasingly looking towards password managers for relieving password fatigue. LastPass, a web-based password manager that syncs across devices, claimed to have over a million users in January 2011 [25]. PasswordBox, launched in May 2013, claims to have over a million users in less than three months [42].

Our work aims to evaluate the security of popular password managers in *practice*. While idealized password managers provide a lot of advantages, implementation flaws can negate all the advantages of an idealized password manager, similar to previous results with other password replacement schemes such as SSOs [40, 38]. We aim to understand the current state of password managers and identify best practices and anti-patterns to guide the design of current and future password managers.

Widespread adoption of insecure password managers could make things worse: adding a new, untested single point of failure to the web authentication ecosystem. After all, a vulnerability in a password manager could allow an attacker to steal *all* passwords for a user in a single swoop. Given the increasing popularity of pass-

word managers, the possibility of vulnerable password managers is disconcerting and motivates our work.

We conduct a comprehensive security analysis of five popular, modern web-based password managers. We identified four key concerns for modern web-based password managers: bookmarklet vulnerabilities, "classic" web vulnerabilities, logic vulnerabilities, and UI vulnerabilities. Using this framework for our analysis, we studied each password application and found multiple vulnerabilities of each of the four types.

Our attacks are severe: in four out of the five password managers we studied, an attacker can learn a user's credentials for arbitrary websites. We find vulnerabilities in diverse features like one-time passwords, bookmarklets, and shared passwords. The root-causes of the vulnerabilities are also diverse: ranging from logic and authorization mistakes to misunderstandings about the web security model, in addition to vulnerabilities like CSRF and XSS.

All the password manager applications we studied are proprietary and rely on code obfuscation/minification techniques. In the absence of standard, cross-platform mechanisms, the password managers we study implement features like auto-fill, client-side encryption, and one-time password in diverse ways. The password managers we study also lack a published security architecture. All these issues combine to make analysis difficult.

Our main contribution is systematically identifying the attack surface, security goals, and vulnerabilities in popular password managers. Modern web-based password managers are complex applications and our systematic approach enables a comprehensive security analysis (in contrast to typical manual approaches).

Millions of users trust these vulnerable password managers to securely store their secrets. Our study strikes a note of caution: while in theory password managers provide a number of advantages, it appears that real-world password managers are often insecure.

Finally, to guide future development of password managers, we provide guidance for password managers. We identify anti-patterns that could hide more vulnerabilities; architectural and protocol changes that would fix the vulnerabilities; as well as identify mitigations (such as Content Security Policy [14]) that could have mitigated some vulnerabilities. Our focus is not on finding fixes for the vulnerabilities we identified; instead, our guidance is broader and aims to reduce and mitigate any future vulnerabilities. Given the diversity of vulnerabilities we identified, we believe a defense-in-depth approach has the best shot at ensuring the security of password managers.

Ethics and Responsible Disclosure. We experimentally verified all our attacks in an ethical manner. We reported all the attacks discussed below to the software vendors affected in the last week of August 2013. Four out of the five vendors responded within a week of our report, while one (NeedMyPassword) still has not responded to our report. Aside from linkability vulnerabilities and those found in NeedMyPassword, all other bugs that we describe in the paper have been fixed by vendors within days after disclosure. None of the password managers had a bug bounty program.

Alice	a legitimate user
Bob	a legitimate collaborator
hunter2	an example password
`dropbox.com`	a benign web application
`facebook.com`	a benign web application
`/login`	entry point (login page) for a web application
Mallory	an attacker
Eve	an attacker
`evil.com`	a website controlled by an attacker
`dropbox.com`	The dropbox.com JavaScript code running in the browser

Figure 1: Naming convention used in the paper. URLs default to https unless otherwise specified.

Organization. We organize the rest of the paper as follows: Section 2 provides background on modern web-based password managers and their features. We also articulate their security goals and explain our threat model in Section 2. Next, we present the four key sources of vulnerabilities we used to guide our analysis (Section 3). Section 4 presents our study of five representative password managers, broken down by the source of vulnerabilities (per Section 3). We provide guidance to password managers in Section 5. We present related work in Section 6 before concluding (Section 7).

2 Background

To start, we explain the concept of a password manager and discuss some salient features in modern implementations. We also briefly list the password managers we studied, identify the threat model we work with, and the security goals for web-based password managers. Here and throughout this paper, we rely on a familiar naming convention (presented in Figure 1) to identify users, web applications, and attackers.

2.1 A Basic Password Manager

At its core, a password manager exists as a database to store a user's passwords and usernames on different sites. The password manager controls access to this database via a *master username/password*. A secure password manager, with a strong master password, ensures that a user can rely on distinct, unguessable passwords for each web application without the associated cognitive burden of memorizing all them. Instead, the user only has to

remember one strong master password.

A password manager maintains a database of a user's *credentials* on different *web applications*. A web application is a site that authenticates its users by asking for a username/password combination. The web application's "entry point" is the page where the application's user can enter her username and password. We call the combination of an entry point, username, and password a *credential*. A user can store multiple credentials for the same web application, in which case a name distinguishes each (typically the username).

Figure 2 (a) illustrates the general protocol of how a user (Alice) uses a password manager (e.g., LastPass) to log in to a web application (e.g., Dropbox). Alice first logs in to the password manager using her master username/password (her LastPass username and password), as shown in Step ①. Then, in Step ②, Alice retrieves her credential for `dropbox.com`. Finally, Alice uses this credential to log into `dropbox.com` in Step ③ and ④.

Since manually retrieving and sending credentials is cumbersome, password managers may also automate the process of selecting the appropriate credential and logging in to the opened web application. This may include navigating a web browser to the entry point, filling in some text boxes with the username/password, and submitting the login form. Since these tasks involve executing code inside the web application, password managers often rely on a privileged browser extension or a bookmarklet for the same.

2.2 Features in Modern Password Managers

Modern password managers provide a number of convenience and security features that are relevant to a security analysis. We briefly elucidate three below.

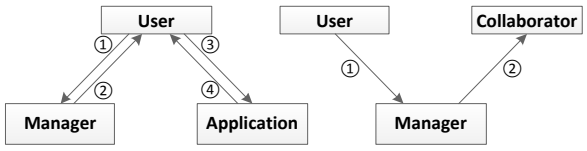

Figure 2: Different parties in a password manager scheme

Collaboration. Modern password managers include the ability to share passwords with a collaborator. Figure 2 (b) illustrates the general protocol of how a user Alice shares a credential of hers with a collaborator Bob. In Step ①, Alice requests that the password manager share a specified credential with Bob. In Step ②, the password manager forwards the credential to Bob when Bob requests it. Both Alice and Bob need accounts with the password manager. My1login even allows the password owner to set read/write permissions on the shared credentials, but the efficacy of these fine-grained controls is not clear, since denying write access does not prevent a collaborator from going to the web application and changing the account's password.

Credential Encryption. Due to the particularly sensitive nature of the data handled by password managers, password managers aim to minimize the amount of code and personnel with access to the credentials in the clear. One common technique is encrypting the credential database on the user's computer, thus preventing a passive attacker at the server-side from accessing the credentials in plaintext. In web-based password managers, this corresponds to using JavaScript to encrypt passwords on the client side (including pages on the password manager's website, browser extensions, and bookmarklets). The password manager encrypts/decrypts the credential database using a key derivation function starting from a user provided secret. If the password manager supports credential encryption, we call the encryption key the user's *master key*. For example, LastPass uses JavaScript to decrypt/encrypt the user's credential database using a key derived from the user's master username and password.

Login Bookmarklets. As discussed above, password managers typically rely on browser extensions to implement auto-fill and auto-login functionality. Unfortunately, users can only install these in a browser that supports extensions. With the popularity of mobile devices whose browsers lack support for extension APIs (e.g., Mobile Safari or Internet Explorer), password managers have adopted a more portable solution by providing a *bookmarklet*. A bookmarklet is a snippet of JavaScript code that installs as a bookmark, which, instead of navigating to a URL when activated, runs the JavaScript snippet in the (possibly malicious) context of the current page (e.g., `evil.com`). This allows the password manager to interact with a login form using widely supported bookmarking mechanisms.

2.3 Representative Password Manager Applications

To evaluate the security of modern password managers, we studied a representative sample of five modern password managers supporting a diverse mix of features. Table 1 provides an overview of their features. The columns "Extension" and "Bookmarklet" indicate support for login automation through the particular mechanism; "Website" indicates the presence of a web-based account management interface; and "Credential Encryption" and "Collaboration" refer to the features described in Section 2.2. For password managers supporting credential encryption, Table 1 also lists their key derivation

	Bookmarklet	Extension	Website	Credential Encryption		Collaboration
				Master Key Derivation	Encrypted Fields	
LastPass	✓	✓	✓	KDF(mp,mu,5000,32)	usernames and passwords	✓
RoboForm	✓	✓	✓	×		×
My1login	✓	×	✓	MD5(ph_{even})+MD5(ph_{odd})	usernames and passwords	✓
PasswordBox	×	✓	×	KDF(mp,mu,10000,32)	passwords only	✓
NeedMyPassword	×	×	✓	×		×

mu: master username mp: master password
ph: passphrase $ph_{even(odd)}$: characters at even (odd) positions of ph
KDF(p,s,c,l) is a key derivation function [23], which derives key of length l octets for the password p, the salt s, and the iteration count c.

Table 1: List of Password Managers Studied.

function and the fields encrypted.

2.3.1 LastPass

LastPass [24] is a popular, award-winning password manager available on phones, tablets, and desktops for all the major operating systems and browsers. It is the top-rated and Editors' Choice password manager for both PC Magazine [29] and CNET [11]. As of August 2013, LastPass had over one million users.

LastPass is one of the most full-featured password manager applications available. It supports nearly all major browsers and mobile/desktop platforms and includes features such as bookmarklets, one-time passwords, and two-factor authentication. LastPass users can access their credentials using the LastPass extension, through a bookmarklet, or directly through the LastPass website. LastPass stores the credential database encrypted on the LastPass servers and also allows users to share passwords with each other.

2.3.2 RoboForm

RoboForm (Everywhere) [33] is another top-rated password manager [29].[1] In RoboForm, each credential (i.e., username, password, and entry point tuple) has its own file named (by default) after the web application's domain. For example, RoboForm uses "dropbox" as the default filename when saving credentials for `dropbox.com`. The user can also choose arbitrary names for the files. Unless the user creates a master password to protect the files, these credential files are sent to RoboForm servers in the clear. The user can access her credential files directly through the RoboForm website or via the RoboForm extension or bookmarklet.

[1] RoboForm (Desktop) is a version of RoboForm that only stores credentials on a single computer and does not sync across devices using a web server. We focus only on the web-based RoboForm (Everywhere) software.

2.3.3 My1login

My1login is a web-based password manager, launched in April 2012; it started a special business-targeted product launched in May 2013. Our study was based on a then-beta version of their consumer-facing service. For maximum compatibility, My1login relies exclusively on bookmarklets and does not provide any browser extensions. Users can access credentials via a web application. My1login also supports sharing of credentials between two My1login accounts. My1login stores all credentials encrypted at the server-side with a special passphrase that the user sets up. In contrast to other password managers, which use the standard PBKDF algorithm, My1login concatenates the MD5 hash of odd and even characters of the passphrase to generate a 256-bit key. We do not comment on this further because we found a simpler, more severe flaw in My1login [27].

2.3.4 PasswordBox

PasswordBox [31], a web-based password manager that launched in 2013, is highly rated by both PC Magazine [29] and CNET [11]. Within three months of its inception in May 2013, PasswordBox had attracted over one million users [42]. PasswordBox, unlike other password managers discussed earlier, does not support bookmarklets; instead, it requires users to install a browser extension. PasswordBox also allows sharing credentials between users and encrypts all passwords using a 256-bit key derived using 10000 iterations of PBKDF2 and the PasswordBox username as the salt.

2.3.5 NeedMyPassword

Finally, we also studied a basic password manager named NeedMyPassword [30]. NeedMyPassword lacks common features such as auto-login, credential sharing, and password generation. Instead, it provides only credential storage, accessible through the NeedMyPassword website. User credentials are not encrypted before send-

ing to NeedMyPassword servers.

2.4 Threat Model

Our main threat model is the *web attacker* [2]. Briefly, a web attacker controls one or more web servers and DNS domains and can get a victim to visit domains controlled by the attacker. We believe this is the key threat model for web-based password managers that often run in the browser. For our study, we extend this model a bit: the user may create an account on the attacker's web application and use the password manager for managing the credentials for the same. Our threat model allows the victim to rely on the password manager's extension, the bookmarklet, and website as she sees fit. The attacker can also create accounts in the password manager service and make requests to the password manager directly.

The password manager's code often runs in a web application's origin (via an extension or a bookmarklet). We assume that the password manager's code is not malicious and does not steal sensitive data from web applications. We also assume that the password manager does not share Alice's credentials with user Bob, unless asked to do so by Alice. Additionally, we assume that the user uses a unique password for the password manager and does not share it with other applications such as `evil.com`.

2.5 Security Goal

At a high level, a password manager only has one key security invariant: ensure that a stored password is accessed only by the authorized user(s) and the website the password is for. We discuss how password managers (attempt to) achieve this invariant by following four security goals. A related taxonomy appears in Bonneau et al.'s analysis of general web authentication schemes [10], but ours is a bit different since we focus exclusively on web-based password managers. Nonetheless, all our goals map to goals mentioned in Bonneau et al.'s work. As we present in Section 4, we found attacks that violate *all* of the security goals identified below and range from complete (password manager) account takeover to privacy violations.

Master Account Security. The first goal of password manager application is the integrity of the master account. It should be impossible for an attacker to authenticate as the user to the password manager. It is crucial that the password manager maintain the security of the master account and safeguard credentials such as master password and cookies. In case of password managers that encrypt credentials, the master key/password used to encrypt the credential database should always remain at the client-side.

Credential Database Security. The main responsibility of a password manager is securely storing the list of a user's credentials. A password manager needs to ensure the security—including confidentiality, integrity, and availability—of the credential database. The attacker, Eve, should not be able to learn Alice's credentials, which would allow Eve to log in as Alice; or modify credentials, which would allow Eve to carry out a form of login CSRF attacks; or delete credentials, which would allow Eve to carry out a denial-of-service attack on Alice.

Collaborator Integrity. The collaboration, or sharing, feature in modern password managers complicates credential databases. Now, each credential has an access-control list identifying the list of users allowed to read/write the credential. A password manager must ensure the security of this feature: e.g., flaws in this feature could allow an attacker to learn a user's credential. While we realize that these goals are a subset of the broader goal of credential database security (above), we separated them out to highlight the security concerns of the sharing credentials feature.

Unlinkability. The use of a password manager should not allow colluding web applications to track a single user across websites, possibly due to leaked identifiers. We use the Bonneau et al.'s definition of unlinkability [10]: a password manager violates unlinkability if it allows tracking a user across web applications even in the absence of other techniques like web fingerprinting [16]. For example, a privacy-minded user could rely on different browsers or computers to foil web browser fingerprinting; a password manager should not add a reliable fingerprinting mechanism that makes that effort moot. Such a fingerprinting mechanism would violate the user's privacy expectations. Equivalently, relying on a password manager should not allow a web application to link two accounts owned by the user with the (same) web application.

3 Attack Surface

The key difference between web-based password managers and "local" password managers is their need to work in web browsers. Web-based password managers store credentials in the cloud and a user logs on to the manager to retrieve his/her credentials. Access to the stored credentials is via extensions, a website, or even bookmarklets—all of which run in the browser.

To guide our investigation, we identified four key concerns for modern web-based password managers: bookmarklet vulnerabilities, classic web vulnerabilities, authorization vulnerabilities, and UI vulnerabilities. We discuss each in turn below. In the next section, we will present representative vulnerabilities of each type.

3.1 Bookmarklet Vulnerabilities

JavaScript is a dynamic, extensible language with deep support for meta-programming. The bookmarklet code, running in the context of the attacker's JavaScript context cannot trust *any* of the APIs available to typical web applications—an attacker could have replaced them with malicious code. Relying too much on these APIs has created a class of vulnerabilities unique to web-based password managers.

To fill in a password on (say) `dropbox.com`, a password manager needs to successfully authenticate a user, download the (possibly encrypted) credential, decrypt it (if necessary), authenticate the web application, and, finally, perform the login. Doing all this in an untrusted website's scripting environment (as a bookmarklet does) is tricky. In fact, three of the five password managers we studied (Table 1) provide full-fledged bookmarklet support, and *all* of them were vulnerable to attacks ranging from credential theft to linkability attacks (Section 4).

Browser extensions, which modified the webpage, faced a similar problem in the past. Currently, both Firefox and Chrome instead provide native or isolated APIs for browser extensions. Unfortunately, popular mobile browsers, including Safari on iOS, Chrome on Android/iPhone, and the stock Android Browser, do not support extensions. As a result, web-based password managers often rely on bookmarklets instead.

3.2 Web Vulnerabilities

A password manager runs in a web browser, where it must coexist with the web applications whose passwords it manages as well as other untrusted sites. Unfortunately, relying on the web platform for a security-sensitive application such as password managers is fraught with challenges.

Web-based password manager developers need to understand the security model of the web. For example, browsers share authentication tokens such as cookies across applications (including across applications and extensions), leading to attacks such as cross-site request forgery (CSRF). Applications running in the browser runtime also need to sanitize all untrusted input before inserting it into the document; insufficient sanitization could lead to cross-site scripting attacks, which in the web security model implies a complete compromise.

3.3 Authorization Vulnerabilities

Sharing credentials increases the complexity of securing password managers. While previously, each credential was only accessible by its owner, now each credential needs an access control list. Any user could potentially access a credential belonging to Alice, if Alice has authorized it. A password manager needs to ensure that all actions related to sharing/updating credentials are fully authorized. Confusing authentication for authorization is a classic security vulnerability, one that we find even password managers make (Section 4). We separate out authorization vulnerabilities from web vulnerabilities since they are often due to a missing check at the server-side. For example, all our authorization vulnerabilities involve requests made by an attacker from his own browser, not via Alice's browser (when Alice visits `evil.com`).

3.4 User Interface Vulnerabilities

A major benefit of password managers is their ability to mitigate phishing attacks. Users do not actually memorize the password for a web application; instead, they rely on the password manager to detect which application is open and fill in the right password. The logic that performs this is impervious to phishing attacks: it will only look at the URL to determine which credential to use.

These advantages are moot if the password manager itself is vulnerable to phishing attacks. Even worse, in the case of password managers, a single phishing attack can expose *all* of a user's credentials. Thus, we believe it behooves password managers to take extra precautions against phishing attacks. While it is possible that password managers are susceptible to classic phishing attacks, we focus on anti-patterns that make password managers more vulnerable than the typical website.

For example, consider what happens when a user clicks on a password manager's bookmarklet while not logged in to the password manager. A simple option is asking the user to login in an iframe. Unfortunately, this is trivial for the attacker to intercept and replace the iframe with a fake dialog. Since users cannot see the URL of an iframe, there is no way for a user to identify whether a particular iframe actually belongs to the password manager and is not spoofed. We argue that this is an anti-pattern that password managers should avoid.

4 Security Analysis of Web-based Password Managers

Next, we report the results of our security analysis of five popular password managers. We organize our results per the discussion in Section 3. Table 2 summarizes the vulnerabilities we found. Our discussion below highlights the presence of different types of security vulnerabilities in web-based password managers. We do not present complete architectural details of each password manager; instead, we only provide enough technical details to understand each vulnerability.

4.1 Bookmarklet Vulnerabilities

As discussed earlier, a bookmarklet allows a user of a password manager to log in to web applications without needing to install any extension, a particularly useful

	Bookmarklet Vulnerabilities	Web Vulnerabilities	Authorization Vulnerabilities	User Interface Vulnerabilities
LastPass	✓(§ 4.1.1)	✓(§ 4.2.1)		✓([27])
RoboForm	✓([27])	✓([27])	NA	✓(§ 4.4)
My1login	✓([27])		✓(§ 4.3.1)	
PasswordBox	NA		✓(§ 4.3.2)	NA
NeedMyPassword	NA	✓([27])	NA	NA

Table 2: Summary of Vulnerabilities Discovered. NA identifies vulnerabilities not applicable to the particular password manager because it does not provide the relevant functionality.

feature with mobile browsers that lack extension support. Three of the password managers we studied—LastPass, RoboForm, and My1login—provide access to credentials and auto-fill functionality using bookmarklets. In fact, My1login *only* provides bookmarklet for auto-fill support, advertising it as a feature ("No install needed").

We found critical vulnerabilities in all three bookmarklets we studied. If a user clicks on the bookmarklet on an attacker's site, the attacker, in all three cases, learns credentials for arbitrary websites. We only discuss one representative vulnerability here and provide details of the other two vulnerabilities in our extended technical report [27].

While in 2009 Adida et al. identified attacks on password manager bookmarklets [1], our study indicates that these issues still plague password managers. This is particularly a cause of concern given the popularity of mobile devices that lack full-fledged support for extensions.

4.1.1 Case Study: LastPass Bookmarklet

LastPass stores the credential database on the `lastpass.com` servers encrypted with a `master_key`, which is a 256-bit symmetric key derived from the user's master username and master password. The LastPass client-side code never sends the master password or master key to the LastPass servers.

Recall that a bookmarklet runs in the context of the (possibly malicious) web application. At the same time, due to LastPass's credential encryption, the bookmarklet needs to include the secret `master_key` (or a way to get to it), to decrypt the credential database. Including this secret in the bookmarklet, while still keeping it secret from the web application, is tricky. LastPass also provides the ability to revoke a previously created bookmarklet, further complicating this feature.

Installing a Bookmarklet. A user, Alice, wishing to install a bookmarklet needs to create a special link through her LastPass settings page. On Alice's request, the LastPass page code creates a new random value `_LASTPASS_RAND` and encrypts the `master_key` with it, all within Alice's browser. The LastPass servers then store this encrypted master key (called `key_rand_encrypted`) and an identifier `h` along with

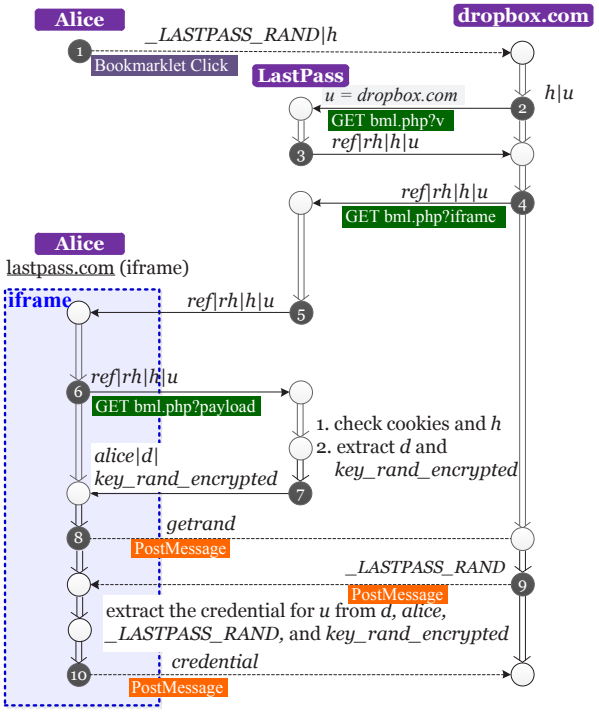

Figure 3: LastPass: Automatic login using bookmarklet. `u` is the domain on which Alice clicked on the bookmarklet.

Alice's credential database. The page then creates a JavaScript snippet containing `_LASTPASS_RAND` and `h`, which Alice can save as a bookmark. This design allows Alice to revoke this bookmarklet in the future by just deleting the corresponding `h` and encrypted master key from the LastPass servers.

Using the Bookmarklet. Figure 3 illustrates how Alice uses her LastPass bookmarklet to log in to `dropbox.com`. At the Dropbox entry point, Alice clicks on her LastPass bookmarklet, which includes the token `_LASTPASS_RAND` and `h`. The bookmarklet code first checks the current page's domain and adds a script element to the page sourced from `lastpass.com`. The request for the script element (Step 2 in Figure 3) sends

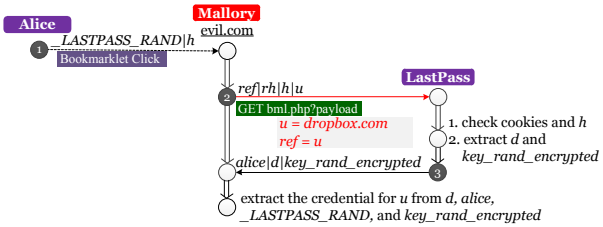

Figure 4: Attack on LastPass bookmarklet based autologin. The `rh,h` values are random; `u` and `ref` identify the Malloy's target website.

`h` and the web application domain `dropbox.com` as parameters `h` and `u`. LastPass checks `h` and if the parameter is valid (i.e., Alice has not revoked the bookmarklet), responds with a JavaScript file containing the additional parameters `ref` and `rh`.

Next, the newly fetched JavaScript file creates an iframe to `lastpass.com` using four parameters: `ref,rh,h,u`. This iframe includes a script located at `lastpass.com/bml.php?u=dropbox.com` that, when downloaded, includes the encrypted master key `key_rand_encrypted` and the credential for `dropbox.com` encrypted with the master key. The iframe then receives the bookmarklet's `_LASTPASS_RAND` value via a `postMessage` call, decrypts the `dropbox.com` credential and sends them back.

Vulnerability. The resource at `bml.php?u=dropbox.com` (Step 6 Figure 3) is at a predictable URI and contains sensitive information. It provides the encrypted master key `key_rand_encrypted` and the credential for `dropbox.com`. The same-origin policy allows an attacker to include a script from any origin and execute it in the attacker's webpage.

LastPass Bookmarklet Attack. Figure 4 illustrates how a malicious web application `evil.com` can steal Alice's credential for `dropbox.com`. When Alice visits the attacker's site `evil.com` and clicks her LastPass bookmarklet, the attacker uses any of a number of hijack techniques [1, 8] (e.g., `Function.toSource`) and extracts both `h` and `_LASTPASS_RAND`. Then, the attacker imitates Step 6 from Figure 3 (as Step 2 here) by writing a `<script>` tag with `src` set to `lastpass.com/bml.php?u=dropbox.com` and adding the parameters `rh` (any string of length 64), `r` (any number), and `h` (from the bookmarklet).

The downloaded script, which runs on the attacker's page, includes all the information needed to decrypt credential for `dropbox.com` (notably, `key_rand_encrypted`). Again, the attacker uses the JavaScript hijack technique to extract out the encrypted credential and decrypts them with the `_LASTPASS_RAND` value stolen earlier. The attacker can repeat the attack to steal *all* of Alice's credentials, violating the confidentiality of the credential database.

LastPass Linkability Attack. Finally, we note that the `h` and `_LASTPASS_RAND` remain the same across browsers but differ by user. As discussed above, any website where the user clicks the bookmarklet can learn these pseudo-identifiers `h` and `_LASTPASS_RAND` [1]. This allows colluding websites to track a user, violating the user's privacy expectations [10]. Additionally, this also allows a single website to identify and link multiple accounts belonging to the same user, which violates the unlinkability goal.

4.2 Web Vulnerabilities

Next, we study vulnerabilities in password managers caused due to subtleties of the web platform. We focus on CSRF and XSS vulnerabilities, which are common in web applications. We find CSRF vulnerabilities in LastPass, RoboForm, and NeedMyPassword as well as XSS vulnerabilities in NeedMyPassword.

Our attacks are severe: XSS vulnerabilities in NeedMyPassword allow for complete account takeover, while the CSRF vulnerabilities in RoboForm allow an attacker to update, delete, and add arbitrary credentials to a user's credential database. We only discuss the CSRF vulnerability in LastPass here and discuss the remaining CSRF and XSS vulnerabilities in our extended technical report[27].

4.2.1 Case Study: LastPass One Time Password

One-Time password (OTP) is a feature of LastPass that allows a user to generate an authentication code for the master account that is only valid for one use. A user can use a one-time password to prevent a physical observer from gaining access to her LastPass account [10].

Generating an OTP. Before getting into the details, we point out that Alice's LastPass OTP must be able to authenticate Alice to LastPass *and* allow Alice to recover her master key; all without revealing anything extra (including the OTP itself) to LastPass servers (since that would defeat the credential encryption feature).

Figure 5 illustrates how Alice creates an OTP `otp`. This starts with Alice creating a string `otp` locally in her browser. Next, Alice computes `h = hash(hash(alice|otp)|otp)` with her LastPass username `alice`. LastPass will use `h` to authenticate Alice, without having to know the exact value of `otp`. Then, Alice encrypts her master key with `hash(alice|otp)`. Alice sends `h` and the encrypted master key (`rand_encrypted_key`) to LastPass. Notice that the LastPass servers never see the generated one-time password or Alice's master key in the clear. LastPass saves a record associating the values `h` and

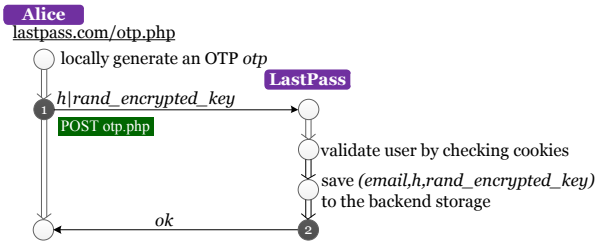

Figure 5: LastPass OTP Creation. Note the absence of any CSRF token in the request in Step 1.

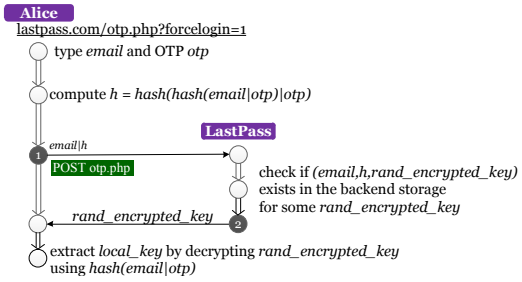

Figure 6: Using the LastPass OTP.`rand_encrypted_key` is the master key encrypted with `hash(alice|otp)`,

`rand_encrypted_key` with Alice's LastPass username.

Using the OTP. To sign in with her OTP (Figure 6), Alice recomputes `h` from her knowledge of `otp`, and sends it to LastPass along with her LastPass username. LastPass checks its records for a matching username and `h`. It starts an authenticated session for (i.e., sets session cookies identifying) Alice and sends back her `rand_encrypted_key`. Alice then decrypts `rand_encrypted_key` to recover her master key.

Vulnerability. We found that the request used to set up the OTP (Step 1 Figure 5) is vulnerable to a classic CSRF attack. The LastPass server authenticates Alice (in Step 1) only with her cookies. Since LastPass does not know the OTP or the master key, it cannot validate that `rand_encrypted_key` actually corresponds to an encrypted value of the master key. Fixing this vulnerability involves adding a CSRF token to the OTP creation form.

OTP Attack on LastPass. An attacker, Mallory, who knows Alice's LastPass username, can come up with a string `otp'` and using the same algorithm as above, generate a forged value `h'` and `rand_fake_key` with a made-up master key. On submitting the CSRF POST request, LastPass will store `h'` as authenticating Alice.

Mallory can then use `otp'` to log-in to LastPass using `otp'`. Of course, decrypting the `rand_fake_key` will not give Mallory Alice's real master key. Nonetheless, using this CSRF attack, Mallory obtains Alice's encrypted password database. We find this leads to three attacks.

First, LastPass stores the list of web application entry points unencrypted, and Mallory can now read this list. This is a breach of privacy: starting with just Alice's LastPass username, Mallory now knows all the web applications Alice has accounts on.

Secondly, the encrypted password database is now available to Mallory for offline guessing. Recall that the LastPass uses a key derived from Alice's *master* password, which Alice has to memorize. Unlike the passwords randomly generated by LastPass, this master password is likely vulnerable to guessing. It is instructive to consider that, after a server breach, LastPass requires all its users to reset their passwords [41].

Finally, we also find that this attack leads to a denial of service attack. Mallory, logged in as Alice, can delete any credential in Alice's database, *despite* being unable to decrypt the database. Since the username is part of the credential, recovering all these credentials would be tedious, or in some cases impossible.

4.3 Authorization Vulnerabilities

Looking beyond vulnerabilities stemming from the nature of the web platform, we now discuss some vulnerabilities that come from logic errors in the password manager. We found that two of the three password managers that support credential sharing both mistake authentication for authorization. An attacker can create two fake accounts, Eve and Mallory, in the password manager and share Alice's credentials with Mallory by sending a correctly crafted message from Eve's account. Importantly, the actual errors do not ever involve Alice or her browser and thus the attacks work in the absence of Alice visiting the attacker's website.

4.3.1 Case Study: My1login Sharing Credentials

My1login relies on client-side encryption of the credential database. This complicates sharing: Alice and Bob need to share credentials, through My1login as an untrusted channel. My1login relies on public-keys for both Alice and Bob to share credentials: when Alice shares a credential with Bob, My1login first encrypts it with Bob's public-key before sending it to Bob. This ensures that only Bob can see the shared credentials.

Sharing My1login Credentials. Figure 7 illustrates how Alice shares a credential with Bob in My1login. In the first two steps, Alice obtains Bob's public key k_b. Then, in Step 3, Alice (i.e., Alice's My1login instance) encrypts the credential with k_b and sends the encrypted username `alice.dropbox@gmail.com` and password `hunter2` to My1login.

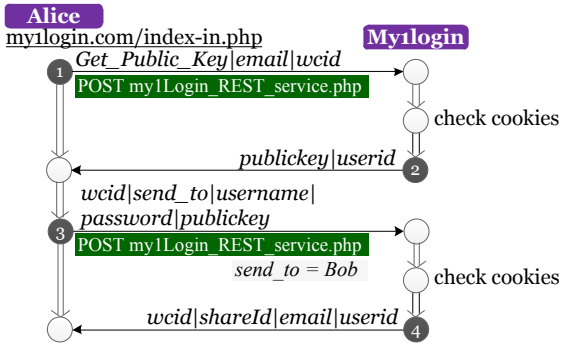

Figure 7: Sharing Credentials on My1login

```

  "settings": "{\"autologin\":\"1\", ...} ",
  "member_fullname": "Alice Gordon",
}
```

Listing 1: Example PasswordBox asset

Using the Shared Credential. Bob's My1login instance polls the My1login server for any updates. The My1login server notifies Bob of the newly shared credential, sending him the information that Alice encrypted with his public key. Bob decrypts the shared credentials (`username` and `password`) for website `url` with his private key. Once Alice shares a credential with Bob, he can also update it. In such cases, My1login automatically updates the credential globally by sharing the update with collaborators on the web card (Alice, in this case). This occurs through essentially the same request as Step 3 in Figure 7, but this time Bob encrypts the credential with Alice's public-key.

Vulnerability. Our analysis revealed that My1login only *authenticates* Alice before sharing a web card; it does not check whether Alice owns or has the authority to share the web card identified in the `wcid` (Step 3, Figure 7).

My1login Share Attack. Since My1login does not check `wcid` in Figure 7 Step 3, an attacker Mallory can share any web card (given its id) to a collaborator Eve. This vulnerability allows Mallory to steal any credential whose ID she knows (perhaps because Eve shared it in the past but revoked it later).

Worse, further analysis revealed that web card ids are globally unique, auto-incrementing numbers. In Step 3, Figure 7, Mallory can even use numbers referring to cards not yet created.

Suppose that `wcid` refers to a web card that belongs to (or will belong to) Alice. Mallory generates a dummy username and password like "userabc" and "pwdabcm," encrypts it and shares it with Eve. Eve receives the dummy credentials. While these credentials are useless, notice that this registered Eve as a collaborator on this web card, even if it belongs to Alice.

In the future, whenever Alice or any other collaborator updates the web card, the My1login client automatically re-encrypts the real credential and sends it to each collaborator, *including Eve*. It is trivial for Mallory to share all web cards, current and future, to Eve, who awaits updates to steal real credentials.

In the attack above, Eve learns Alice's credentials only if Alice updates them after the attack. Alternatively, Eve can install new credentials to Alice's database without authorization from Alice. This allows Eve to execute a form of login CSRF attack [5]. Alternatively, Eve can install wrong credentials to Alice's database, which would cause an error when Alice attempts to use them. It is likely that Alice, in response, would update the web card with her correct credentials and unknowingly share them with Eve.

One concern is how to ethically verify the My1login authorization flaw without sharing another user's credential by mistake. We observed over multiple days that it is rare that any other user creates a new web card between 2am - 3am PST. We then verified this vulnerability one day between 2am and 3am without sharing another user's credential by mistake.

4.3.2 Case Study: PasswordBox Sharing Credentials

PasswordBox stores a user's credential for a web application in a JSON-encoded *asset* file. Listing 1 presents an example asset for Dropbox. We focus on two salient properties: first, `password_k` is the encrypted value of Alice's password for `dropbox.com` and is the *only* encrypted field in the asset. Other details such as entry point URL, the name Alice used to register (`member_fullname`) and so on, are all in cleartext.

Second, our analysis revealed that `asset_id` is an auto-incrementing, unique (across all users) id for each asset. Assuming `asset_id` started at 1, we can infer that PasswordBox manages over 4 million assets, an assumption anyone can verify with the flaw we discuss next. (We did not, because of the obvious ethical concerns.)

Sharing Credentials. Figure 8 shows how a user Alice shares one of her assets identified by `asset_id` to a collaborator Bob. On clicking share, the PasswordBox extension on Alice's browser makes a POST request to the `passwordbox.com` servers that includes the

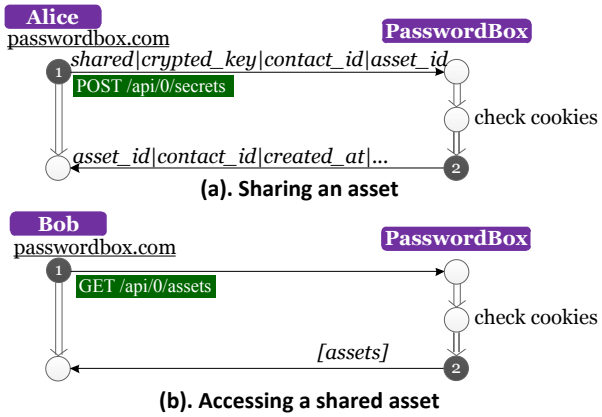

Figure 8: PasswordBox: Sharing an asset. The underlined `passwordbox.com` on the left indicates that the code making the request runs in the `passwordbox.com` origin.

```
function share(asset_id){
  var xmlhttp = new XMLHttpRequest();
  var jsn = '{"shared":true, "crypted_key:" "ABC", "contact_id": 123,
    "asset_id": '  + asset_id + '}';
  xmlhttp.open("POST","https://api0.passwordbox.com/api/0/secrets",true);
  xmlhttp.setRequestHeader("Content−type", "application/json");
  xmlhttp.send(jsn);
}
```

Listing 2: JavaScript snippet to share a asset with Eve

`contact_id`, the contact to share credentials with (in this case, Bob's id); and `asset_id`, the id of the credential to share (as in Listing 1). In the future, whenever Bob downloads the list of assets accessible to him, PasswordBox includes Alice's shared credential.

Vulnerability. The absence of a CSRF token suggested the possibility of a CSRF flaw in the protocol. Fortunately (or, unfortunately), we found that PasswordBox implemented a strong defense against CSRF attacks: it checks the `Referer` header as well as includes a special `X-CSRF-Token` in the headers of the HTTP request. Instead, we found a far more serious logic bug in the sharing assets functionality. In its sharing logic, PasswordBox never checks whether Alice owns the `asset_id` she is sharing. This allows Mallory to share assets she does not own with Eve, similar to the My1login attack (Section 4.3.1).

PasswordBox Share Attack. Similar to the "share-and-update" attack on My1login, Mallory and Eve run through the protocol in Figure 8. Mallory can share any asset to Eve by simply setting `asset_id`. Since `asset_id` is an auto increment number, Mallory can iterate through all possible `asset_id` and share all existing 4 million assets with Eve. Listing 2 is the JavaScript snippet that Mallory used to share an arbitrary asset to Eve, whose `contact_id` is assumed to be `123`.

As we noted above, PasswordBox only encrypts the password field in an asset; disclosure of every user's full name, usernames, web application URLs, and creation times is a severe privacy breach.

4.4 User Interface Vulnerabilities

Earlier, discussing bookmarklet vulnerabilities (Section 4.1), we focused on the behavior of a password manager when the user is already authenticated to the password manager. If the user is not authenticated to the password manager, then the user needs to log in to her master account. This provides a potential avenue for phishing vulnerabilities and the password manager should not train bookmarklet users towards insecure practices. The ideal secure option in such a scenario is asking the user open a new tab (manually) and logging in to the password manager.

We find that only the My1login bookmarklet defaults to this secure behavior. Clicking on the My1login bookmarklet, when not logged in, results in a message asking the user to open a new window and log in. We found that both RoboForm and LastPass bookmarklets were vulnerable to phishing attacks. Below, we discuss the RoboForm vulnerability and present the LastPass vulnerability in our technical report [27]. We also have recorded video demonstrations of these attacks online [4].

Case Study: RoboForm. Recall that when Alice clicks her RoboForm bookmarklet, the bookmarklet creates an iframe in the current web application. If Alice has not logged in to RoboForm, the iframe request redirects to the RoboForm login page, displaying a login form in the iframe. This design is insecure: it trains Alice to fill in her RoboForm password even when the URL bar (belonging to the surrounding web application) does not point to `roboform.com`. An attacker can trivially block the RoboForm iframe load and spoof an authentication dialog that steals Alice's RoboForm credentials. A secure design would ask Alice to open a new tab to RoboForm and log in.

One concern with successfully carrying out this attack is detecting whether Alice is already logged in to RoboForm. We found that the height of the RoboForm iframe (the dialog) is greater than 200px if and only if Alice is already logged-in. Using this side-channel, the attacker can modify the spoofed iframe to make the attack convincing.

5 Lessons and Mitigations

We now attempt to distill the lessons learnt from our study and provide guidance to password managers on closing the vulnerabilities we found and mitigating future ones. Our focus here is on concrete guidance and defense-in-depth. We identify improvements in architectures and protocols to mitigate vulnerabilities as well as the use of browser mitigations like CSP. We also identify anti-patterns that developers of password managers should avoid. Security reviewers and users can also rely on the patterns and (absence of) the mitigations we discuss as indicators of the security of a password manager.

5.1 Bookmarklet Vulnerabilities

All the bookmarklets we studied were vulnerable. The root cause of these vulnerabilities is that the bookmarklet code executes in the untrusted context of the webpage. The web browser guarantees a secure, isolated execution environment for iframes and we advocate an iframe-based architecture for securing password manager bookmarklets. Modern features such as credential encryption, which requires secure client-side code execution, makes the use of defenses proposed in previous work impractical [1].

Recommendation. We recommend password-managers rely on a design similar to proposed by Bhargavan et al. [8]. When the user clicks the bookmarklet, the bookmarklet code loads the password manager code in an iframe, running in the password manager's origin. The browser's same-origin policy isolates code executing in the iframe from the web application page and guarantees integrity of DOM APIs.

The password manager's iframe uses `postMessage` for communicating with the application page and maintains a simple invariant: a message carrying a credential for dropbox.com has a target origin of `https://www.dropbox.com`. The browser guarantees that only the Dropbox page receives the message. The only secret in the bookmarklet code is an HMAC function (protected by DJS [8]) that the password manager iframe can use to provide *click authentication* (i.e., the user actually clicked the bookmarklet). Unfortunately, the presence of the secret in the bookmarklet allows linkability attacks.

For unlinkability, we recommend password managers do not rely on such a secret and HMAC function. Disabling this secret loses the "click authentication" property. Since password manager browser extensions typically include "auto fill" functionality, we believe the loss of click authentication is acceptable. If needed, the code in the password manager iframe could draw a dialog to ask for user confirmation before sharing credentials with the website. Such a design is vulnerable to clickjacking and we also recommend the use of upcoming mitigations for UI security [39].

Instead, password managers could rely on asking the user for permission to share credentials in the iframe created.

The core issue behind bookmarklet vulnerabilities is the absence of secure (or "isolated") DOM APIs for bookmarklets. An alternative possibility is for browser vendors to provide bookmarklets with secure access to these DOM APIs, similar to the access granted to Chrome/Firefox extensions.

5.2 Web Vulnerabilities

We found a number of "classic" web application vulnerabilities in password managers. Based on the critical and sensitive nature of data handled by password managers, we recommend defense-in-depth features such as CSP and identify anti-patterns that developers should beware of.

XSS. XSS is a well-studied problem and we will not recapitulate all the defenses for the same here. We recommend that web applications, in addition to validating input and sanitizing outputs, should also turn on Content Security Policy to provide a second layer of defense against XSS. The absence of a strong CSP policy in a password manager should raise red flags for users and reviewers. In the applications we studied, only LastPass shipped with a Content-Security-Policy header, albeit with an unsafe policy that allows eval and inline scripts.

CSRF. The prevalence of CSRF vulnerabilities in password managers surprised us. We recommend password managers should include CSRF protection (via tokens) for *all* their pages and forms. For defense in depth, these applications should also check the Referer and Origin headers for all requests. While not a reliable defense, these headers provide a useful secondary layer of defense.

One concern with CSRF tokens is the need to create and maintain state at the server-side. This could be cumbersome for password managers that provide an interface through a browser extension: it is infeasible to request a new token before rendering every form. Instead, these applications can rely on special headers (e.g., X-CSRF-Token) for CSRF defense. The web security model disallows `evil.com` from setting headers for a cross-origin request.[2]

Secrets in JavaScript files. An anti-pattern we noticed was the presence of secret values—based off of tokens in the request URI or cookies in the request—in script files. Unfortunately, the web platform does not provide strong isolation guarantees for scripts: any (untrusted) origin can include scripts from the password manager's website. We recommend password managers

[2] Unless explicitly whitelisted by the receiving server via Access-Control-* headers.

serve *all* secret values in HTML or separate JSON files. This requirement is easy to check: the scripts used by the password managers should be the same across all users of the password manager. Serving user-specific JavaScript files based on tokens in the URI is a clear anti-pattern. An alternative is Defensive JavaScript [8], which provides a principled defense to ensure secrecy of values in JavaScript code.

5.3 Authorization Vulnerabilities

The web application vulnerabilities discussed above stemmed from quirks of the web platform (e.g., ambient authentication with cookies). Worryingly, we found a number of *logic* flaws in password managers classified under two broad categories. The first category, insufficient authorization, creates vulnerabilities exacerbated by the second category, predictable identifiers. We identify an anti-pattern, predictable identifiers, and the core security vulnerability, insufficient authorization, below and discuss mitigations.

Insufficient Authorization. Confusing authentication with authorization is a classic security vulnerability. Out of the three password managers that support collaboration, we found insufficient authorization vulnerabilities in two of them. Unfortunately, these are logic flaws, and a simple mitigation is difficult. One possibility is for password managers to use a simpler sharing model. For example, let each credential have only one owner—only the credential's owner can change it or its collaborator list. A simple model eases authorization checks and could make insufficient authorization stand out.

Predictable Identifier. Both our attacks on logic vulnerabilities rely on predictable identifiers (e.g., consecutive integers). We recommend password managers switch to cryptographically secure random numbers for identifiers—this adds defense in depth, even if the server is careful to check authorization. The use of predictable identifiers should be rare and any use should be a cause for a security review. As we discussed earlier, the nature of the data handled by password managers warrants such a default-secure posture.

5.4 User Interface Vulnerabilities

Our proposed solution of relying on iframes and storing tokens in localStorage/cookies works seamlessly only if the user is already logged in. If this is not true, the iframe needs to ask the user to log in. As our attacks demonstrated, the only secure way to do this is asking the user to manually open a new tab and login. My1login is the only password manager relying on this design and we recommend other password managers adopt a similar design. Cautious users can protect themselves against such an attack by always logging in using a new tab instead of trusting a popup or iframe.

6 Related Work

A number of researchers have investigated security of web-based password managers. Bhargavan et al. did a study on five password managers, along with a number of other web services that provide encrypted storage of data in the cloud, and presented a number of web attacks that could violate the intended security of the products [7]. This work inspired a redesign of the LastPass bookmarklet to decrypt a user's credentials inside LastPass's iframe, making it harder for an attacker to steal the master key. Adida et al. provide a comprehensive overview of a number of attacks on password manager bookmarklets; we reuse some of the ideas but find that, with modern password managers relying on encrypted credentials, a new defense based on iframes is needed [1]. Belenko et al. studied the cryptographic properties of password managers for mobile devices and their vulnerability to brute force attacks [6].

In concurrent work, Blanchou and Youn [9] as well as Silver et al. [35] found a number of serious flaws in the auto-fill functionality in password managers. In contrast, we analyze a broader range of functionality but focus on third-party web-based password managers only.

Bonneau et al. [10] presented a framework for evaluating alternatives to passwords in terms of usability, deployability, and security. This framework highlights advantages of an idealized password manager, but our work demonstrates that, in practice, password managers have flaws in their implementations that critically undermine their security. Similarly, recent work found implementation flaws in other password alternatives such as SSOs [40, 38].

The common web attack vectors we considered, such as CSRF and XSS, have seen a lot of work in the past decade. For attacks and defenses, we defer to prior literature for comprehensive surveys on CSRF [43], XSS [18], and server-side defenses for both [26]. Recent work also focused on logic flaws and insufficient authorization in web applications [17, 37, 36].

The security of mutually distrusting JavaScript running in the same origin (an important consideration in bookmarklet code) has not been a concern in the design of the web platform. Bhargavan et al. identified a number of flaws in bookmarklets and proposed a new subset of JavaScript called Defensive JavaScript to mitigate them, which we discussed in depth in Section 5.1. Defensive JavaScript [8] is the only work we are aware of that aims to protect a JavaScript gadget from the host webpage. A large body of work exists for the converse goal of protecting a host webpage from third party JavaScript code (such as code that draws a gadget) [22, 3, 13, 28]; a survey compares these approaches [15].

7 Conclusions

We presented a systematic security analysis of five web-based password managers. We found critical vulnerabilities in all the password managers and in four password managers, an attacker could steal arbitrary credentials from a user's account. Our work is a wake-up call for developers of web-based password managers. The wide spectrum of discovered vulnerabilities, however, makes a single solution unlikely. Instead, we believe developing a secure web-based password manager entails a systematic, defense-in-depth approach. To help such an effort, we provided guidance and mitigations based on our analysis. Since our analysis was manual, it is possible that other vulnerabilities lie undiscovered. Future work includes creating tools to automatically identify such vulnerabilities and developing a principled, secure-by-construction password manager.

Abstract

This paper presents SpanDex, a set of extensions to Android's Dalvik virtual machine that ensures apps do not leak users' passwords. The primary technical challenge addressed by SpanDex is precise, sound, and efficient handling of implicit information flows (e.g., information transferred by a program's control flow). SpanDex handles implicit flows by borrowing techniques from symbolic execution to precisely quantify the amount of information a process' control flow reveals about a secret. To apply these techniques at runtime without sacrificing performance, SpanDex runs untrusted code in a data-flow sensitive sandbox, which limits the mix of operations that an app can perform on sensitive data. Experiments with a SpanDex prototype using 50 popular Android apps and an analysis of a large list of leaked passwords predicts that for 90% of users, an attacker would need over 80 login attempts to guess their password. Today the same attacker would need only one attempt for all users.

1 Introduction

Today's consumer mobile platforms such as Android and iOS manage large ecosystems of untrusted third-party applications called "apps." Apps are often integrated with remote services such as Facebook and Twitter, and it is common for an app to request one or more passwords upon installation. Given the critical and ubiquitous role that passwords play in linking mobile apps to cloud-based platforms, it is paramount that mobile operating systems prevent apps from leaking users' passwords. Unfortunately, users have no insight into how their passwords are used, even as credential-stealing mobile apps grow in number and sophistication [12, 13, 24].

Taint tracking is an obvious starting point for securing passwords [11]. Under taint tracking, a monitor maintains a *label* for each *storage object*. As a process executes, the monitor dynamically updates objects' labels to indicate which parts of the system state hold secret information. Taint tracking has been extensively studied for many decades and has practical appeal because it can be transparently implemented below existing interfaces [11, 19, 5, 14].

Most taint-tracking monitors handle only *explicit flows*, which directly transfer secret information from an operation's source operands to its destination operands. However, programs also contain *implicit flows*, which transfer secret information to objects via a program's control flow. Implicit flows are a long-standing problem [8] that, if left untracked, can dangerously understate which objects contain secret information. On the other hand, existing techniques for securely tracking implicit flows are prone to significantly *overstating* which objects contain secret information.

Consider secret-holding integer variable s and pseudocode **if** s != 0 **then** $x := a$ **else** $y := b$ **done**. This code contains explicit flows from a to x and from b to y as well as implicit flows from s to x and s to y. A secure monitor must account for the information that flows from s to x and s to y, regardless of which branch the program takes: y's value will depend on s even when s is non-zero, and x's value will depend on s even when s is zero.

Existing approaches to tracking implicit flows apply static analysis to all untaken execution paths within the scope of a tainted conditional branch. The goal of this analysis is to identify all objects whose values are influenced by the condition. Strong security requires such analysis to be applied conservatively, which can lead to prohibitively high false-positive rates due to variable aliasing and context sensitivity [10, 14].

In this paper, we describe a set of extensions to Android's Dalvik virtual machine (VM) called SpanDex that provides strong security guarantees for third-party apps' handling of passwords. The key to our approach is focusing on the common access patterns and semantics of the data type we are trying to protect (i.e., passwords).

SpanDex handles implicit flows by borrowing tech-

niques from symbolic execution to precisely quantify the amount of information a process' control flow reveals about a secret. Underlying this approach is the observation that as long as implicit flows transfer a safe amount of information about a secret, the monitor need not worry about where this information is stored. For example, mobile apps commonly branch on a user's password to check that it contains a valid mix of characters. As long as the implicit flows caused by these operations reveal only that the password is well formatted, the monitor does not need to update any object labels to indicate which variables' values depend on this information.

To quantify implicit flows at runtime without sacrificing performance, SpanDex executes untrusted code in a data-flow defined sandbox. The key property of the sandbox is that it uses data-flow information to restrict how untrusted code operates on secret data. In particular, SpanDex is the first system to use constraint-satisfaction problems (CSPs) at runtime to naturally prevent programs from certain classes of behavior. For example, SpanDex does not allow untrusted code to encrypt secret data using its own cryptographic implementations. Instead, SpanDex's sandbox forces apps that require cryptography to call into a trusted library.

SpanDex does not "solve" the general problem of implicit flows. If the amount of secret information revealed through a process' control flow exceeds a safe threshold, then a monitor must either fall back on conservative static analysis for updating individual labels or simply assume that all subsequent process outputs reveal confidential information. However, we believe that the techniques underlying SpanDex may be applicable to important data types besides passwords, including credit card numbers and social security numbers. Experiments with a prototype implementation demonstrate that SpanDex is a practical approach to securing passwords. Our experiments show that SpanDex generates far fewer false alarms than the current state of the art, protects user passwords from a strong attacker, and is efficient.

This paper makes the following contributions:

- SpanDex is the first runtime to securely track password data on unmodified apps at runtime without overtainting or poor performance.
- SpanDex is the first runtime to use online CSP-solving to force untrusted code to invoke trusted libraries when performing certain classes of computation on secret data.
- Experiments with a SpanDex prototype show that it imposes negligible performance overhead, and a study of 50 popular, non-malicious unmodified Android apps found that all but eight executed normally.

The rest of this paper is organized as follows: Section 2 describes background information and our motivation, Section 3 provides an overview of SpanDex's design, Section 4 describes SpanDex's design in detail, Section 5 describes our SpanDex prototype, Section 6 describes our evaluation, and Section 7 provides our conclusions.

2 Background and motivation

Under dynamic information-flow tracking (i.e., taint tracking), a monitor maintains a *label* for each *storage object* capable of holding secret information. A label indicates what kind of secret information its associated object contains. Labels are typically represented as an array of one-bit *tags*. Each tag is associated with a different source of secret data. A tag is set if its object's value depends on data from the tag's associated source. *Operations* change objects' state by transferring information from one set of objects to another. Monitors *propagate tags* by interposing on operations that could transfer secret information, and then updating objects' labels to reflect any data dependencies caused by an operation. We say that information derived from a secret is *safe* if it reveals so little about the original secret that releasing the information poses no threat. However, if information is *unsafe*, then it should only be released to a trusted entity.

2.1 Related work: soundness, precision, and efficiency

The three most important considerations for taint tracking are soundness, precision, and efficiency. Tracking is *sound* if it can identify all process outputs that contain an unsafe amount of secret information. Soundness is necessary for security guarantees, such as preventing unauthorized accesses of secret information. Tracking is *precise* if it can identify how much secret information a process output contains. Precision can be tuned along two dimensions: better *storage precision* associates labels with finer-grained objects, and better *tag precision* associates finer-grained data sources with each tag.

Imprecise tracking leads to *overtainting*, in which safe outputs are treated as if they are unsafe. A common way to compensate for imprecise tracking is to require users or developers to *declassify* tainted outputs by explicitly clearing objects' tags.

Tracking is *efficient* if propagating tags slows operations by a reasonable amount. The relationship between efficiency and precision is straightforward: increasing storage precision causes a monitor to propagate tags more frequently because it must interpose on lower-level operations; increasing tag precision causes a monitor to do more work each time it propagates tags. Finding a suitable balance of soundness, precision, and efficiency

is challenging, and prior work has investigated a variety of points in the design space.

One approach to information-flow tracking is to use static analysis in combination with a secrecy-aware type system and programmer-defined declassifiers to prevent illegal flows [20]. This approach is sound, precise, and efficient but is not compatible with legacy apps. Integrating secrecy annotations and declassifiers into apps and platform libraries requires a non-trivial re-engineering effort by developers and platform maintainers.

An alternative way to ensure soundness is to propagate tags on high-level operations that generate only *explicit flows*. An explicit flow occurs when an operation directly transfers information from from a set of well-defined source objects to a set of well-defined destination objects [8]. For example, process-level monitors such as Asbestos [9], Flume [15], and HiStar [23] maintain labels for each address space and kernel-managed communication channel (e.g., file or socket), and propagate tags for each authorized invocation of the system API.

Such process-grained tracking is sound and efficient, but operations defined by a system API commonly manipulate fine-grained objects, such as byte ranges of memory. The mismatch between the granularity of labeled objects and operation arguments leads to imprecision. For example, once a process-grained monitor sets a tag for an address space's label, it conservatively assumes that any subsequent operation that copies data out of the address space is unsafe, even if the operation discloses no secret information.

As with language-based flow monitors, process-grained monitors must rely on trusted declassifiers to compensate for this imprecision. These declassifiers proxy all inter-object information transfers and are authorized to clear tags from labels under their control. However, because declassifiers make decisions with limited context, they can be difficult to write and require developers to modify existing apps.

Other monitoring schemes have improved precision by associating labels with finer-grained objects such as individual bytes of memory [5, 19]. While tracking at too fine a granularity leads to prohibitively poor performance [5, 19] (e.g., 10x to 30x slowdown), propagating tags for individual variables within a high-level language runtime is efficient [11]. The primary challenge for such fine-grained tracking is balancing soundness and precision in the presence of *implicit flows*.

As before, consider secret-holding variable s and pseudo-code **if** s != 0 **then** $x := a$ **else** $y := b$ **done**. Borrowing terminology from [18], we say that all operations between **then** and **done** represent the *enclosed region* of the conditional branch. Thus, the enclosed region contains explicit flows from a to x and from b to y. Operations like conditional branches induce implicit flows by transferring information from the objects used to evaluate a condition to any object whose value is influenced by an execution path through the enclosed region. We refer to the set of influenced objects as the *enclosed set*. The enclosed set includes all objects that are modified along the taken execution path as well as all objects that *might have been modified* along any untaken paths. To ensure soundness, a monitor must propagate s's tags to all objects in the enclosed set.

Propagating tags to members of the enclosed set can lead to overtainting in two ways. First, because a conditional branch does not specify its enclosed set, the membership must be computed through a combination of static and dynamic analysis [5, 18]. In our example, a simple static analysis of the program's control-flow graph could identify the complete enclosed set consisting of x and y. However, strong soundness guarantees require an overly conservative analysis of far more complex untaken paths containing context-sensitive operations and aliased variables. This can overstate which objects' values are actually influenced by a branch. Less conservative tag propagation creates opportunities for malicious code to leak secret information.

Second and more important, the amount of information transferred through a process' control flow is often very low. These information-poor flows expose the problem with tag imprecision. In particular, conventional monitors can only account for an implicit flow by propagating single-bit tags from the branch condition to members of the enclosed set. And yet members of the enclosed set can only reflect as much new information as the branch condition reveals. When the condition reveals very little information (e.g., s != 0), a single-bit tag cannot be used to differentiate between an object whose value is weakly dependent on secret information and one whose value encodes the entire secret. Thus, when an execution's control flow transfers very little information, propagating tags to members of the enclosed set significantly overstates how much secret information the branch transfers to the rest of the program state.

Prior work on DTA++[14] and Flowcheck [18] have articulated similar insights about the causes of overtainting. DTA++ propagates tags to an enclosed set only if an execution's control flow reveals the entire secret (i.e., the execution path is injective with respect to a secret input). However, DTA++ relies on offline symbolic execution of several representative inputs to select which branches should propagate tags to their enclosed sets. Offline symbolic execution provides limited code coverage for moderately complex programs and is unlikely to deter actively malicious programs.

Flowcheck focuses on the imprecision of single-bit taint tags and precisely quantifies the total amount of secret information an execution reveals (as measured in

bits). However, Flowcheck imposes significant performance penalties and must compute the enclosed set (often with assistance from the programmer) to quantify the channel capacity of enclosed regions.

To summarize, we are unaware of any prior work on information-flow tracking that provides a combination of soundness, precision, and efficiency that would be suitable for tracking passwords on today's mobile platforms.

2.2 Android-app study

To test our hypothesis that conventional handling of implicit flows leads to overtainting and false alarms, we created a modified version of TaintDroid [11] called TaintDroid++ that supports limited implicit-flow tracking. TaintDroid and TaintDroid++ track explicit flows the same way. Each variable in a Dalvik executable is assigned a label consisting of multiple tags, and tags are propagated according to a standard tag-propagation logic.

The primary difference between the two monitors is that TaintDroid ignores implicit flows and TaintDroid++ does not. First, for a Dalvik executable, TaintDroid++ constructs a control-flow graph and identifies the immediate post-dominator (ipd) for each control-flow operation. It then uses smali [1] to insert custom Dalvik instructions that annotate (1) each ipd with a unique identifier, and (2) each control-flow operation with the identifier of its ipd. Like Dytan [5], TaintDroid++ does not propagate tags to objects that might have been updated along untaken execution paths.

Using these two execution environments, we ran four popular Android apps that require a user to enter a password: the official apps for LinkedIn, Twitter, Tumblr, and Instagram. Both systems tagged password data as it was input but before it was returned to an app. We then manually exercised each app's functionality and monitored its network and file outputs for tainted data.

Figure 1 shows the number and type of tainted outputs we observed for apps running under TaintDroid and TaintDroid++. For each tainted output, we manually inspected the content to determine whether it contained password data or not. Each tainted output under TaintDroid appeared to be an authentication message that clearly contained a password. TaintDroid++ also tainted these outputs, but generated many more tainted network and file writes. We were unable to detect any password information in these extra tainted outputs, and regard them as evidence of overtainting.

Overtainting is only a problem if incorrectly tainted data is copied to an inappropriate sink. Thus, a false positive occurs when an app copies data that is safe but tainted to an inappropriate sink. Apps authenticate using the OAuth protocol and should not store a local copy

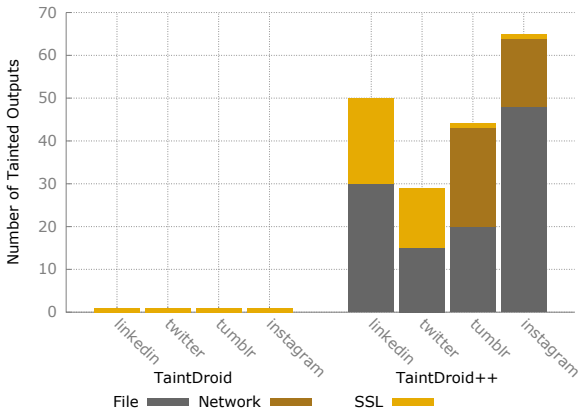

Figure 1: Tainted outputs for apps running under TaintDroid and TaintDroid++.

of a password once they receive an OAuth token from a server. Thus, each tainted file write generated under TaintDroid++ is a false positive.

For network writes, we also consider whether the password data was sent over an encrypted connection (i.e., over SSL) and the IP address of the remote server. Both Tumblr and Instagram under TaintDroid++ generated unencrypted tainted network writes. None of these writes were tainted under TaintDroid. Furthermore, TaintDroid only taints outputs to appropriate servers, but under TaintDroid++ several overtainted outputs were sent to third-parties such as the cloudfront.net CDN and flurry.com analytics servers. These results are consistent with previous work on overtainting [4, 22], and confirm that securing users' passwords requires a better balance of soundness and precision.

3 System Overview

This section provides an overview of SpanDex, including the principles and attacker model that inform its design.

3.1 Principles

SpanDex's primary goal is to soundly and precisely track how information about a password circulates through a mobile app. For example, if an app requests a Facebook password, then SpanDex should raise an alert only if the app tries to send an unsafe amount of information about the password to a non-Facebook server. Preventing leaks also requires a way for users to securely enter and categorize their passwords, and to address these issues we rely on secure password-entry systems such as ScreenPass [17]. SpanDex is focused on tracking information *after* a password has been securely input and handed over to an untrusted app. The following design principles guided our work.

Monitor explicit and implicit flows differently. In practice, explicit and implicit flows affect a program's state in very different ways. Operations on secret data that trigger explicit flows transfer a relatively large amount of secret information to a small number of objects. The inverse is true of control-flow operations that depend on secret data. These operations often transfer very little secret information to members of a large enclosed set. These observations led us to apply different mechanisms to tracking explicit and implicit flows.

First, SpanDex uses conventional taint tracking to monitor explicit flows. SpanDex is integrated with TaintDroid and Android's Dalvik VM, and maintains a label for each program variable. Each label logically consists of a single-bit tag indicating whether the variable contains an unsafe amount of information about a character within a user's password. Because explicit flows transfer a relatively large amount of information between objects, when an object's tag is set, SpanDex assumes that the variable contains an unsafe amount of secret information.

Second, when SpanDex encounters a branch with a tainted condition, it does not immediately propagate tags to objects in the enclosed set. Rather, SpanDex first updates an upper bound on the total amount of secret information the execution's control flow has revealed to that point. This upper bound precisely captures the maximum amount of secret information that an attacker could encode in untagged objects. As long as the total amount of secret information transferred through implicit flows is safe, SpanDex can ignore where that information is stored.

Like DTA++, SpanDex borrows techniques from symbolic execution to quantify the amount of information revealed through implicit flows. In particular, SpanDex integrates operation logging with tag propagation to record the chain of operations leading from a tainted variable's current state back to the original secret input. When SpanDex encounters a tainted conditional branch, it updates its information bounds by using these records to solve a constraint-satisfaction problem (CSP). The CSP solution identifies a set of secret inputs that could have led to the observed execution path. This set precisely captures the amount of information transferred through implicit flows.

The drawback of applying these techniques at runtime is the potential for poor performance. A monitor can efficiently record operations on tainted data at runtime, but solving a CSP when encountering a tainted branch could be disastrous. In the worst case, trying to solve a CSP could cause a non-malicious app to halt. For example, passwords must be encrypted before they are sent over the network, but it is infeasible to compute the set of all plaintext inputs that could have generated an encrypted output. Balancing the need to track implicit flows while preventing common primitives such as cryptography from slowing, or even halting, non-malicious apps led to our second design principle.

If commonly used functionality makes tracking difficult, force apps to use a trusted implementation. Mobile apps typically receive a password, perform sanity checks on the characters, encode the password as an http-request string, encrypt the http-request, and forward the encrypted string to a server. The code used to transform password data from one representation to another (e.g., encoding a character array as an http-request string and then encrypting the string) is problematic because it uses a number of operations that make quantifying implicit flows prohibitively slow or even impossible. This code includes a large number of bit-wise and array-indexing operations interleaved with tainted conditional branches. If SpanDex tracked implicit flows within this code as we have described thus far, non-malicious apps would become unusable.

Fortunately, it is exceedingly rare for apps to implement this functionality themselves. Instead, apps rely on platform libraries for common transformations, such as character encoding and cryptography. On Android this library code is small in size, easy to understand, and protected by the Java type system.

Tracking explicit flows remains the same for trusted libraries as for untrusted app code. However, within a trusted library, SpanDex does not solve CSPs when encountering a tainted branch and may directly update the information bound of a secret before exiting. This approach is sound for library code whose state is strongly encapsulated and whose semantics are well understood.

For example, encrypting a tainted string involves a sequence of calls into a crypto library for initializing the algorithm's state, updating that state, and retrieving the final encrypted result. Ignoring tainted conditional branches within this code is sound for two reasons. First, tracking explicit flows within the library ensures that any intermediate outputs as well as the final output are properly tagged. Second, external code can only access library state through the narrow interface defined by the library API; there is no way for untrusted code to infer properties about the plaintext except those that the library explicitly exposes through its interface or by branching on the plaintext data itself. SpanDex tracks both cases.

The protection boundary separating untrusted code from trusted library code has two novel properties. First, the boundary is defined by both data flow and control flow. An app is allowed to use a custom cryptographic implementation on untainted data, but must use the trusted crypto library to encrypt tainted data. Second, the boundary is enforced by the aggregate complexity of

the operations performed rather than by hardware or a conventional software guard. If an app attempts to encrypt password data using a custom implementation *or* branches on encrypted data returned by the trusted library, it will be forced to solve an intractable CSP and halt.

Thus, the key property of a SpanDex's sandbox is that it restricts the classes of computation that untrusted code may directly perform on secret data. Instead, an app must yield control to the trusted platform so that these computations can be performed on its behalf.

Given an execution environment that can efficiently quantify the amount of secret information transferred through implicit flows, SpanDex's final challenge is determining whether the quantified amount is safe to release. This challenge led to our final design principle.

Use properties of a secret's data type to set release policies. Like SpanDex, DTA++ requires a threshold on the amount of information revealed through implicit flows. DTA++ applies a strict policy to determine when to propagate tags by doing so only when the control flow is injective. That is, DTA++ propagates tags when a single secret value could have led to a particular execution path.

Though simple, this policy is inappropriate for SpanDex. Revealing an entire secret value via implicit flows is clearly unsafe, but revealing partial information about a password may be too. For example, using carefully crafted branches, malware could cause significant harm by narrowing every character of a password to two possible values. However, as we have seen, treating all implicit flows as unsafe leads to prohibitive overtainting. SpanDex's challenge is to support practical release policies that sit between these two extremes.

SpanDex benefits from its focus on passwords. Passwords have a well-defined representation and fairly well understood attacker model. For example, it is reasonable to assume that an attacker knows that a password consists of a sequence of human-readable characters (i.e., ASCII characters 32 through 126), many of which are likely to be alphanumeric. An attacker gains no new information from observing the control flow of a process if the flow reveals that each character is within the expected range of values. We investigate what apps' control flows reveal in Section 6.

3.2 Trust and attacker model

SpanDex is implemented below the Dalvik VM interface (i.e., the Dex bytecode ISA), and the protections provided by this VM provide the foundation for SpanDex's trust model. Most Android app logic is written in Java and compiled into Dex bytecodes, which run in an isolated Dalvik VM instance. SpanDex cannot protect passwords from an app that executes third-party native code *while there is password data in its address space*. Thus, objects tainted with password data must be cleared before an app is allowed to execute its own native code. In addition, once a process invokes third-party native code, it may not receive password data. SpanDex must rely on the kernel to maintain information about which processes have invoked third-party native code. Finally, apps may not write tainted data to persistent storage or send it to another app via IPC.

SpanDex is focused on securely tracking how password data flows within an app. Attacks on other aspects of password handling are outside the scope of our design. First, we assume that users can securely enter their password before it is given to an app, and that users will tag a password with its associated domain. A secure, unspoofable user interface, such as the one provided by ScreenPass [17], can provide such guarantees. Special purpose hardware, such as Apple's Touch ID fingerprint sensor and secure enclave [2], could also provide this guarantee.

Second, SpanDex can help ensure that password data is shared only with servers within the domain specified by the user, but provides no guarantees once it leaves a device. For example, SpanDex cannot prevent an attacker from sending a user's Facebook password as a message to a Facebook account controlled by the attacker. Preventing such cases requires cooperation between SpanDex and the remote server. SpanDex could notify the service when a message contains password data, and the service could determine whether such messages should contain password data.

We assume that an attacker completely controls one or more apps that a user has installed, and that the attacker is also in control of one or more remote servers. The attacker's servers can communicate with the attacker's apps, but the servers reside in a different domain than the one the user associates with her password. The attacker can make calls into the platform libraries and manipulate its apps' data and control flows to send information about passwords to its remote servers.

Based on the large-scale leakage of large password lists from major services, such as Gawker [21] and Sony Playstation [3], we assume that an attacker has access to a large list of unique passwords, and that the user's password is on the list. However, we assume that the attacker does not know which usernames are associated with each entry in its list (though it does know the user's username).

Thus, our attacker's goal is to de-anonymize the user within its password list using information gathered from its apps. The attacker can send its servers as much untainted data describing a user's password as SpanDex's release policies allow (i.e., the password length as well

as a range of possible values for each password character). In the worst case, the attacker will eliminate all but one of the passwords in its list. On the other hand, if the app provides no new information, then the user's password could be any on the list.

Once the attacker has computed the set of possible passwords for a username, it can only identify the correct username-password combination through online querying. For example, if an attacker infers that Bob's Facebook password is one of ten possibilities, then the attacker needs at most ten tries to login to Facebook as Bob.

The attacker may also have extra information about the usage distribution of passwords in its database. For example, the attacker may know that one password is used by twice as many users as another. While information from the app can help the attacker narrow a user's password to a smaller set of possibilities, the usage distribution allows the attacker to prioritize its login attempts to reduce the expected number of attempts before a successful login. We return to this issue in Section 6.

4 SpanDex

As with conventional taint tracking, SpanDex updates objects' labels on each operation that generates an explicit flow. If the monitor encounters a control-flow operation with a tainted condition, it does not update the labels of objects in the enclosed set. Instead, the monitor updates an upper bound on the amount of information the execution's control flow has revealed about the secret input.

SpanDex represents this bound as a *possibility set (p-set)*. SpanDex maintains a p-set for each password character an app receives. P-sets logically contain the possible values of a character revealed by a process' control flow. Each time the app's control flow changes as a result of tainted objects, SpanDex attempts to remove values from the secret's p-set.

4.1 Operation dag

In order to narrow a p-set, SpanDex must understand the data flow from the original secret values to a tainted condition. We capture these dependencies in an *operation dag (op-dag)*. This directed acyclic graph provides a record of all taint-propagating operations that influenced a tainted object's value as well as the order in which the operations occurred.

SpanDex reuses TaintDroid's label-storage strategy, and stores each 32-bit label adjacent to its object's value. However, whereas each bit in a TaintDroid label represents a different category of sensitive data (e.g., location or IMEI), SpanDex labels are pointers to nodes in the op-dag. If an object's label is null, then it is untainted. If an object's label is non-null, then its value depends on secret data.

Label storage in SpanDex most significantly differs from TaintDroid for arrays. In TaintDroid, each array is assigned a single label for all entries. If any array element becomes tainted, then the entire array is treated as tainted. This approach is inappropriate for SpanDex because we want to track individual password characters. Thus, SpanDex maintains per-entry labels. However, the reason that TaintDroid maintains a single label for each array is storage overhead. Byte and character arrays account for a large percentage of an app's memory usage, and assigning a 32-bit label for each byte-array entry could lead to a minimum fourfold increase in memory overhead for array labels.

To avoid this overhead, SpanDex allocates labels for arrays only after they contain tainted data. Each array is initially allocated a single label. If the array is untainted, then its label points to null. If the array contains tainted data, then its label points to a separate label array, with one label for each array entry. As with local-variable and object-field labels, array-element labels point to nodes in the op-dag. Since very few arrays contain password data, the overhead of maintaining per-entry labels is low overall.

The roots of the op-dag are special nodes that contain the original value of each secret (i.e., each password character), a pointer to the secret's p-set, and domain information. A p-set is represented as a doubly-linked list of value ranges. Each entry in the list contains a pointer to the previous and next entries, as well as a minimum and maximum value. Ranges are inclusive, and the union of the ranges specifies the set of possible secret values revealed by an app's control flow. SpanDex initializes p-sets to the range $[32, 126]$ to represent all printable ASCII characters. A secret's domain can be specified by the user through a special software keyboard [17].

Each tainted object version has an associated non-root node that records the operation that created the version, including its source operands. Source operands can be stored as concrete values (when operands are untainted) or as pointers to other nodes in the op-dag (when operands are tainted).

A node can point to more than one node, and there may be multiple paths from a node to one or more roots. The more complex the paths from a node to the op-dag roots are, the more complex updating p-sets becomes.

4.2 Example execution

If a tainted variable influences an app's control flow (e.g., via a conditional branch), then SpanDex traverses the op-dag from the node pointed to by the object's label toward

the roots. To demonstrate how SpanDex maintains and uses op-dags and p-sets, consider the simple snippet of pseduo-code below. Figure 2 shows the resulting op-dag and p-set.

```
0000: mov v1, v0          // v0, v1 label=ROOT
0002: add v2, v1, 3       // v2's label=N1
0004: add v2, v2, 2       // v2's label=N2
0006: sub v3, 6, v2       // v3's label=N3
0008: add v2, v2, 7       // v2's label=N4
000a: const/16 v4, 122    // v4's label=0
000c: if-le v3, v4, 0016
000e: ...
```

The first character of the password is 'p', or numeric value 112, and is stored in register v0. The password's domain is Facebook. v0's label points to the Root node for the secret character. v0 is then copied into v1, whose label must also point to Root. The sum of v1 and 3 is then stored in v2, whose label then points to new node, N1. N1 contains the addition operation, the 3 operand, and points to Root. The next line adds 2 to v2. This creates a new version of v2, which is recorded in N2. N2 contains the 2 operand and points to the node for the previous version of v2, node N1. The remaining arithmetic operations proceed similarly. Finally, the code loads the constant value of 122 into v4 for an upcoming conditional branch. v4's label is null, since it is not tainted.

When the code reaches the conditional branch, v3 is less than or equal to v4, since v3's value is 111, and v4's value is 122. Because v3's label is non-null, SpanDex uses the op-dag node in v3's label (N3) to update the p-set.

Updating the p-set is equivalent to solving a CSP to determine which secret values could have led to the control-flow change. In our example, updating the p-set is easy. SpanDex solves the inequality $v0+6-2-3 \leq 122$, leading to $v0 \leq 121$. Thus, the control flow reveals that the first character of the user's password is within the range of $[32, 121]$. SpanDex updates the p-set to reflect this before resuming execution. Figure 2 shows the state of the op-dag and p-set at this point.

This simple example demonstrates some of the challenges and nuances of SpanDex's approach. First, each node in the op-dag represents a version of a tainted variable. N3 points to the version of v2 used to update v3, so that when SpanDex reaches the conditional branch, it can retrieve the sequence of operations that led to v3's current value.

Second, reversible operations such as addition and subtraction make updating p-sets straightforward. Unfortunately, Dalvik supports a number of instructions that are much trickier to handle. For example, Dalvik supports instructions for operating on Java Object references and arrays that behave very differently than simple arithmetic operations. Even some classes of arithmetic operations, such as bit-wise operators and division, can make solving a CSP non-trivial.

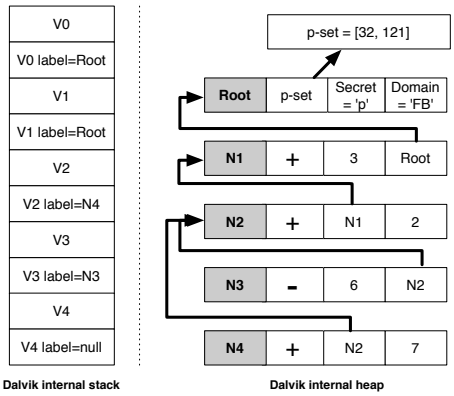

Figure 2: Simple op-dag and p-set example.

Third, there was a single path from N3 to Root in our example. If N3 had forked due to multiple tainted operands, or had led to multiple root nodes due to mixing secret characters, solving the CSP would have been far more complex. Compression and cryptography often mix information from multiple characters, which creates a complex nest of paths from nodes to the op-dag roots.

Fortunately, among the popular non-malicious apps that we have studied, difficult-to-handle operations occur only in platform code such as the Android cryptography library. Furthermore, it is rare to find apps that branch on the results of these operations outside of platform code. Thus, as long as SpanDex can ensure that all outputs from these libraries are explicit and tainted, then we can ignore implicit flows within them (and, thus, avoid CSP solving).

This approach is intuitive. First, outside of simple sanity checking on a password, there is little reason for an app to operate on password data itself. Second, libraries such as a crypto library are designed to suppress implicit flows. Observing an encrypted output or a cryptographic hash should not reveal anything about the plaintext input. Third, there is no obvious reason why app code should branch on either encrypted data or a cryptographic hash. Apps simply use the platform libraries to encode these outputs as strings and send them to a server.

There are many difficult operations that we have not observed in either app code or library code. Our general approach to these operations is to propagate taint to the results of these operations, but to fault if they cause the control flow to change. For example, an app may use bit-wise operations to encode a character, but branching on the encoded result is not allowed. This is secure and does not disrupt non-malicious apps. In the next section, we describe how SpanDex treats each class of Dex bytecodes in greater detail.

4.3 Dex bytecodes

In this section, we describe how SpanDex handles each of the following classes of bytecodes: type-conversion operations, object operations, control-flow operations, arithmetic operations, and array operations.

Type conversions. Dalvik supports the following data types: boolean, byte, char, short, int, long, float, double, and Object reference, as well as arrays of each of these types. P-set ranges are represented internally as pairs of floats. Solving CSPs involving conversions to alternate representations is supported as long as the type is a native and numeric.

Object operations. Dex provides a number of instructions for converting between data types, but conversions can also occur through Object-method invocations and arrays. For example, an app could index into an Object array with a tainted character, where the fields of each Object encodes its position in the array. The returned Object reference would be tainted, and would identify the character used to index into the array. The return value of any method used to access a field of the tainted Object would also be tainted. However, SpanDex would have to understand the internal semantics of the Object in order to solve a CSP involving the tainted returned value. Thus, branching on data derived from a tainted Object reference is not allowed.

Control-flow. A Dalvik program's control flow can change as a result of secret data in many ways. Conditional branch operations such as `if-eq` are the most straightforward, and SpanDex handles these as described in Section 4.2.

Dalvik also supports two case switching operations: `packed-switch` and `sparse-switch`. Both instructions take an index and a reference to a jump table as arguments. The difference between the instructions is the format of the jump table and how it is used. The table for a `packed-switch` is a list of key-target pairs, in which the keys are consecutive integers. Dalvik first checks to see if the index is within the table's range of consecutive keys. If it is not, then the code does not branch and execution resumes at the instruction following the switch instruction. If it is in the table, then the code computes the new PC by adding the matching target to the current PC.

The table for a `sparse-switch` is also a list of key-target pairs, but the keys do not have to be consecutive integers (though they have to be sorted from low-to-high). To handle this instruction, the VM checks whether the index is greater than zero and less than or equal to the table size. It then uses the index to perform a binary search on the keys to find a match. If it finds a match, then it jumps to the instruction at the sum of the matching target and current PC.

Although more complex than conditional branches, handling these switch instructions is straightforward. If the code falls through the switch instruction, then the resulting implicit flow reveals that the index is not equal to any of the table keys. SpanDex can solve a CSP for each of the keys and update its p-sets accordingly. If the control-flow is diverted by the switch instruction, then the resulting implicit flow reveals that the index is equal to the matching table key. SpanDex can solve a CSP for this condition as well. In practice, most switch instructions are packed and the corresponding jump tables are small, which makes solving CSPs for these operations fast.

Finally, a program's control flow can be influenced by tainted data if an operation on tainted data causes an exception to be thrown. For example, an app could divide a number by a tainted variable with a value of zero, or it could use a tainted variable to index beyond the length of an array. SpanDex could compute a CSP for the information revealed by each of these conditions, e.g., that a tainted variable is equal to zero or that a tainted variable is greater than the length of an array. However, we have not seen this behavior in any of the apps we have studied. As a result, our current implementation simply stops the program when an instruction with a tainted operand causes an exception to be thrown.

Arithmetic. As we saw in Section 4.2, reversible arithmetic operations are straightforward to handle. Other arithmetic operations are not impossible to handle, but require a complex solver. For example, reversing multiplication and division operations is tricky because of rounding. Bit-wise operations are even more difficult to reason about. Fortunately, it is exceedingly rare for app code to branch on the results of these operations. Instead, we have observed that trusted library code is far more likely to branch on the results of these operations. As long as we can ensure that all library outputs are explicit, then we do not need to solve CSPs involving difficult operations when in trusted code.

Arrays. Dex provides instructions for inserting (`iput`) and retrieving (`iget`) data from an array. Due to type-conversion problems, SpanDex does not allow tainted indexing of non-numeric arrays. In particular, an app may not use a tainted variable to index into an Object array.

Handling an `iget` operation requires keeping a checkpoint of the array in the op-dag node for the variable holding the result. For example, say that all of the entries in an int array are zero or one, and that an app indexes into the array with a tainted variable. The returned value would be stored in a tainted variable. If the app later branched on the tainted variable, then SpanDex must look at the array checkpoint to determine which indexes would have returned the same value as the exe-

cuted `iget`. In practice, tainted `iget` instructions are rare, and when they do occur the arrays are small.

Unlike a tainted `iget`, a tainted `iput` instruction is dangerous. Consider an attacker that initializes an array a with known size, such that all entries are equal to zero. It then stores the first password character in the variable s and inserts a one into $a[s]$. Because SpanDex maintains per-entry labels for arrays, $a[s]$ is tainted, but no other entries are. The attacker can then incrementally send each value in the array to its server: only $a[s]$ is tainted and will be stopped by SpanDex. Unfortunately, stopping the app at this point is too late, since the number of received zeros reveals the value of s. As a result of this attack, tainted `iput` instructions are illegal.

Finally, Dex also provides instructions such as `filled-new-array` for creating and populating arrays, and SpanDex disallows tainted operands on these instructions.

4.4 Trusted libraries

As described above, there are a number of operations on tainted data that would add significant complexity to SpanDex's CSP solver to support. Even worse, the complexity of the op-dags that combinations of these operations would create make it doubtful that even a sophisticated solver could handle them quickly, if at all. Ideally, these operations would never arise, and if they did, an app would never branch on their results. Sadly, this not the case. Many apps require cryptographic and string-encoding libraries to handle passwords, and these libraries are rife with difficult to handle operations as well as branching on the results of those operations.

Trying to solve such complex CSPs would make SpanDex unusable: non-malicious apps would halt just trying to encrypt a password. At the same time, ignoring flows generated by these operations is not secure. Luckily, we have observed that branching on the results of difficult operations consistently occurs within a handful of simple platform libraries.

Thus, SpanDex's approach to handling difficult implicit flows is to identify the functionality that creates them in advance and to isolate these flows inside trusted implementations. As long as the outgoing information flows from these libraries are always tainted and explicit, SpanDex does not need to worry about their internal control-flow leaking secret information. Furthermore, this code is open and well known, is protected by the Java type system, and can be modified to eliminate implicit flows through the library API.

The set of libraries that SpanDex trusts not to leak information implicitly is: java.lang.String (selected methods excluded), java.lang.Character, java.lang.Math, java.lang.IntegralToString, java.lang.RealToString, java.lang.AbstractStringBuilder, java.net.URLEncoder, java.util.HashMap, android.os.Bundle, android.os.Parcel, and org.bouncycastle.crypto. Nearly all of this code is either stateless string encoding and decoding or cryptography.

4.5 Various attacks and counter-measures

We described several attacks in Section 3.2 that are beyond the scope of SpanDex. In this section, we describe several other attacks and how SpanDex might handle them.

First, SpanDex does not allow tainted data to be written to the file system or copied to another process via IPC. This is reasonable because mobile apps should only require a user's password to retrieve an OAuth token from a remote server. After receiving the token, the app should discard the user's password. If an app tries to copy tainted data to an external server, then SpanDex must consult the domains in the set of reachable op-dag root nodes.

Second, an attacker could have multiple apps under its control generate multiple overlapping (but not identical) p-sets. Each individual p-set would appear safe, but when combined at the attacker's server, they could collectively reveal an unsafe amount of information. Relatedly, a malicious app could request a user's password multiple times and compute different ranges on each password copy.

One way to detect this class of attacks is by inspecting the membership of a secret's p-sets. For the apps that we have observed, p-sets usually correspond to natural character groupings, e.g., numbers, lower-case letters, upper-case letters, and related special characters. P-sets containing unusual character groupings could be a strong signal that an app is malicious.

The solution to this attack suggests a larger class of counter-measures that use information from the p-sets and op-dag to detect malicious behavior. For example, anomalous operation mixes or an unusually large op-dag could indicate an attack. One of the advantages of SpanDex is that it gives the monitor a great deal of insight into how an app operates on password data. We believe that this information could enable a rich universe of policies, though enumerating all of them is beyond the scope of this paper.

Finally, it is possible that SpanDex is vulnerable to certain classes of side-channel and timing attacks that we have not considered. However, any attack that relies on branching on tainted data would be detected. For example, consider the well-known attack on Tenex's password checker [16]. Even though the attack uses a page-fault side channel that is out of SpanDex's scope, SpanDex would have prevented it because each additional charac-

ter comparison would have narrowed its p-set to an unsafe level.

5 Implementation

Our SpanDex prototype is built on top of TaintDroid for Android 2.3.4. We modified TaintDroid to support p-sets and op-dags, and made several modification to the Android support libraries. Most of our changes to these libraries were made in java.lang.String.

First, public String methods whose return value could reveal something about a tainted string's value are not considered trusted to ensure that p-sets are updated properly (e.g., equals(Object), compareTo(String)).

Second, as a performance optimization, the Dalvik VM replaces calls to certain performance-critical Java methods with inlined "intrinsic" functions that are written in C and built in to the Dalvik VM (e.g., String.equals(Object), String.compareTo(String)). However, if an intrinsic inlined function operates on a tainted string and performs comparisons involving the string's characters, we are unable to update the p-sets accordingly. To avoid this, we modified Dalvik's intrinsic inlines that operate on strings to check if the string is tainted and, if so, invoke the Java version instead.

Third, Android's implementation of java.lang.String performs an optimization when converting an ASCII character to its String value: it uses the character's ASCII code to index into a constant char array containing all ASCII characters. If the character to be converted is tainted, we prevent this optimization from being used, as it would result in an array lookup with a tainted index.

Finally, we modified the android.widget.TextView and implemented a custom IME with a special tainted input mode that can be enabled to indicate to SpanDex when a sequence of characters is sensitive (i.e., a password).

6 Evaluation

In order to evaluate SpanDex, we sought answers to the following questions: How well does SpanDex protect users' passwords from an attacker? What is the performance overhead of SpanDex?

6.1 Password protection

As described in Section 3.2, we have designed SpanDex based on an attacker that has access to a large list of cleartext passwords. The attacker knows that a user's password is in the list, and uses untainted information from its malicious app to narrow a user's password to a smaller set of possibilities. To understand how well SpanDex can protect users from such an attack, we need to know the kind of p-sets that real apps induce, we need access to a large list of cleartext passwords, and we need a realistic distribution of how passwords are used. All of these pieces of information will allow us to calculate the number of expected logins an attacker would need to guess a user's password, given the amount of untainted password information that SpanDex allows apps to reveal.

First, we ran 50 popular apps from Google's Play Store. Each of these apps required a login, and we used the same 35-character password for each app. The password contained one lower-case letter ("a"), one upper-case letter ("A"), one number ("0"), and one of each of the 32 non-space special ASCII characters. 42 ran without modification[1]. The top row of Table 1 shows each character in the password.

Eight apps invoked native code before requesting a user's password[2]. While these apps would have to be modified to run under SpanDex, waiting to invoke native code before requesting a user's password is unlikely to require major changes. All other apps ran normally.

For the 42 apps that ran unmodified, after their password was sent, we inspected the p-set for each password character and counted its size. Table 1 shows the maximum, 75th percentile, median, 25th percentile, and minimum p-set size for each password character. The header of the table shows the password. The first thing to notice is that the p-sets for the letters in our password (i.e., "A" and "a") were never smaller than 26. This makes sense, since each app is branching to determine that the character is either a lower or upper case letter. The same is true for the number in our password, "0". No numeric p-set was smaller than 10.

The more difficult cases are the non-alphanumeric special characters. For these cases, the p-sets are fairly app specific. In some cases, the app's control flow depends on a specific character (e.g., Skout with several special characters), but most characters' p-sets remain large across most apps. With the exception of "*", "-", ".", and "_", all non-alphanumeric characters had large p-sets for 75% of apps or more.

Given this observed app behavior, we next obtained the uniqpass-v11 list of 131-million unique passwords [7]. The list contains passwords from a number of sources, including the Sony [3] and Gawker [21] leaks. To simulate an attack, we selected a password, p, from the list and computed the p-sets that a typical app would generate for p. In particular, we assume that the at-

Table 1: Password-character p-set sizes for 42 popular Android apps

tacker can infer p's length and whether each character is a lower-case letter (26 possibilities), an upper-case letter (26 possibilities), a number (10 possibilities), or a member of a block of special ASCII characters (i.e., the 16 characters below "0", the seven characters between "9" and "A", the six characters between "Z" and "a", and the four characters after "z").

This information gave us a kind of regular expression for p based on the type of each of its characters. We call the set of passwords matching this expression the *match set* and the size of the match set the *match count*. The larger a password's match count, the more uncertain an attacker is about what password the user entered. We computed the match count for all passwords in the uniqpass list in this way. Finally, we counted the number of passwords with a given match count to arrive at the inverse distribution function.

These calculations show that if SpanDex allows an attacker to learn the p-sets for a password from a typical app, the attacker will have trouble narrowing the set of possible passwords for the user. In particular, 92% of passwords have a match count greater than 10,000, 96% of passwords have a match count greater than 1,000, 98% of passwords have a match count greater than 100, and 99% of passwords have a match count greater than 10.

Unfortunately, recent work on a variety of password databases suggest that password usage follows a zipf distribution [6]. Thus, we also model the N passwords in a match set as a population of N elements that contains exactly one success (as a user would only have one correct password). Next, we let n be the random variable denoting the number of tries required to guess the correct password and find $E[n]$, the expected value of n. If the passwords are all equally probable, we try them in random order. Otherwise, we try them in the descending order of their probability. Note that each password try is done without replacement, i.e., after trying i passwords, we only consider the remaining $(N-i)$ passwords when picking the next most probable password.

A study of the distribution of passwords publicly leaked from Hotmail, flirtlife.de, computerbits.ie, and RockYou found that the passwords in each of these sets can be reasonably modelled by a zipf distribution with s parameter values of 0.246, 0.695, 0.23, and 0.7878 respectively [6]. Using these values of s, we modeled the passwords in each match set and computed the CDF of

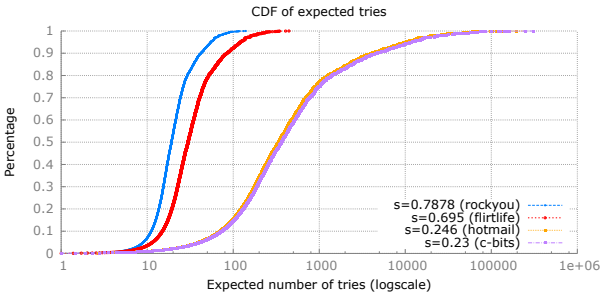

Figure 3: CDFs of expected login attempts using the uniqpass password list.

$E[n]$.

When $s = 0.7878$, 95% of the time, the attacker is likely to guess the correct password within 50 tries. When the s value for the zipf distribution is 0.246 or less, 99% of passwords are expected to require 10 or more login attempts, and 90% of passwords are expected to require 80 or more attempts. Figure 3 shows the CDFs for all four s values.

Unfortunately, we do not know the usage distribution for the uniqpass dataset since it contains only unique passwords.

6.2 Performance overhead

To measure the performance overhead of SpanDex we used the CaffeineMark benchmark and compared it to stock Android 2.3.4 and TaintDroid. Both TaintDroid and SpanDex ran without any tainted data. Since SpanDex only handles password data that is discarded after an initial login, this is SpanDex's common case. The benchmark was run on a Nexus S smartphone. The results are in Figure 4.

Overall, SpanDex performs only 16% worse than stock Android and 7% worse than TaintDroid. Stock Android performs significantly better than either TaintDroid or SpanDex in the string portion of the benchmark. This is because TaintDroid and SpanDex both disable some optimized string-processing code to store labels.

Finally, we would like to note that when testing apps in Section 6.1, we did not encounter any noticeable slow down under SpanDex. This was due to login being dominated by network latency and the simplicity of the CSPs these apps generated.

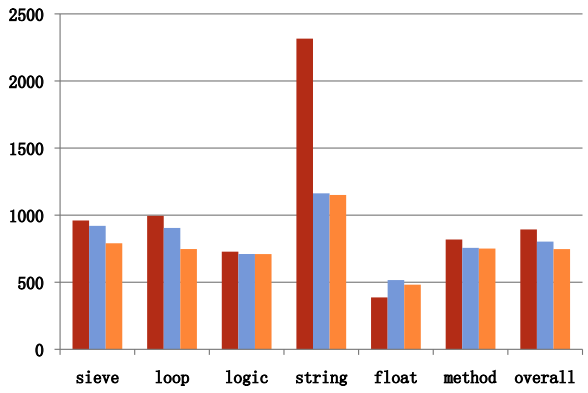

Figure 4: CaffeineMark results for Android (left bar), TaintDroid (middle bar), and SpanDex (right bar).

7 Conclusion

SpanDex tracks implicit flows by quantifying the amount of information transferred through implicit flows when an app executes a tainted control-flow operation. Using a strong attacker model in which a user's password is known to exist in a large password list, we found that for a realistic password-usage distribution, for 90% of users an attacker is expected to need 80 or more login attempts to guess their password.

SSOScan: Automated Testing of Web Applications for Single Sign-On Vulnerabilities

Yuchen Zhou David Evans
University of Virginia
[*yuchen*, *evans*]@*virginia.edu*
http://SSOScan.org

Abstract

Correctly integrating third-party services into web applications is challenging, and mistakes can have grave consequences when third-party services are used for security-critical tasks such as authentication and authorization. Developers often misunderstand integration requirements and make critical mistakes when integrating services such as single sign-on APIs. Since traditional programming techniques are hard to apply to programs running inside black-box web servers, we propose to detect vulnerabilities by probing behaviors of the system. This paper describes the design and implementation of SSOScan, an automatic vulnerability checker for applications using Facebook Single Sign-On (SSO) APIs. We used SSOScan to study the twenty thousand top-ranked websites for five SSO vulnerabilities. Of the 1660 sites in our study that employ Facebook SSO, over 20% were found to suffer from at least one serious vulnerability.

1 Introduction

Single Sign-On (SSO) services are increasingly used to implement authentication for modern applications. SSO-enabled applications allow users to log into an application using an established account (with a service such as Facebook or Twitter) and connect their account on the new site to an established Internet identity. Should the application need more information from the user, it may ask the user for extra permissions from the established service. Once granted, the requested information is returned to the application, which can then be used in the transparent account registration process.

Although these services provide SDKs intended to enable developers without security expertise to integrate their services, actually integrating security-critical third-party services correctly can be difficult. Wang et al. identified several ways applications integrating SSO SDKs can be vulnerable to serious attacks even when developers closely follow the documentation [27].

To better understand and mitigate these risks, we developed SSOScan, an automated vulnerability checker for applications using SSO. SSOScan takes a website URL as input, determines if that site uses Facebook SSO, and automatically signs into the site using Facebook test accounts and completes the registration process when necessary. Then, SSOScan simulates several attacks on the site while observing the responses and monitoring network traffic to automatically determine if the application is vulnerable to any of the tested vulnerabilities. We focus only on Facebook SSO in this work, but our approach could be used to check SSO integrations using other identity providers or other protocols. Many of our techniques could also be adapted to scan for vulnerabilities in integrating other security-critical services such as online payments and file sharing APIs.

1.1 Contributions

Our work makes two types of contributions: those related to the construction of our scanning tool which are largely independent of the particular vulnerabilities, and those resulting from our large-scale study of Facebook SSO implementations.

SSOScan. We explain the design and implementation of SSOScan (Section 3), as well as how to handle some of the challenges in the automation process. We describe techniques that automatically perform user interactions to walk through the SSO process (Section 3.1), including clicking the correct buttons and filling in registration forms. We collected information of almost 30,000 click attempts for sites that implement Facebook SSO which shows in detail how the individual heuristics are affecting SSOScan's behavior (Section 5.2). This provides experimental evidence to support our design choices and shed light on future research that shares a similar goal. SSOScan can detect whether a target application contains any of the five vulnerabilities listed in Section 2.2 with an

average testing time of 3.5 minutes, and is able to check 792 (81%) of the 973 websites that implement functional Facebook SSO from the top 10,000 with *no* human intervention at all.

Large-scale study. We ran SSOScan on the top 20,000 US websites (Section 4). Key results from the study include finding at least one vulnerability in 345 of the 1660 sites that use Facebook SSO (Section 4.1). We also learn how vulnerability rates vary due to different ways of integrating Facebook SSO (Section 4.1.1). We manually analyzed the 228 sites ranked in the top 10,000 that SSOScan cannot test automatically and report on the reasons for failures (Section 4.2). Our study reveals the complexity of automatically interacting with web sites that follow a myriad of designs, while suggesting techniques that could improve future automated testing tools. In Section 6, we discuss our experiences reporting the vulnerabilities to site owners and possible ways SSOScan could be deployed.

2 Background

This section provides a brief introduction to single sign-on systems, describes the vulnerabilities we checked, and summarizes relevant previous work.

2.1 Single Sign-On

A typical single sign-on process involves three parties. Alice first visits a web application and elects to use SSO to login. She is then redirected to the identity provider's SSO entry point (e.g., Facebook's server). After she logs into Facebook, her OAuth credentials are issued to the application server. The application server confirms the identity and authenticates the client.

OAuth uses three different types of (rather confusingly-named) credentials:

Access_token. An *access_token* represents permissions granted by the user. For example, the application may request that user grant permission to access the birthday and friend lists from her Facebook account. Upon the user's consent, a token will be issued and forwarded to the application which may then use it to obtain the granted information from Facebook. An *access_token* eventually expires, but may be valid for a long time.

Code. A *code* is used to exchange for an *access_token* through the identity provider. This exchange requires the application's unique *app_secret* to proceed. If the secret does not match, Facebook will not issue the token. This means a *code* is bound to a user as well as a target application. With Facebook SSO, the *code* expires after being used in the first exchange.

Signed_request. A *signed_request* is a base64 encoded string that contains a user identity, a *code*, and a signature that can be verified using an application's *app_secret* and some other metainformation. Once issued, it is not tied to Facebook (except for the enveloped *code*), and the signature can be verified locally.

2.2 Vulnerabilities

Our interest in building an automatic scanning tool was initially motivated by the *access_token* misuse vulnerability reported by Wang et al. [27]. We further identified four new vulnerabilities that are both serious and suitable for automatic testing. The first two vulnerabilities concern confusions about how authentication and authorization are done; the other three concern failures to protect important secrets.

Access_token misuse. This vulnerability stems from confusion about authentication and authorization. In OAuth 2.0, an *access_token* is intended for authorization purposes only because it is not tied to any specific application. When a service uses an *access_token* to authenticate users, it will also accept ones granted to any other application. Figure 1 illustrates an impersonation attack that exploits this vulnerability: Alice visits Mallory's website (step 1), logs in using Facebook SSO (2), and receives an *access_token* from Facebook (3). Then, Mallory's client-side code running in Alice's browser forwards the *access_token* to Mallory (4), which presents the token to a vulnerable application's server (5). After confirming the token represents Alice, Foo's application server authenticates Mallory as Alice (6).

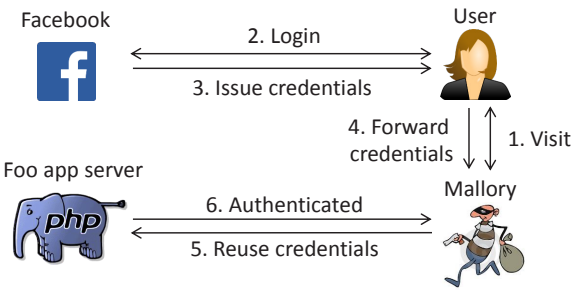

Figure 1: OAuth credential misuse

Signed_request misuse. Sometimes developers have chosen the correct OAuth credentials to use, but still end up with a vulnerable implementation. One way this happens is when information decoded from a *signed_request* is used but the signature is never checked using the *app_secret*. The attack to exploit this vulnerability is

similar to the previous one, except that Mallory needs to reuse the *signed_request* in addition to *access_token*.

App_secret leak. When a developer registers an application with Facebook, she receives an *app_secret*. It is essential for the application owner to keep it a secret because the *app_secret* is used as the key to create *signed_request*s and to access many other privileged functionalities. However, careless developers may reveal this secret to clients, especially when using *code* flow to authenticate users. By design, the *code* and *app_secret* must be sent from the application's back end server to Facebook in exchange for an *access_token*. When this exchange is carried out through the client instead of the server, *app_secret* is exposed to any malicious client.

User OAuth credentials leak. The last two vulnerabilities both leak a user's OAuth credentials. When the Facebook OAuth landing page contains third-party content, requests to retrieve those contents will automatically include OAuth credentials in the referer header, which leaks them to the third-party. To thwart this leakage, Facebook offers a layer of protection by only allowing *access_token* and *signed_request* to appear in the URL fragments, which are not visible in the referer header. Therefore only *code* can be leaked via referer unless the application intentionally pulls the credentials and puts it in the URL[1]. In addition, credentials can be exfiltrated by third-party scripts if they are present in the page content. If a malicious party is able to obtain these credentials, it could carry out impersonation attacks or perform malicious actions using permissions the user granted the original application, such as posting on the user's timeline or accessing sensitive information. Note the difference between embedding OAuth credentials in the URL and in the body content is that the former will directly leak them to third parties, while the latter only leaks the credential when the embedded third party code accesses it explicitly.

2.3 Related Work

Our work builds on extensive previous work on automatically testing applications for vulnerabilities. We briefly describe relevant approaches next, as well as previous works that analyze vulnerabilities in SSO services.

Program analysis. Program analysis techniques such as static analysis [3] and dynamic analysis including symbolic execution [7, 17] automatically identify vulnerabilities with fast testing speed and good code coverage. Runtime instrumentation techniques such as taint tracking [11] and inference [18] also help to safeguard sensitive source-sink pairs. However, these techniques require white-box access to the application (at least at the level of its binary), which is not available for remote web application testing. Automated web application testing tools that work on the server implementation [1, 8, 16] do not apply to large-scale vulnerability testing well. They either require access to application source code or other specific details such as UML or application states. For our purposes, the test target (application server implementation) is only available as a black box.

Automated security testing. Penetration testing is widely used to check applications for vulnerabilities [15, 28]. The tester analyzes the system and performs simulated attacks on it, often requiring substantial manual effort. More automated testing requires an oracle to determine whether or not a test failed. Sprenkle et al. developed a difference metric by comparing two webpages based on DOM structure and n-grams [21] and improved results using machine learning techniques [22]. SSOScan also requires an oracle (Section 3.2) to determine session identity. For our purposes, a targeted oracle works better than their generic approach.

Automated GUI testing. SSOScan is also closely related to automated GUI testing. The GUI element triggering approach we take shares some similarities with recent works to simulate random user interactions on GUI element to explore application execution space on Android system [14], native Windows applications [29], and web applications [5, 10]. Their common goal is to explore app execution space efficiently to discover buggy, abnormal or malicious behavior. By contrast, our goal is to drive the application through a particular SSO process rather than explore its execution space. Further, we need the tests to proceed fast enough for large-scale evaluation. Since each simulated user interaction with the web application involves round-trip traffic and a non-trivial delay to get the response, our primary focus is to develop useful heuristics to quickly prune search space before triggering any user interactions.

SmartDroid [32] and AppIntent [31] both aim to recover sequences of UI events required to reach a particular program state or follow an execution path obtained from static analysis. These approaches target Android applications and rely on client-side information that is not available for our web application scanning tool, where the necessary state only exists on the (inaccessible) server side.

Human cooperative testing. Off-the-shelf testing tools like Selenium [19] and TestingBot [24] can be used to discover bugs in web applications under developers' assistance. These tools replay user interactions based on testing scripts that are manually created by the applica-

[1] Surpsingly, we found several sites doing this (e.g., dealchicken.com and bloglovin.com).

tion developer. BugBuster [6] offers some automatic web application exploration capabilities, but still does not understand the application context enough to perform any non-trivial actions such as those involving authentication and business logic.

To reduce developer effort, Pirolli et al. [13], Elbaum et al. [9], and the Zaddach tool [12] show promising results by collecting interactions from normal users and replaying them to learn application states and invariants for vulnerability scanning. These works do not require extra manual effort from developers to write testing script or specify user interactions. However, one potential problem these works fail to address is user's privacy concerns when submitting interactions. This could be especially sensitive when the actions involve passwords or payments. SSOScan avoids this problem and is complementary to this line of work — SSOScan attempts to scan applications in a fully automatic fashion and does not require traces from any party.

Single sign-on security. Single sign-on has emerged as an important security service and has been well-studied in recent years. Previous works have discovered problems in protocols, bugs in SDK code and missed assumptions in developers' implementations [4, 20, 23, 25, 27]. Automated scanning is especially valuable for vulnerabilities that cannot be simply fixed by upgrading SDKs or improving the protocols, but stem from mistakes integrating the SSO service.

Integuard [30] and AuthScan [2] have similar goals with SSOScan. Integuard infers invariants across requests and responses and uses them to perform intrusion detection on future activities. AuthScan [2] is an automated tool to extract specifications from SSO implementations by using both static program analysis and dynamic behavior probing. Our goals differ in that we focus on detecting specific vulnerabilities rather than generic ones. This enables us to establish clear automation goals and build well-defined state machines for the scanner, and removes the uncertainties the previous works incur when inferring invariants or modeling unknown functions. The drawback is our approach relies on knowledge of particular vulnerabilities. For many integrated web services, including SSO, many vulnerabilities are known or can be obtained using systematic explication [27].

3 SSOScan

SSOScan consists of two main parts: the *Enroller* and the *Vulnerability Tester*. The Enroller automatically registers two test accounts at a web application using Facebook SSO. The Vulnerability Tester simulates attacks and monitors traffic to test for each vulnerability. In this section, we describe the general workflow of these modules necessary to understand the results in Section 4, but defer the details of our heuristics to Section 5.

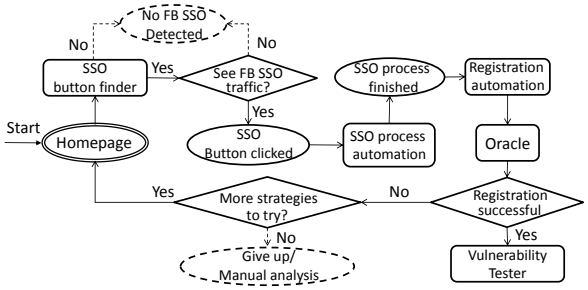

Figure 2: Enroller Overview.
Ovals represent testing states, curved rectangles represent different modules in our tool, and diamonds represent control flow decisions.

3.1 Enroller

Figure 2 shows the workflow of the Enroller. Given a target web application, our tool first removes all cookies from the browser and navigates to the target URL. A short delay after the page has fired its onload event, the SSO button finder (Section 3.1.1) analyzes the DOM and outputs the most likely candidate elements for SSO button. The Enroller then simulates clicks on those elements, monitoring traffic to listen for the Facebook SSO traffic pattern. Once a click or sequence of clicks is found that produces the recognizable SSO traffic, SSOScan automatically logs into Facebook and grants the requested permissions to the application.

About 44% of sites we tested still require a user to register when using SSO, so it is important to automate this process. SSOScan combines heuristics with random inputs to fill in and submit the forms (Section 3.1.2), and then uses an oracle (Section 3.2) to determine if the submission succeeds. If the oracle deems the registration to be a failure, the Enroller tries using different strategies (Section 5) until either the oracle passes or a threshold level of effort is exceeded. The entire process succeeds for 80% of the websites using Facebook SSO in the top 10,000 sites (Section 4 presents detailed results).

3.1.1 SSO Button Finder

A typical starting page, taken from huffingtonpost.com, is shown in Figure 3. SSOScan needs to first find and click the "Log in" button on the main page, and then the "Log in with Facebook" button on the overlay that pops up afterwards. As illustrated in Figure 4, SSOScan first extracts a list of qualifying elements from all nodes in an HTML page, and then extracts content strings from such elements. The Button Finder relies on the assumption that developers put one of a small pre-defined set

of expected words in the text content or attributes of the SSO button. It computes a score for each element by matching its content with regular expressions such as [Ll][Oo][Gg][liOo][Nn] which indicates its resemblance to "login". SSOScan forms a candidate pool consisting of the top-scoring elements and triggers clicks on them. (Section 5 describes the heuristic choices SSOScan uses to filter elements and compute scores.)

3.1.2 Completing Registration

The required interactions to complete the registration process after single sign-on vary significantly across web applications. They range from simply clicking a submit button (e.g., Figure 5, in which all input fields are pre-populated using information taken from the SSO process), to very complicated registration processes that involve interactively filling in multiple forms.

SSOScan attempts to complete all forms on the SSO landing page by leaving pre-populated fields untouched and processing the remaining inputs in the order of radios, selects, checkboxes and finally text inputs. We found this ordering to be very important to achieve higher automation success, as some forms may dynamically change what needs to be filled upon selecting different radio or select elements. Processing these elements first allows SSOScan to rescan for dynamically generated fields and process them accordingly.

For radio and select elements, SSOScan randomly chooses an option; for checkboxes, it simply checks all of them. For text inputs, SSOScan tries to infer their requirements using heuristics and provide satisfactory mock values. Once all the inputs have been filled, the next step is to reuse the SSO Button Finder (Section 3.1.1) with different settings designed to find submit buttons. After SSOScan attempts to click on a submit button candidate, it refers to the oracle to determine if the entire registration process is successful.

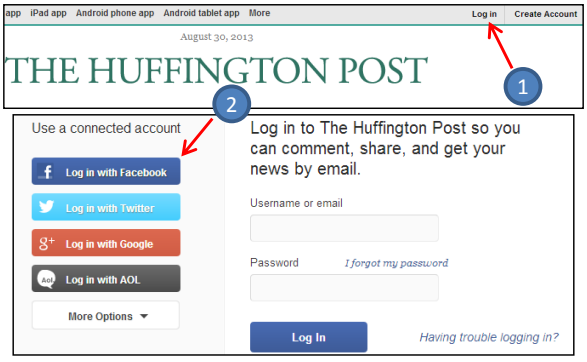

Figure 3: SSO Buttons (huffingtonpost.com)

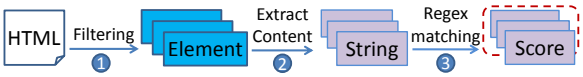

Figure 4: SSO button finder workflow

3.2 Oracle

The Oracle analyzes the application and determines whether it is in an authenticated state, and if so, further identifies the session identity. This module is necessary for SSOScan to decide if a registration attempt is successful. It is also used by the Vulnerability Tester to determine if a simulated impersonation attack succeeds.

The key observation behind the Oracle is that web applications normally remove the original login button and display some identifying information about the user in an authenticated session. For example, after a successful registration many websites display a welcome message that includes the user's first name.

After the page finishes loading, the Oracle searches the entire DOM and **document**.cookie for test account user information (e.g., names, email, or profile images). We evaluate the correctness of our assumptions and effectiveness of our Oracle in Section 4.2.

3.3 Vulnerability Tester

After the Enroller successfully registers two test accounts, control is passed to the Vulnerability Tester which checks the target application for the vulnerabilities described in Section 2.2. We use two different probing approaches to cover the five tested vulnerabilities: *simulated attacks* and *passive monitoring*.

Simulated Attacks. The two credential misuse vulnerabilities are tested using simulated impersonation attacks. We describe how this is done for *signed_request* misuses; the method for checking *access_token* misuses is similar.

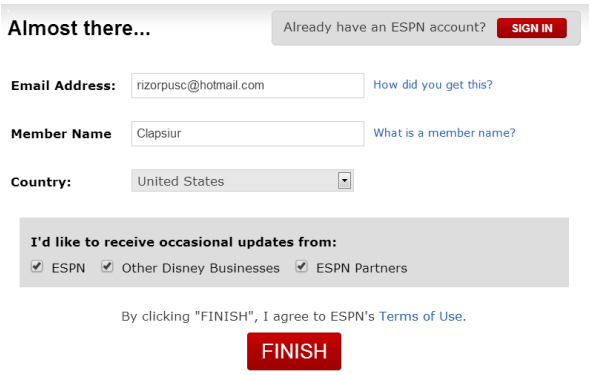

Figure 5: Registration Form (espn.go.com).

To set up the tests, we created a test application *Mal* which uses Facebook SSO, and obtained Alice's *signed_request* for *Mal*. This mimics the scenario where Alice is tricked into visiting and signing into an arbitrary malicious website using Facebook. After the account registration finishes, we use Bob's credentials to sign into Facebook for target application, but replace the *signed_request* in Facebook's response with the prior response received for Alice. For consistency, we also replace all *access_token*s found in the traffic.

The attack is successful if Bob is able to login as Alice using the replayed *signed_request*. The Vulnerability Tester deems the site vulnerable if the Oracle determines that Alice is logged in after the simulated attack.

Passive Monitoring. The three credential leakage vulnerabilities are detected using passive approaches. For brevity, we only explain how leaks through the referrer header are detected; the other leaks are detected similarly by observing network traffic and web page contents.

To check if an application leaks the user's OAuth credentials through the referrer header, SSOScan monitors all request data during the account registration process and compares each referrer header to OAuth credentials recorded in earlier stages. If a match is found, SSOScan then checks if the requesting page contains any third-party content such as scripts, images, or other elements that may generate an HTTP request. SSOScan reports a potential leakage when credentials are found in the referrer header for a page that contains third-party content.

4 Results

We evaluated SSOScan by running it on the list of the most popular 20,000 websites based on US traffic downloaded from quantcast.com as of 7 July 2013. Of those 20,000 sites, 715 of the sites are shown as *hidden profile* (that is, no URL is given, thus excluded from our study).

We ran SSOScan on the remaining 19,285 sites in September 2013, and found that homepages of 1372 sites failed to load during two initial attempts (most likely due to either expired or incorrect domain name, server error, or downtime). We excluded these sites from our data set, leaving a final test dataset containing 17,913 sites.

Completing the tests took about three days, running 15 concurrent sessions spread across three machines. The average time to test a site is 3.5 minutes. We limited the maximum stalling time for each site on any one module to four minutes, and the overall testing time to 25 minutes per site. If this timeout is reached, SSOScan restarts and retries a second time before skipping it. We ran extra rounds on tests that failed or stalled during initial round until either the test is completed or the four rounds maximum limit has been reached. The extra rounds involved fewer sites (<10%) and took a week to complete running on one machine with four concurrent sessions.

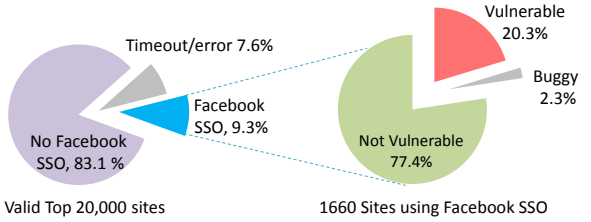

Figure 6: Results overview

In July 2014, we re-ran the tests on the vulnerable sites to see how many sites had corrected the vulnerabilities. The results from that scan are reported in Section 6.2.

4.1 Automated Test Results

Figure 6 presents results purely based on automatic tests run by SSOScan. SSOScan found a total of 1660 sites using Facebook SSO among the 17,913 sites (9.3% of the total). Figure 7 shows the number of Facebook SSO supported sites, sites that misuse credentials, and sites that leak credentials distributed by site ranking. The dotted lines on top of the bars show the average stats of all sites that are more popular than that rank. In Section 4.3, we report on our manual analysis on failed tests for sites ranked in the top 10,000.

Facebook SSO integration. Figure 7 (a) shows that more popular sites are more likely to integrate Facebook SSO. Of the top 1000 sites, 270 (27%) of them include Facebook SSO, compared to only 52 out of the 1000 lowest-ranked sites in our dataset. This supports our believe that covering the top-ranked 20,000 websites is sufficient to get a clear picture of prevailing Facebook SSO usage since less popular sites are both less visited and less likely to use Facebook SSO.

Faulty implementations. To implement Facebook SSO, an application must be configured correctly in the Facebook developer center. Using incorrect parameters to call the SSO entry point also result in errors that will prevent any user from authenticating to that application through SSO. Such cases, automatically identified by SSOScan, were more common than we expected. The most popular errors include setting the application to 'sandbox' mode (for development stage only) in the developer center, or providing a wrong application ID. SSOScan found 39 (2.3% out of 1660 sites that incorporate Facebook SSO buttons) sites that display visible Facebook SSO buttons but have implementations so buggy that no user could ever login using them. A possible explanation is that the buttons are there for SEO purposes and the developers

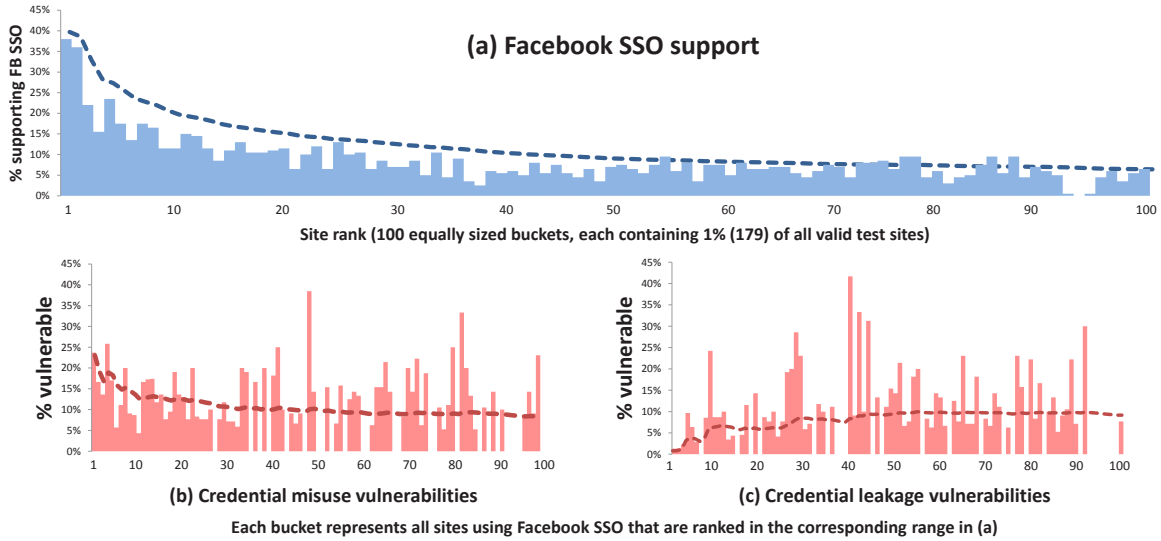

Figure 7: Facebook integration results by site rank

never actually bothered to implement it, or the developers simply copied and pasted an SSO snippet customized for another application without ever testing it.

Vulnerability trends. We found 202 sites (12.1%) that misuse credentials (126 of which are misusing both *access_token* and *signed_request*) and 146 sites (8.6%) that leak Facebook SSO credentials (of which 72 sites are leaking through both referrer headers and DOM). A total of 345 sites (20.3%) suffered from at least one of the five tested vulnerabilities, and 3 sites suffered from both credential misuse and leakage problems.

It is also worth noting that SSOScan did not find any sites leaking their *app_secret* to the public by calling the token exchange API on the client side. To verify that we implemented the check correctly, we have confirmed that SSOScan does correctly identify this vulnerability on our manually-crafted faulty application. This is an interesting result, especially compared to the high number of sites that have at least one of the other vulnerabilities. We suspect this is partly due to explicit warnings in the documentation and the increased effort required to actually implement the token exchange on the client side.

As shown in Figure 7 (b) and (c), more popular sites appear to be more likely to have credential misuse vulnerabilities, while less popular sites tend to have more credential leakage problems. This fact certainly raises concern — credential leakage could potentially do damage to users' Facebook accounts, and it would be hard to contact numerous low-profile problematic sites to have them all fixed. The victim's Facebook account is in jeopardy if any of the applications he or she uses have such problem. Even though credential misuse cannot harm Facebook accounts directly, the fact that such vulnerabilities exist in high-profile websites is worrisome, as impersonation attacks carried against sites with millions of users have more severe consequences thank similar attacks on lower-profile sites.

Of the top-1000-ranked sites, 60 of the 270 (22.2%) that support Facebook SSO are found to have at least one vulnerability. The vulnerability rate is 21.3% across all sites in the top 10,000 and 18.5% for sites ranked from 10,001 to 20,000. This overal vulnerability rate suggests that development practices at larger companies do not appear to be more stringent (at least with respect to SSO) than they are at less popular sites.

As we do not have access to server side source code, we cannot measure how reusing code may positively or negatively affect the vulnerability trend. However, we did notice that some sites use fourth party services (e.g. Janrain, Gigya) to implement the Facebook SSO. In such scenarios, the user effectively does two SSO processes during authentication — the user, Facebook (IdP) and Janrain (RP) initially; the user, Janrain (IdP) and the true relying party afterwards. As the Facebook SSO process is entirely handled by the fourth party and is hidden to the relying party, the RP's behavior is not relevant to this vulnerability. We have manually tested both Janrain and Gigya's Facebook SSO implementation for credential misuse vulnerabilities and confirmed that both of them correctly implement the process by only using *code* flow to authenticate users. As a result, sites using these services contribute to a lower vulnerability rate. Note that the RP would still need to implement the second SSO process correctly to avoid vulnerabilties, but SSOScan currently does not check IdPs other than Facebook.

4.1.1 Front-end Integration

There are three basic client-side methods to integrate Facebook SSO: a JavaScript SDK, a pre-configured widget, or a custom implementation. (We have no way to determine how the developers are integrating Facebook SSO at the back end.) We used SSOScan to aggregate front-end integration choices and compare them with vulnerability reports. Table 1 summarizes the results. Websites using client side SDKs and pre-configured widgets are more likely to misuse credentials (29.1% and 15.5% vs. 1.3% in non SDK/widget implementations). Our guess is that this is due to the way SDKs and widgets conveniently expose raw *access_token*, *signed_request*, or even user name Facebook ID values. This convenience may lead to the developers to neglect to check the signature and the intended audience of the credential. However, our results also show that websites using SDKs and widgets are better in hiding credentials (3.6% and 2.2% compared to 12.4% vulnerable rate in SDK/widget implementations). This is likely because such applications use the Facebook-provided landing page which has safe redirect URLs and no third-party content. Applications built this way are secure unless the developers explicitly add the credentials in the page content or URL.

4.1.2 Examples

We describe two examples of vulnerabilities found by SSOScan here to illustrate the potential risks. Section 6 discusses our experiences reporting vulnerabilities to site owners and Facebook.

Match.com. Ranked 118th on the list, Match.com is a popular online dating website. SSOScan revealed that match.com is also vulnerable to *signed_request* replacement attacks. To use match.com services, users need to provide sensitive information including their birthday, location, photos, personal interests, and sexual orientation. Impersonators will not only have access to this information, but also learn whom the victim is dating and possibly the time and location of the dates.

Fodors.com. Fodor's is a travel advice website that is the 217th-ranked US site. Its redirection landing page contains *access_token* information along with some other third-party scripts in its content. The scripts come from various sources including quantserve.com, fonts.com, yahooapis.com, and multiple domains owned by Google. The permission Fodor's requests includes user's basic information, email address, and more importantly, permission to post to user's wall on the his or her behalf. This means if the *access_token* is leaked to a malicious party, it can post to a user's Facebook wall without consent in addition to accessing the user's basic information.

Method	Number	Misuse	Leakage
SDK	578	29.1%	3.6%
Widget	132	15.5%	2.2%
Custom Code	950	1.3%	12.4%
All	1660	12.1%	8.6%

Table 1: Rate of credential misuse and credential leakage for different Facebook SSO front-end implementations

4.2 Detection Accuracy

To evaluate the detection accuracy of SSOScan, we sampled test cases from all results (including sites reported to have no Facebook SSO support, secure and vulnerable cases) and manually examined them. We consider two types of mistakes: misreporting whether the site integrates Facebook SSO, and incorrectly determining whether or not a Facebook SSO-enabled website exhibits a vulnerability.

Facebook Login Detection Correctness. SSOScan searches SSO button based on heuristics and cannot guarantee success for all websites. Indeed, it is not possible for anyone to determine with complete confidence if a website uses Facebook SSO by just browsing the site. To roughly measure how many Facebook SSO-enabled websites were missed by SSOScan, we randomly sampled the 100 sites that were reported by SSOScan to have no Facebook SSO support and manually examined them. To make the samples representative of the whole set, we picked one site out of every 200 sites ordered by their rank. From manually investigating these 100 sites, we could only find one site that included Facebook SSO but was missed by SSOScan. As we introduce later in Section 6, we also deployed SSOScan as a web service that is made available to use in our research group. The web service has received a total of 69 valid submissions so far and we have also manually examined the vulnerability reports.[2] We found four cases (5.8%) where a submitted site included Facebook SSO but SSOScan was not able to trigger it.

The sites that SSOScan fails to find Facebook login present unusual interfaces which our heuristics are not able to navigate to. Specifically, oovoo.com and bitdefender.com do not show any login button on its homepage, but instead the user needs to click a 'my account' button to initiate the login process. The sears.com site displays a login button on its homepage, but the SSO process is not initiated until the user interacts with the popup window three times, which exceeds the maximum

[2]These have mostly been sites suggested by people we have demoed SSOScan scan to, since the service has not yet been publicized. Hence, it is a small and non-representative sample, so not clear what we can conclude from this at this point.

click depths (two) in this evaluation. We have also seen one case (coursesmart.com) in which the login process is rather typical, but SSOScan still missed the correct login button (that button is scored the 4th highest while SSOScan only attempts to click the top 3 candidates.). Most of these issues may be addressed with more relaxed restrictions and more regular expression matching as described in Section 5.2. Finally, our prototype implementation is limited to English-language websites due to its string matching algorithm, but could be extended to include keywords in other languages.

SSOScan may also incorrectly conclude that a website supports Facebook SSO when it does not. We have seen sites (e.g., msn.com) that only use Facebook SSO to download user activities and display them on the page, but do not integrate their identity system with Facebook SSO. Although SSOScan is designed to skip searching on typical Facebook-provided social plugins and widgets, non-standard integration of such functionalities may rarely lead to false positives.

Vulnerability Status Correctness. Since SSOScan simulates potential attacks and verifies their success or failure, detection is likely to be highly accurate. Nevertheless, we consider several possible reasons that might cause false positives/negatives to be reported.

SSOScan should be able to capture all credential leakage vulnerabilities with no false positives. A false negative may occur since SSOScan only looks for exact matches to the original OAuth credential string, so it will not report a leakage if the credential is slightly transformed or encoded. Further, SSOScan only observes traffic involving the web client, so does not detect application that leak OAuth credentials outside the SSO process.

SSOScan only reports a credential misuse vulnerability when it can successfully execute an impersonation attack. So, the only risk for incorrect reports is if the Oracle incorrectly determines the session identity. We designed the Oracle to minimize this risk. For example, information for the test account is chosen carefully to be unlikely to appear otherwise but to be close enough to real names to pass sanity checks. For example, the randomly generated name "Syxvq Ldswpk" was rejected by a small number of websites, but "Jiskamesda Quanarista" always passed sanity checks and only appeared in an authenticated session in all of our tests. Barring an unlikely name collision, there does not appear to be any way SSOScan would produce a false positive credential misuse report.

The Oracle checks the whole response for identifying information instead of only the DOM content to handle sites which only embed such information in first-party cookies after logging in. In some rare cases, these cookies could be issued even before SSOScan finishes registration forms. This means that before the Enroller searches for registration forms to fill in, the Oracle deems registration as unnecessary because it concludes that the application is already in an authenticated state. Although SSOScan is able to proceed and determine vulnerability status, the application never enters an authenticated state and false negatives might occur.

Trusted Third-Party Domains. For credential leakage vulnerabilities, SSOScan reports an application as vulnerable if it identifies visible credentials co-existing with *any* content or script that comes from *any* origin other than the host or Facebook. This could overestimate the vulnerable sites because the host may own other domains and serve content over them, which should not be considered untrusted. For example, content delivery networks and sub-company scenarios (e.g., cnn.com embedding content from turner.com which owns CNN) are common among popular websites.

4.3 Automation Failures

For about 19% of the top 10,000 tested site that include functional Facebook SSO, SSOScan is not able to fully automate the checking process. Figure 8 shows the distribution of rank of failed test websites.

To better understand the reasons why SSOScan fails, we manually studied all 228 failed cases reported by SSOScan for sites ranked in the top 10,000. We found that although 47 out of these 228 cases set their Facebook application configurations and SSO entry points properly, they never respond to credentials returned by Facebook SSO, which means no users would be able to successfully log into these sites through Facebook SSO. Excluding these 47 left us a total of 181 failure cases.

Registration automation failure. By far the most common reason for SSOScan to fail is due to complicated or highly-customized registration process. We found 43.7%

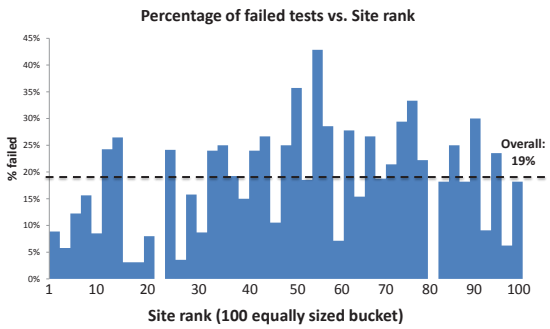

Figure 8: Failed tests rank distribution

Failure reason	Number	Percent
linking/subscription	51	28.1%
CAPTCHAs	34	18.8%
identity invisible to oracle	28	15.5%
atypical input elements	20	11.0%
atypical submit buttons	19	10.5%
email verification	10	5.5%
non-HTTPS submission forms	9	5.0%
other (e.g., timeouts)	10	5.5%
Total failures	181	100.0%

Table 2: Automation Failure Causes (top 10,000 sites)

of the sites that implement Facebook SSO still require users to perform additional actions to complete the registration (roughly evenly distributed by site popularity). SSOScan failed to complete registration on 143 (33.6%) of them. Table 2 shows the major reasons contributing to this failure ordered by their occurrences: 1) sites that require SSO users to link to an existing account or provide payment information to subscribe to the service; Currently SSOScan cannot handle the "linking" action: automatically registering a "traditional" account and perform the linking poses an out-of-scope challenge — doing so often requires solving CAPTCHAs[3]. 2) registration forms after the SSO process include CAPTCHAs; 3) special input elements (e.g. div, span or image as opposed to input) cannot be found automatically, or special requirements for the input that cannot be fulfilled; 4) sites where the registration submission button cannot be located; 5) sites that requires users to confirm email addresses before continuing (usually this involves clicking a link in an email sent by the server to the user's email address); and 6) sites that insecurely send registration data using a non-HTTPS form which causes the testing browser to pop up a warning and stall.

Oracle confusion. SSOScan may also fail because the oracle reports failure (15.5%), which occurs when it detects the login button no longer exists after Facebook SSO but cannot identify the session identity. We manually analyzed such cases and found the biggest obstacle is that the application homepage does not include any identifying information at all. For example, instead of showing 'Welcome, {username}', it shows 'Welcome, customer', or simply 'Welcome', and the user name is only displayed when accessing the account information page. In other cases, SSO authentication serves only a sub-service of the website such as its affiliated forum, but not the homepage which does not display any identifying information.

Others. During the testing, we have also seen a number of sites with extremely long loading time or inconsistent network latencies after Facebook SSO or upon navigating to certain pages. While the latency spikes can likely be resolved by re-running the tests, frequent long delays which accumulate to SSOScan's maximum timeout will always halt the automation process. For example, this happens when SSOScan accidentally triggers a browser confirmation dialog that requires user interaction, or asking users to stop a busy script execution.

[3]On the contrary, most tested applications (942 out of 973, see Section 4.3) do not ask users to solve CAPTCHAs when an account is created through SSO. This is a reasonable practice, since the user who is able to provide a valid Facebook account should have already passed Facebook's requirements, and adding additional CAPTCHAs would be unnecessarily annoying to the users.

5 Heuristics Evaluation

The ability of SSOScan to successfully complete the Facebook single sign-on and registration process depends on heuristics it uses to find buttons and fill in registration forms. Since each attempted button click involves a high-latency round-trip with the server, early pruning of search space and prioritization of elements is important for achieving successful completion within a reasonable amount of time. This section describes and analyzes the heuristics SSOScan uses. We analyze the click data collected from the top 10,000 sites that use Facebook SSO and show how tweaking the heuristics significantly improves performance.

5.1 Options

Each step in the automation process can be controlled by many options, including filters that can be enabled to eliminate candidate elements that are unlikely to be the correct target, weightings that adjust the contribution of different element properties to its score, and other behavior modifiers. The ones SSOScan used when running the Section 4 study are described below; additional options are described in our tech report [33].

Candidate rank. The button finder produces a candidate element list ranked by score. SSOScan will first attempt clicking on the highest-ranked element, but sometimes

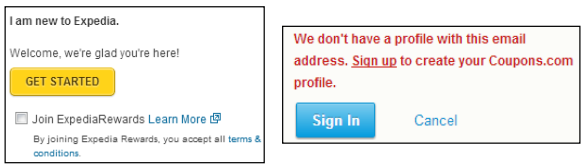

Figure 9: Example corner cases

the correct element is ranked lower. This option controls the maximum number of click attempts SSOScan makes before succeeding or giving up. For Section 4's experiment, the lowest ranked element SSOScan clicks is the third.

Visibility filter. Most websites only expect users to click on UI elements that are visible, so the button finder includes a filter that ignores all invisible elements (e.g., elements with zero height or width, shadowed in the background layer, or those which appear only when the user scrolls the initial screen position).

Position filter. We noticed that SSOScan sometimes gets distracted by a search box submit button when completing the registration form, even if it is able to correctly fill in the required information in all input elements. To eliminate these misclicks, the position filter eliminates the submit buttons which are displayed above any inputs based on our observation that submit buttons nearly always come last in a registration form.

Registration form filter. As mentioned earlier in Section 4.3, many websites provide two actions for the user after SSO is completed: 'create new account' or 'link an existing account'. The latter option requires the user to enter the user name and password of an existing account to finish the enrollment process. To avoid these, the registration form filter rejects a candidate submit button if its parent form contains only two visible text inputs, one has the meaning of 'name' or 'email' and the other is of type password, since such an element is most likely to be a submit button of a linking form.

Element content matching. SSOScan searches for elements whose labels are close to "login with Facebook" for SSO buttons by default. However, quite a few popular websites (e.g. coupons.com, right side of Figure 9) only allow users to "sign up with Facebook" first before logging in with Facebook. If the user has yet to do this, attempting to login with Facebook will produce an error. To handle this situation, SSOScan will search for elements with semantics similar to "sign up with Facebook" when it fails to register using the "login" buttons.

A filter may significantly reduce the number of misclicks. However, it may also occasionally exclude correct elements. For example, not every correct submit button is below all inputs (e.g., left of Figure 9, and expedia.com's submit button would have been missed with the element position filter enabled).

Hence, SSOScan is designed to explore target sites using different option settings if enrollment does not succeed with the initial settings. It will continue to attempt to complete the enrollment process using different settings until either all configurations have been exhausted or the timeout threshold is reached. SSOScan avoids doing duplicate work by detecting if a click attempt has resulted in a previously visited or completely explored state (see our tech report for details [33]).

5.2 Experiment Setup

In theory, SSOScan could exhaustively trigger clicks on every element on the page (and on all response pages up to some maximum depth), which would result in nearly 100% success rate. This would be prohibitively slow in practice, though, so the number of attempted clicks must be limited for any realistic test. Given the time needed for each click attempt, it is important to configure our scoring heuristics well to maximize the probability of a successful enrollment in the minimum amount of time.

To gather statistics about the candidate elements, we modified SSOScan to try all possible strategies even if it has already *found* the correct login button and to record information about all attempted clicks, including for example their size, position, visibility to the user, content string feature and whether it is *successful*. We define a click as *successful* if it is included in any sequence of clicks from the start page to triggering the SSO process, regardless of whether it appeared in an attempt that failed to trigger the process. Because SSOScan skips previously explored states to avoid redundant effort, it automatically rejects click sequences which involves cyclic state transitions such as clicking on an irrelevant link and then clicking on a logo which returns to the initial state.

We set up SSOScan to expand the candidate pool size for each configuration from 3 to 8, add more matching regular expressions (e.g., to match the string "forum" which occasionally leads to a login page on sites where no login is visible on the start page), and use equal weight for each of them. We also removed all candidate filters described in Section 5.1. Our goal is to capture as many ways to trigger the SSO process as possible by doing as close to an exhaustive search as is feasible. This increases the time required to scan a typical site to almost an hour (compared to a few minutes with the setup used in the full study).

We ran the test on the 973 sites from the top-10,000 ranked sites that were detected by SSOScan to support Facebook SSO in our main study (Section 4). This biases the study slightly, since it only includes sites where the configuration used in the initial study was able to find Facebook SSO. Ideally we would like to run all top-10,000 sites to avoid any bias introduced by the data set, but the significantly increased testing time prohibits us to do so, and the result of our subsequent study on a random sample of sites (Section 5.4) supports the claim that only few sites containing Facebook SSO were missed by the main study.

5.3 Results

The experiment recorded 29,539 unique[4] click attempts, of which 5086 (17.2%) are successful (that is, they either directly trigger SSO, or lead to subsequent clicks that trigger SSO). This amounts to approximately 30 unique clicks attempted per site, but the number varies significantly based on the site design, from a few up to 109.

Element type and content. Figure 10 shows how different button types and properties impact success rates. We report the success rate as the number of times that element appeared as a successful click divided by the total number of clicks attempted on elements of that type. The number beneath the element feature gives the total number of times that type of element occurred as a successful click target across all the test sites. For example, the *BUTTON* element type has an excellent success rate — 60% of all *BUTTON* candidates are true positives for the Facebook SSO button. But since it only appears as a successful click on 78 out of 973 sites in our sample, it is rarely useful. By contrast, clicking on *DIV* elements are much less likely to trigger the Facebook login, but such elements are more common. The right side of Figure 10 shows that elements that are directly visible to the user has a higher success rate than invisible ones, and elements residing in iframes are twice as likely to be the correct target as their counterparts in the main page. These results suggest ways of weighting element types to improve the scoring function and increase the likelihood of finding successful clicks early.

[4]If two clicks happens on pages with the same URL, same element XPath and same element outerHTML, we consider them the same click.

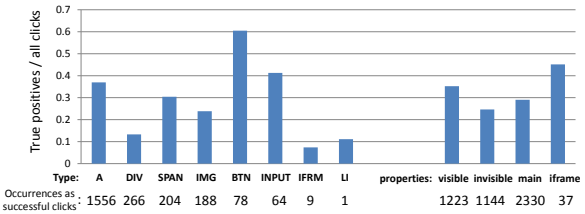

Figure 10: Login button type statistics

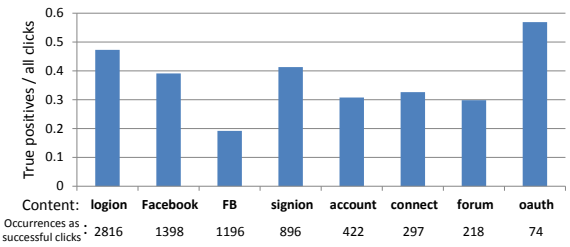

Figure 11: Login button content statistics

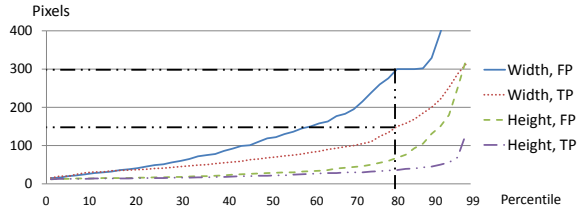

Figure 12: Impact of Login Button Size

Figure 11 shows how the success rate varies with attribute content (matched by the given regular expression). The keyword "oauth" rarely exists in any content, but when it appears it is very likely to identify the target element. The result also shows that "FB" is not a good indicator to predict the target, and we think this is probably because it is very short and may be used for similarly named JavaScript variables or random abbreviations.

Both figures include data for the *first* click only (but do measure first click success based on subsequent clicks). Data for the second clicks are noticeably different from the first, and overall success rates are lower on second clicks. The most interesting fact we found is that "connect" (39%) and "Facebook" (36%) become the most successful matches of all regular expressions, followed by "oauth" at (26%). No other regular expressions exceed 20% success for the second click.

Element size. Figure 12 gives the cumulative distribution function of the width and height of target elements. For example, the 80th percentile width of the true positive elements is approximately 150px, compared to 300px for false positive elements. We did not find any significant difference between first and second clicks, so the figure combines data from all clicks. The key result is that wide elements are less likely to be true positives, possibly due to SSOScan incorrectly including many large underlay elements as candidates. The result is similar for element height (the lower two lines in the figure). This suggests that it would be useful to add a filter function that excludes candidates whose width is greater than 300px. We would expect it to eliminate 20% of the false positives while hardly missing any of the true positives. Alternatively, SSOScan could adjust the final score of a node according to its size based on these results.

Element position. Figure 13 shows the heatmap of the login button's position in a page. The intensity at a location indicates the number of elements found there satisfying the property. Only visible elements are shown, and each successful click only attributes to the intensity once. All four figures are normalized with respect to their maximum intensity (i.e., element density).

The figures show an interesting distinction from first click to second click: successful first clicks almost ex-

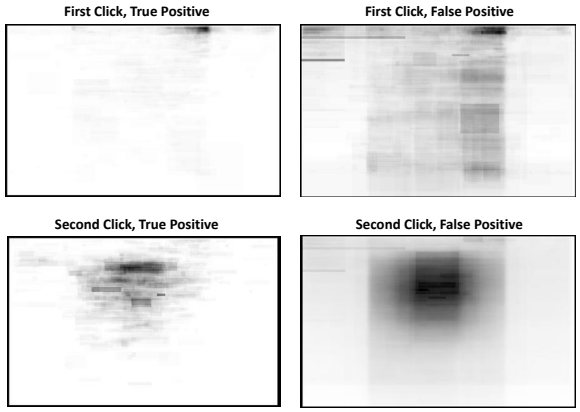

Figure 13: Login button location heatmap

clusively appear in the upper right corner of the page, while the second click appears generally in the upper-middle part of a page. The false positives are relatively more scattered everywhere on the page[5]. This result suggest we should assign a higher weight for elements for these locations, and focus on elements in the vicinity of the upper right corner for the first click. We could potentially even ignore the other criteria and only consider position to find login buttons on foreign-language sites.

5.4 Validation

After incorporating what we learned from these results (e.g., weight adjustment for different button sizes and types), we reran the SSOScan with the new heuristics on the sites ranked from 10,000 to 20,000 that SSOScan determined to support Facebook in the original study, which were not included in the heuristics evaluation. We compare the results with those obtained by using a "control" version of SSOScan, with equal weights on all features and no candidate filtering. All other settings such as candidate pool size are the same between two versions.

The results support the hypothesis that adjusting heuristics according to the results of the evaluation can improve the speed and robustness of detection of Facebook SSO integrations. The naïve control version missed 72 out of the 601 sites while the new heuristics missed only two. The average rank of correct candidate elements for the first and second click is 1.32 and 1.23 for the control experiment, which improves to 1.23 and 1.17 respectively with the new heuristics.

We also randomly picked 500 random sites from the sites that SSOScan have yet to find Facebook support in the experiment in Section 4. We tested the expanded heuristics on these sites, and further increased the maximum click depth to three to see if more SSO integrations could be found. Individual tests took an average of 31 minutes to finish, but varies significantly from a few minutes up to an hour (threshold) based on site content.

Four additional sites were found that support Facebook SSO from this sample in total. Two are found due to the added regular expression [Ff][Oo][Rr][Uu][Mm], one of which required three clicks to trigger the SSO process. Another site is found due to the improved candidate ranking algorithm, and the fourth was found using the new candidate selection method that includes all elements in the right corner of the page, even if they do not match any regular expressions. This provides a reasonable degree of confidence that our original study found a large enough fraction of all the popular sites using Facebook SSO to be representative, although likely missed around 1% of Facebook SSO sites. We did not try click depths greater than 3 because of the exponential time growth required to complete each test, but we feel confident that the number of Facebook SSO interfaces that can only be discovered by attempting more than 3 clicks is very low.

6 Discussion

This section concludes by discussing limitations of SSOScan, sharing our experiences reporting vulnerabilities, and suggesting ways SSOScan can be deployed to help secure applications integrating SSO services.

6.1 Limitations

While SSOScan is able to automatically synthesize basic user interactions and analyze traffic patterns, this approach is not suitable for detecting all types of vulnerabilities. It only works for vulnerabilities that can be checked by observing traffic or simulating predictable user events, and falls short if the vulnerability testing involves deep server-side application scanning or complicated interactions. For example, Wang et al. [27] point out that the application's *app_secret* might be leaked to arbitrary party if any page including Facebook's PHP SDK invokes two functions in a specific way. This type of vulnerability could be checked at the developer side using program analysis techniques, but cannot be checked by an external tool with no awareness of the sites' implementation details or internal state.

6.2 Communication and Responses

We started contacting the site owners shortly after obtaining our first list of vulnerable sites, manually sending out notifications to 20 vulnerable websites that we thought were interesting. We contacted them either by submitting

[5]The figures also show a clear width boundary. In the experiments the browser resolution is 1920x1200, and it seems that most developers' designs follow a standard width of approximately 960px, which is why the density appears to be cut off.

a form on their website or through email. The responses were very disappointing, especially compared with our previous experiences reporting SDK-level vulnerabilities to identity providers who tend to respond quickly and effectively to vulnerability reports [27]. The vulnerabilities found by SSOScan, on the other hand, are primarily in consumer-oriented sites without dedicated security teams or clear ways to effectively report security issues.

Of the 20 notifications, we only received eight responses, most of which appear to be automated. After the initial response, three websites sent us follow-up status updates. ESPN.com thanked us and told us the message has been passed onto appropriate personnel, but no follow up actions ensued. One of answers.com's engineers asked us for more details, but failed to respond again after we replied with proposed fix. As of July 2014, both sites are still vulnerable. Four months after getting the automated reply from ehow.com, we received a response stating that they have removed Facebook SSO from their website due to "content deemed inappropriate", and we have confirmed that the Facebook SSO button has indeed been removed. Sadly, we think their staff likely did not (bother to) understand our explanation for the fix and simply removed the feature.

The other instance where a reported vulnerability was fixed was for hipmunk.com. Hipmunk was found to be vulnerable to both the *access_token* and *signed_request* replacement attacks. We did not get any response from Hipmunk when the vulnerability was reported through the normal channels, but through a personal connection we were able to contact them directly. This led to a quick response and series of emails with one of Hipmunk's engineers. We explained how to check the signature of a *signed_request*, which should fix both vulnerabilities. However, when they got back to us believing that the fix was complete, we re-ran SSOScan and found that Hipmunk was still vulnerable to the *access_token* replacement attack. This meant Hipmunk checked the signature of *signed_request* after the fix, but never decoded the signed message body and compared its Facebook ID with the one returned by exchanging *access_token*. This surprised us, as we implicitly assumed the developers will consume the signed message body after verifying its signature, and thus only included 'verifying signature' in the proposed fix. After further explanation, the site was fixed and now passes all our tests.

Retesting vulnerable sites. We retested all 345 vulnerable sites in May 2014, nine months after our initial experiment, including the 20 websites we had notified directly. SSOScan found that 48 of the sites had eliminated the vulnerabilities (including one out of the 20 sites we contacted, mapquest.com). Of the 48 fixed sites, 22 had previously been diagnosed as credential leaking sites, and 27 were misusing credentials (one site, trove.com, fixed both problems). We further examined these sites manually to investigate the possible reasons and measures to fix the problems. As for sites that fixed credential misuses, we found that many had abandoned the *token* or *signed_request* flow in favor of the more secure *code* flow, which automatically protects them from credential reuse attacks. For credential leakages, we found that a number of sites redesigned their SSO process to feature a smoother user experience, e.g., replaced traditional redirection flows with AJAX operations, which naturally eliminated credential leakage via referer header.

Communication with Facebook. Due to the ineffectiveness of our direct communication with site owners, we contacted Facebook's platform integrity team in May 2014. Facebook's engineers indicated that they are particularly worried about *access_token* leakage through referer headers (because a malicious party in possess of the token may perform privileged Facebook actions on behalf of the user, which potentially directly harms Facebook), but are also concerned with the credential misuse scenario. Facebook asked for a list of the vulnerable applications and contacted all the sites with *access_token* leakage and credential misuse vulnerabilities (a total of 95 sites that we were able to re-confirm at the time of report), and informed us that they would "take enforcement action as necessary" upon the ten sites that are leaking *access_token*s in the referer headers. Facebook's engineers could not provide us with more information about what this entails or any direct responses they received, but an SSOScan re-run one month later (early July 2014) revealed that only four out of the 95 sites had fixed their problems (of the ten sites leaking *access_token*s, only two had been fixed). Even for Facebook, it appears to be difficult to convince consumer-focused websites to take security vulnerabilities seriously.

6.3 Deployment

Our experiences reporting vulnerabilities found by SSOScan suggest that notifying vendors individually will have little impact, which is consistent with experiences reported by Wang et al. with on-line stores [26]. Hence, we consider two alternate ways of deploying SSOScan to improve the security of integrated applications.

App center integration. We believe SSOScan would be most effective when used by an application distribution center (e.g. Apple store, Google Play) or identity provider (e.g., Facebook) as part of the application validation process. The identity provider has a strong motivation to protect users who use its service for SSO, and could use SSOScan to identify sites that can compromise those users. It could then deliver warning messages

to visitors of vulnerable applications during the log in through Facebook SSO process, or even go so far as to shut down SSO logins for that application. We also believe our results can provide guidance to vendors developing SSO services. The results in Section 4.1 indicate that sites are more likely to misuse credentials when using the Facebook JavaScript SDK. With Facebook's help, this problem could be mitigated by placing detailed instructions inside the SDK. The instructions could be presented as (non-executable) code in the SDK rather than as comments, so that the developers cannot get by without reading and removing them.

Checking-as-a-service. Without involving an centralized infrastructure, the best opportunity to deploy SSOScan is as a vulnerability scanning service that developers can use to check their implementations before their applications are launched (our prototype service at http://www.ssoscan.org/ can be used for this now). For a developer-directed test, it would be reasonable to ask the developer to either guide the tool through the registration process or provide a special test account that bypasses this step in cases where it cannot be fully automated. Even if we assume no aid from the developers, they should at least be able to tolerate a longer testing time than is feasible in doing a large-scale scan.

Availability

When Governments Hack Opponents: A Look at Actors and Technology

Abstract

Repressive nation-states have long monitored telecommunications to keep tabs on political dissent. The Internet and online social networks, however, pose novel technical challenges to this practice, even as they open up new domains for surveillance. We analyze an extensive collection of suspicious files and links targeting activists, opposition members, and non-governmental organizations in the Middle East over the past several years. We find that these artifacts reflect efforts to attack targets' devices for the purposes of eavesdropping, stealing information, and/or unmasking anonymous users. We describe attack campaigns we have observed in Bahrain, Syria, and the United Arab Emirates, investigating attackers, tools, and techniques. In addition to off-the-shelf remote access trojans and the use of third-party IP-tracking services, we identify commercial spyware marketed exclusively to governments, including Gamma's FinSpy and Hacking Team's Remote Control System (RCS). We describe their use in Bahrain and the UAE, and map out the potential broader scope of this activity by conducting global scans of the corresponding command-and-control (C&C) servers. Finally, we frame the real-world consequences of these campaigns via strong circumstantial evidence linking hacking to arrests, interrogations, and imprisonment.

1 Introduction

Computer security research devotes extensive efforts to protecting individuals against indiscriminate, large-scale attacks such as those used by cybercriminals. Recently, the problem of protecting institutions against targeted attacks conducted by nation-states (so-called "Advanced Persistent Threats") has likewise elicited significant research interest. Where these two problem domains intersect, however—targeted cyber attacks by nation-states against *individuals*—has received virtually no significant, methodical research attention to date. This new problem space poses challenges that are both technically complex and of significant real-world importance.

In this work we undertake to characterize the emergent problem space of nation-state Internet attacks against individuals engaged in pro-democracy or opposition movements. While we lack the data to do so in a fully comprehensive fashion, we provide extensive detail from both technical and operational perspectives as seen in three countries. We view such characterizations as the fundamental first step necessary for the rigorous, scientific pursuit of a new problem space.

For our study we draw upon several years of research we have conducted into cases from Bahrain, Syria and the United Arab Emirates. We frame the nature of these attacks, and the technology and infrastructure used to conduct them, in the context of their impacts on real people. We hope in the process to inspire additional research efforts addressing the difficult problem of how to adequately protect individuals with very limited resources facing powerful adversaries.

As an illustration of this phenomenon, consider the following anecdote, pieced together from public reports and court documents.

At dawn on 3/12/13,[1] police raided the house of 17-year-old Ali Al-Shofa, confiscated his laptop and phone, and took him into custody. He was charged with referring to Bahrain's King as a "dictator" (الطاغية) and "fallen one" (الساقط) on a pseudonymous Twitter account, `@alkawarahnews`. According to court documents, Bahrain's Cyber Crime Unit had linked an IP address registered in his father's name to the account on 12/9/12. Operators of `@alkawarahnews` later forwarded a suspicious private message to one of the authors. The message was received on 12/8/12 on a Facebook account linked to the Twitter handle, and contained a link to a protest video, purportedly sent by an anti-government individual. The link redirected through `iplogger.org`, a service that records the IP address of anyone who clicks. Analytics for the link indicate that it had been clicked once from inside Bahrain. On 6/25/13, Ali was sentenced to one year in prison.

Ali's case is an example of the larger phenomenon we investigate: attacks against activists, dissidents, trade unionists, human rights campaigners, journalists, and members of NGOs (henceforth "targets") in the Middle East. The attacks we have documented usually involve the use of malicious links or e-mail attachments, designed to obtain information from a device. On the one hand, we have observed attacks using a wide range of off-the-shelf spyware, as well as publicly available third-party services, like `iplogger.org`. On the other hand, some attacks use so-called "lawful intercept" trojans and related equip-

[1] Dates in the paper are given MM/DD/YY.

ment, purportedly sold exclusively to governments by companies like Gamma International and Hacking Team. The latter advertises that governments need its technology to "look through their target's eyes" rather than rely solely on "passive monitoring" [1]. Overall, the attacks we document are rarely technically novel. In fact, we suspect that the majority of attacks could be substantially limited via well-known security practices, settings, and software updates. Yet, the attacks are noteworthy for their careful social engineering, their links to governments, and their real-world impact.

We obtained the majority of our artifacts by encouraging individuals who might be targeted by governments to provide us with suspicious files and unsolicited links, especially from unfamiliar senders. While this process has provided a rich set of artifacts to analyze, it does not permit us to claim our dataset is representative.

Our analysis links these attacks with a common class of actor: an attacker whose behavior, choice of target, or use of information obtained in the attack, aligns with the interests of a government. In some cases, such as Ali's, the attackers appear to be governments themselves; in other cases, they appear instead to be pro-government actors, ranging from patriotic, not necessarily skilled volunteers to cyber mercenaries. The phenomenon has been identified before, such as in Libya, when the fall of Gaddafi's regime revealed direct government ties to hacking during the 2011 Civil War [2].

We make the following contributions:

- We analyze the technology associated with targeted attacks (e.g., malicious links, spyware), and trace it back to its programmers and manufacturers. While the attacks are not novel—and indeed often involve technology used by the cybercrime underground—they are significant because they have a real-world impact and visibility, and are connected to governments. In addition, we often find amateurish mistakes in either the attacker's technology or operations, indicating that energy spent countering these threats can realize significant benefits. We do not, however, conclude that all nation-state attacks or attackers are incompetent, and we suspect that some attacks have evaded our detection.
- When possible, we empirically characterize the attacks and technology we have observed. We map out global use of two commercial hacking tools by governments by searching through Internet scan data using fingerprints for command-and-control (C&C) servers derived from our spyware analysis.
- We develop strong evidence tying attacks to government sponsors and corporate suppliers, countering denials, sometimes energetic and sometimes indirect, of such involvement [3, 4, 5, 6], in contrast to denials [7] or claims of a corporate "oversight" board [8]. Our scanning suggests use of "lawful intercept" trojans by 11 additional countries considered governed by "authoritarian regimes." We believe that activists and journalists in such countries may experience harassment or consequences to life or liberty from government surveillance.

Finally, we do not explore potential defenses appropriate for protecting the target population in this work. We believe that to do so in a sufficiently well-grounded, meaningful manner first requires developing an understanding of the targets' knowledge of security issues, their posture regarding how they currently protect themselves, and the resources (including potentially education) that they can draw upon. To this end, we are now conducting (with IRB approval) in-depth interviews with potential targets along with systematic examination of their Internet devices in order to develop such an understanding.

2 Related Work

In the past decades, a rich body of academic work has grown to document and understand government Internet censorship, including nationwide censorship campaigns like the Great Firewall of China [9, 10, 11]. Research on governmental Internet surveillance and activities like law-enforcement interception is a comparatively smaller area [12]. Some academic work looks at government use of devices to enable censorship, such as keyword blacklists for Chinese chat clients [13], or the Green Dam censorware that was to be deployed on all new computers sold in China [14]. We are aware of only limited previous work looking at advanced threat actors targeting activists with hacking, though this work has not always been able to establish evidence of government connections [15].

Platforms used by potential targets, such as GMail [16], Twitter [17], and Facebook [18] increasingly make transport-layer encryption the default, obscuring communications from most network surveillance. This use of encryption, along with the global nature of many social movements, and the role of diaspora groups, likely makes hacking increasingly attractive, especially to states who are unable to request or compel content from these platforms. Indeed, the increasing use of encryption and the global nature of targets have both been cited by purveyors of "lawful intercept" trojans in their marketing materials [1, 19]. In one notable case in 2009, UAE telecom firm Etisalat distributed a system update to its then 145,000 BlackBerry subscribers that contained spyware to read encrypted BlackBerry e-mail from the device. The spyware was discovered when the update drastically slowed users' phones [20]. In contrast to country-scale distribution, our work looks at this kind of pro-government and government-linked surveillance through highly *targeted* attacks.

The term APT (Advanced Persistent Threat) refers to a sophisticated cyber-attacker who persistently attempts to target an individual or group [21]. Work outside the academic community tracking government cyberattacks typically falls under this umbrella. There has been significant work on APT outside the academic community, especially among security professionals, threat intelligence companies, and human rights groups. Much of this work has focused on suspected government-on-government or government-on-corporation cyber attacks [22, 23]. Meanwhile, a small but growing body of this research deals with attacks carried out by governments against opposition and activist groups operating within, as well as outside their borders. One of the most notable cases is GhostNet, a large-scale cyber espionage campaign against the Tibetan independence movement [24, 25]. Other work avoids drawing conclusions about the attackers [26].

Country	Date Range	Range of Targets	Number and Type of Samples	Distinct Malware C&C's
Bahrain	4/9/12—7/31/13	$\geq$ 12 activists, dissidents, trade unionists, human rights campaigners, and journalists	8 FinSpy samples, 7 IP spy links received via private message, $>$ 200 IP spy links observed publicly	4 distinct IP addresses
Syria	2011 to present	10–20 individuals with technical backgrounds who receive suspect files from their contacts	40–50: predominantly BlackShades, DarkComet, Xtreme RAT, njRAT, ShadowTech RAT.	160 distinct IP addresses
UAE	7/23/12—7/31/13	7 activists, human rights campaigners, and journalists	31 distinct malware samples spanning 7 types; 5 distinct exploits	12 distinct IP addresses

Table 1: Range of data for the study.

Country	Possible Impacts	Probable Impacts
Bahrain	1. 3 individuals arrested, sentenced to 1–12 mo in prison 2. Union leader questioned by police; fired	1. Activist serving 1 yr in prison 2. Police raid on house
Syria	1. Sensitive opposition communications exposed to government 2. Exfiltrated material used to identify and detain activists	1. Opposition members discredited by publishing embarrassing materials 2. Exfiltrated materials used during interrogation by security services
UAE	Contacts targeted via malware	Password stolen, e-mail downloaded

Table 2: Negative outcomes plausibly or quite likely arising from attacks analyzed.

3 Data Overview and Implications

Our study is based on extensive analysis of malicious files and suspect communications relevant to the activities of targeted groups in Bahrain, Syria, and the UAE, as documented in Table 1. A number of the attacks had significant real-world implications, per Table 2. In many cases, we keep our descriptions somewhat imprecise to avoid potential leakage of target identities.

We began our work when contacted by individuals concerned that a government might have targeted them for cyber-attacks. As we became more acquainted with the targeted communities, in some cases we contacted targeted groups directly; in others, we reached out to individuals with connections to targeted groups, who allowed us to examine their communications with the groups. For Bahrain and Syria, the work encompassed 10,000s of e-mails and instant messages. For the UAE, the volume is several thousand communications.

4 Case Studies: Three Countries

This following sections outline recent targeted hacking campaigns in Bahrain, Syria and the UAE. These cases have a common theme: attacks against targets' computers and devices with malicious files and links. In some cases the attackers employed expensive and "government exclusive" malware, while in other cases, attackers used cheap and readily available RATs. Across these cases we find that clever social engineering often plays a central role, which is strong evidence of a well-informed adversary. We also, however, frequently find technical and operational errors by the attackers that enable us to link attacks to governments. In general, the attacks we find are not well-detected by anti-virus programs.

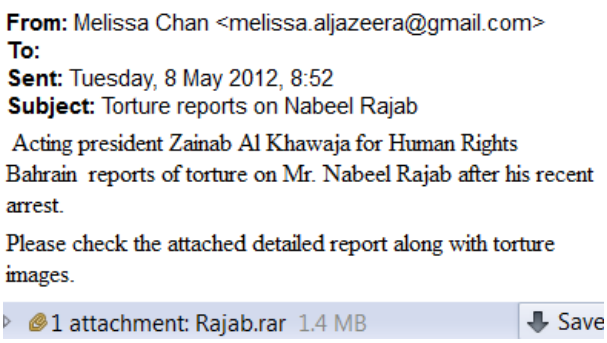

Figure 1: E-mail containing FinSpy.

4.1 Bahrain

We have analyzed two attack campaigns in the context of Bahrain, where the government has been pursuing a crackdown against an Arab-Spring inspired uprising since 2/14/2011.

The first involved malicious e-mails containing *FinSpy*, a "lawful intercept" trojan sold exclusively to governments. The second involved specially crafted *IP spy* links and e-mails designed to reveal the IP addresses of operators of pseudonymous accounts. Some individuals who apparently clicked on these links were later arrested, including Ali (cf. §1), whose click appears to have been used against him in court. While both campaigns point back to the government, we have not as yet identified overlap between the campaigns; targets of FinSpy appeared to reside mainly outside Bahrain, whereas the IP spy links targeted those mainly inside the country. We examine each campaign in turn.

FinSpy Campaign. Beginning in April 2012, the authors received 5 suspicious e-mails from US and UK-based activists and journalists working on Bahrain. We found that some of the attachments contained a PE (`.exe`) file designed to appear as an image. Their filenames contained a Unicode *right-to-left override* (RLO) character, causing Windows to render a filename such as `gpj.1bajaR.exe` instead as `exe.Rajab1.jpg`.

The other `.rar` files contained a Word document with an embedded ASCII-encoded PE file containing a custom macro set to automatically run upon document startup. Under default security settings, Office disables all unsigned macros, so that a user who opens the document will only see an informational message that the macro has been disabled. Thus, this attack was apparently designed with the belief or hope that targets would have reduced security settings.

Identification as FinSpy: By running the sample using Windows Virtual PC, we found the following string in memory: `y:\lsvn_branches\finspyv4.01\finspyv2\`. This string suggests FinSpy, a product of Gamma International [27]. The executables used virtualized obfuscation [28], which appeared to be custom-designed. We devised a fingerprint for the obfuscater and located a structurally similar executable by searching a large malware database. This executable contained a similar string, except it identified itself as `FinSpy v3.00`, and attempted to connect to `tiger.gamma-international.de`, a domain registered to Gamma International GmbH.

Analysis of capabilities: We found that the spyware has a modular design, and can download additional modules from a command & control (C&C) server, including password capture (from over 20 applications) and recording of screenshots, Skype chat, file transfers, and input from the computer's microphone and webcam.

To exfiltrate data back to the C&C server, a module encrypts and writes it to disk in a special folder. The spyware periodically probes this folder for files that match a certain naming convention, then sends them to the C&C server. It then overwrites the files, renames them several times, and deletes them, in an apparent effort to frustrate forensic analysis.

Analysis of encryption: Because the malware employed myriad known anti-debugging and anti-analysis techniques, it thwarted our attempts to attach debuggers. Since it did not include anti-VM code, we ran it in TEMU, an x86 emulator designed for malware analysis [29]. TEMU captures instruction-level execution traces and provides support for taint-tracking.

We found that FinSpy encrypts data using a custom implementation of AES-256-CBC. The 32 byte AES key and 16 byte IV are generated by repeatedly reading the low-order-4-bytes of the Windows clock. The key and IV are encrypted using an embedded RSA-2048 public key, and stored in the same file as the data. The private key presumably resides on the C&C server. The weak AES keys make decryption of the data straightforward. We wrote a program that generally can find these keys in under an hour, exploiting the fact that many of the system clock readings occur within the same clock-update quantum.

In addition, FinSpy's AES code fails to encrypt the last block of data if less than the AES block size of 128 bits, leaving trailing plaintext. Finally, FinSpy's wire protocol for C&C communication uses the same type of encryption, and thus is subject to the same brute force attack on AES keys. While we suspect FinSpy's cryptographic deficiencies reflect bugs, it is also conceivable that the cryptography was deliberately weakened to facilitate one government monitoring the surveillance of others.

C&C server: The samples communicated with `77.69.140.194`, which belongs to a subscriber of Batelco, Bahrain's main ISP. Analyzing network traffic between our infected VM and the C&C server revealed that the server used a global IPID, which allowed us to infer server activity by its progression.

In response to our preliminary work an executive at Gamma told the press that Bahrain's FinSpy server was merely a proxy and the real server could have been anywhere, as part of a claim that the Bahrain FinSpy deployment could have been associated with another government [4]. However, a proxy would show gaps in a global IPID as it forwarded traffic; our frequent observation of strictly consecutive IPIDs thus contradicts this statement.

Exploitation of captured data: Since we suspected the spyware operator would likely seek to exploit captured credentials, particularly those associated with Bahraini activist organizations, we worked with *Bahrain Watch*, an activist organization inside Bahrain. Bahrain Watch established a fake login page on their website and provided us with a username and password. From a clean VM, we logged in using these credentials, saving the password in Mozilla Firefox. We then infected the VM with FinSpy and allowed it to connect to the Bahrain C&C server. Bahrain Watch's website logs revealed a subsequent hit from `89.148.0.41`—made however to the site's homepage, rather than its login page—coming shortly after we had infected the VM. Decrypting packet captures of the spyware's activity, we found that our VM sent the password to the server exactly one minute earlier:

```
INDEX,URL,USERNAME,PASSWORD,USERNAME FIELD,
PASSWORD FIELD,FILE,HTTP 1,
http://bahrainwatch.org,bhwatch1,watchba7rain,
username,password,signons.sqlite,,
Very Strong,3.5/4.x
```

The URL provided to the server did not include the path to the login page, which was inaccessible from the homepage. This omission reflects the fact that the Firefox password database stores only domain names, not full login page URLs, for each password. Repeating the experiment again yielded a hit from the same IP address within a minute. We inspected Bahrain Watch's logs, which showed no subsequent (or previous) activity from that address, nor any instances of the same User Agent string.

IP spy Campaign. In an *IP spy* attack, the attacker aims to discover the IP address of a victim who is typically the operator of a pseudonymous social media or e-mail account. The attacker sends the pseudonymous account a link to a webpage or an e-mail containing an embedded remote image, using one of many freely-available services.[2] When the victim clicks on the link or opens the e-mail, their IP address is revealed to the attacker.[3] The attacker then discovers the victim's identity from their ISP. In one case we identified legal documents that provided a circumstantial link between such a spy link and a subsequent arrest.

Figure 2 illustrates the larger ecosystem of these attacks. The attackers appear to represent a single entity, as the activity all connects back to accounts that sent links shortened using a particular user account *al9mood*[4] on the `bit.ly` URL shortening service.

Recall Ali Faisal Al-Shufa (discussed in Section 1), who was accused of sending insulting tweets from an account

[2] e.g., `iplogger.org`, `ip-spy.com`, `ReadNotify.com`.

[3] Several webmail providers and e-mail clients take limited steps to automatically block loading this content, but e-mails spoofed to come from a trusted sender sometimes bypass these defenses.

[4] A Romanization of the Arabic word for "steadfastness."

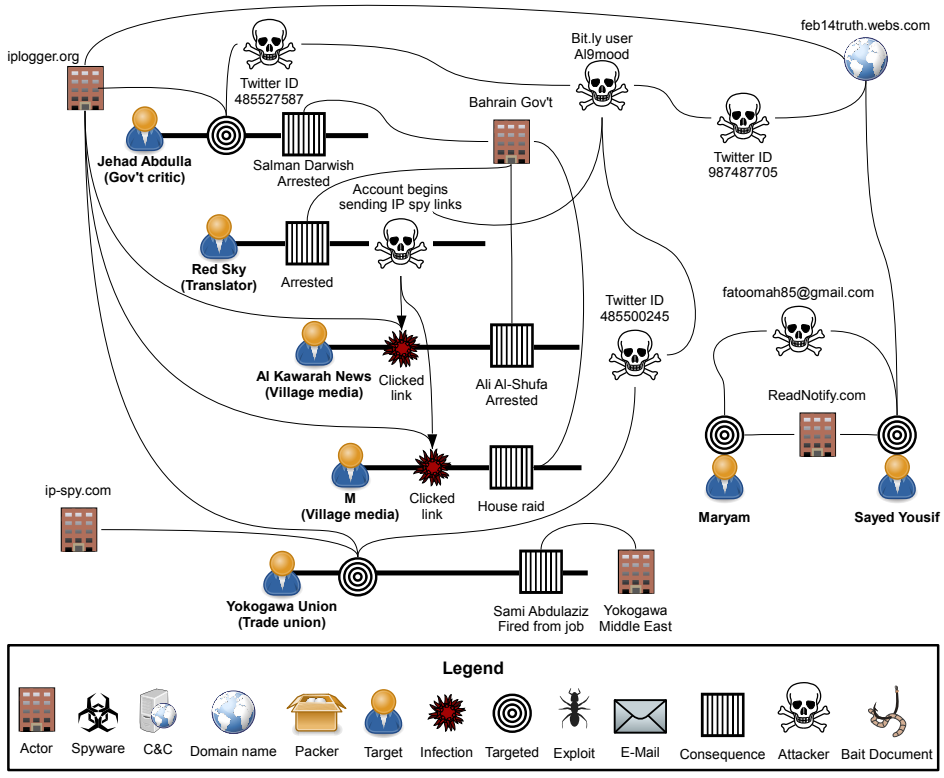

Figure 2: The ecosystem of Bahrain "IP spy" attacks.

`@alkawarahnews` (**Al Kawarah News** in Figure 2). An operator of the account forwarded us a suspicious private message sent to the Al Kawarah News Facebook account from **Red Sky**. Red Sky was purportedly arrested on 10/17/12, was convicted of insulting the King on his Twitter account `@RedSky446`, and was sentenced to four months prison.[5] When released, he found that the passwords for his Twitter, Facebook, and e-mail accounts had been changed, and did not know how to recover his accounts.

The message that Red Sky's account sent to Al Kawarah News included a link shortened using Google's `goo.gl` service. We used the `goo.gl` API to access analytics for the link, finding that it unshortened to `iplogger.org/25SX` and was created on 12/8/12. The link had received only one click, which came from Bahrain with the referrer `www.facebook.com`.

Ali's case files contained a request from the Public Prosecution for information on an IP address that it had linked to Al Kawarah News about 22 hours after the link was created. Court documents indicate that ISP data linked the IP address to Ali, and on this basis he was sentenced to one year in prison.

Red Sky also targeted **M** in Figure 2. M recalled clicking on a link from Red Sky while using an Internet connection from one of the houses in M's village. The house was raided by police on 3/12/13, who were looking for the subscriber of the house's internet connection. Police questioning revolved around Tweets that referred to Bahrain's King as a "cursed one." Red Sky had earlier targeted other users with IP spy links shortened using the *al9mood* `bit.ly` account.

The attack on **Jehad Abdulla** is noteworthy, as the account's activity aligned with communities typically critical of Bahrain's opposition. However, the account also directly criticized the King on occasion, in one case referring to him as "weak" and "stingy." An account linked to *al9mood* sent Jehad Abdulla an IP spy link on 10/2/12 in a public message. On 10/16/12, Salman Darwish was arrested for insulting the King using the Jehad Abdulla account. He was sentenced to one month in prison, partly on the basis of his confession. Salman's father claims that police denied Salman food, drink, and medical care.

Another account linked to *al9mood* targeted `@YLUBH`, the Twitter account of **Yokogawa Union**, a trade union at the Bahraini branch of a Japanese company. `@YLUBH` received at least three IP spy links in late 2012, sent via public Twitter messages. Yokogawa fired the leader of the trade union, Sami Abdulaziz Hassan, on 3/23/13 [30]. It later emerged that Sami was indeed the operator of the `@YLUBH` account, and that the police had called him in for questioning in relation to its tweets [31].

Use of embedded remote images: We identified several targets who received spoofed e-mails containing embedded remote images. Figure 2 shows two such cases, **Maryam** and **Sayed Yousif**. The attacker sent the e-mails using `ReadNotify.com`, which records the user's IP address upon

[5] According to information we received from two Twitter users, one of whom claimed to have met Red Sky in prison; another to be a colleague.

their mail client downloading the remote image.[6]

While ReadNotify.com forbids spoofing in their TOS, the service has a vulnerability known to the attackers (and which we confirmed) that allows spoofing the From address by directly setting the parameters on a submission form on their website We have not found evidence suggesting this vulnerability is publicly known, but it appears clear that the attacker exploited it, as the web form adds a X-Mailer: RNwebmail header not added when sending through ReadNotify.com's other supported methods. The header appeared in each e-mail the targets forwarded to us.

When spoofing using this method, the original sender address still appears in X-Sender and other headers. According to these, the e-mails received by the targets all came from fatoomah85@gmail.com. A link sent in one of these e-mails was connected to the *al9mood* bit.ly account.

In monitoring accounts connected to *al9mood*, we counted more than 200 IP spy links in Twitter messages and public Facebook posts. Attackers often used (1) accounts of prominent or trusted but jailed individuals like "Red Sky," (2) fake personas (e.g., attractive women or fake job seekers when targeting a labor union), or (3) impersonations of legitimate accounts. In one particularly clever tactic, attackers exploited Twitter's default font, for example substituting a lowercase "l" with an uppercase "I" or switching vowels (e.g. from "a" to an "e") to create at-a-glance identical usernames. In addition, malicious accounts tended to quickly delete IP spy tweets sent via (public) mentions, and frequently change profile names.

4.2 Syria

The use of RATs against the opposition has been a well-documented feature of the Syrian Civil War since the first reports were published in early 2012 [36, 39, 40, 32, 34]. The phenomenon is widespread, and in our experience, most members of the opposition know that some hacking is taking place. As summarized in Table 3, the attacks often include fake or maliciously packaged security tools; intriguing, or ideological, or movement-relevant content (e.g. lists of wanted persons). The seeding techniques and bait files suggest a good understanding of the opposition's needs, fears and behavior, coupled with basic familiarity with off-the-shelf RATs. In some cases attacks occur in a context that points to a more direct connection to one of the belligerents: the Syrian opposition has regularly observed that detainees' accounts begin seeding malware shortly after their arrest by government forces [41].

Researchers and security professionals have already profiled many of these RATs, including DarkComet [42, 43], Blackshades Remote Controller [38], Xtreme RAT [44], njRAT [26], and ShadowTech [36]. Some are available for purchase by anyone, in contrast to "government only" FinSpy and RCS. For example, Xtreme RAT retails for €350, while a version of Blackshades lists for €40. Others, like DarkComet, are free. We have also observed cracked versions of these RATs on Arabic-language hacker forums, making them available with little effort and no payment trail. While the RATs are cheaper and less sophisticated than FinSpy and RCS, they share the same basic functionality, including screen capture, keylogging, remote monitoring of webcams and microphones, remote shell, and file exfiltration.

In the most common attack sequence we observed, illustrated with three examples in Figure 3, the attacker seeds malware via private chat messages, posts in opposition-controlled social media groups, or e-mail. These techniques often limit the world-visibility of malicious files and links, slowing their detection by common AV products. Typically, targets receive either (1) a PE in a .zip or .rar, (2) a file download link, or (3) a link that will trigger a drive-by download. The messages usually include text, often in Arabic, that attempts to persuade the target to execute the file or click the link.

The first attacks in Figure 3 date to 2012, and use bait files with a DarkComet RAT payload. These attacks share the same C&C, 216.6.0.28, a Syrian IP address belonging to the Syrian Telecommunications Establishment, and publicly reported as a C&C of Syrian malware since February 2012 [45]. The first bait file presents to the victim as a PDF containing information about a planned uprising in Aleppo. In fact the file is a Windows Screensaver (.scr) that masquerades as a PDF using Unicode RLO, rendering a name such as ".fdp.scr" display to the victim as ".rcs.pdf." The second bait file is a dummy program containing DarkComet while masquerading as a Skype call encryption program, playing to opposition paranoia about government backdoors in common software. The third attack in Figure 3, observed in October 2013, entices targets with e-mails purporting to contain or link to videos about the current conflict, infecting victims with Xtreme RAT, and using the C&C **tn1.linkpc.net**.

For seeding, the attackers typically use compromised accounts (including those of arrested individuals) or fake identities masquerading as pro-opposition. Our illustration shows in abstract terms the use of **Victim A**'s account to seed malware ("Aleppo Plan") via (say) Skype messages to **Victim(s) B**^{n}. In the cases of **Opp. Member C** and **NGO Worker D** (here, actual victims, not abstract), targeting was by e-mail from domains apparently belonging to opposition groups, indicating a potential compromise. One domain remains active, hosting a website of the Salafist Al-Nusra front [46], while the other appears dormant. **Opp. Member C** received a malicious file as an e-mail attachment, while **NGO Worker D** was sent a shortened link (**url[.]no**/Uu5) to a download from a directory of **Mrconstrucciones[.]net**,[7] a site that may have been compromised. Both attacks resulted in an Xtreme RAT infection.

Interestingly, in the case of the fake Skype encryption the deception extended to a YouTube video from "IT Security Lab" [47] demonstrating the program's purported capabilities, as well as a website promoting the tool, **skype-encryption.sytes.net**. The attackers also constructed a basic, faux GUI for their "Encryption" program (see Figure 4). The fake GUI has a number of non-functional buttons like "Encrypt" and "DeCrypt," which generate fake prompts. While distracted by this meaningless interaction, the victim's machine is infected with DarkComet 3.3 [32, 33].

Anecdotally, campaign volume appears to track significant

[6] YahooMail and the iPhone mail client automatically load these remote images, especially in e-mails spoofed from trusted senders.

[7] Obfuscated to avoid accidental clicks on active malware URLs.

Type	Features	Examples (RATs)
Security tools	Executable files presented as a "tool" often accompanied by justifications or statements of its value in the targeted seeding, for example on a social media site, at the download location, or in videos	"Skype Encryption" (DC) [32, 33], "Facebook Security" (custom) [34], Anti-hacker (DC) [35], Fake Freegate VPN (ST) [36]
Ideologically or movement-relevant files	A document or PE as download or attachment with accompanying encouragement to open or act on the material, often masquerading as legitimate PDF documents or inadvertently leaked regime programs. Frequent use of RLO to disguise true extension (such as `.exe` or `.scr`)	"Names of individuals wanted by the Regime," (DC) "Aleppo [uprising] Plan" (DC) [37], important video (BS) [38], "Hama Rebels Council" document (DC) [39], "wanted persons" database frontend (custom), movement relevant video (njRAT), file about the Free Syrian Army (Xtreme RAT)
Miscellaneous tools	Tools pretending to offer functionality relevant to the opposition, such as a fake tool claiming to "mass report" regime pages on Facebook	hack_facebook_pro_v6.9 (DC) [40]

Table 3: Campaigns and RATs employed in Syrian surveillance. BS = Blackshades, DC = DarkComet, ST = ShadowTech.

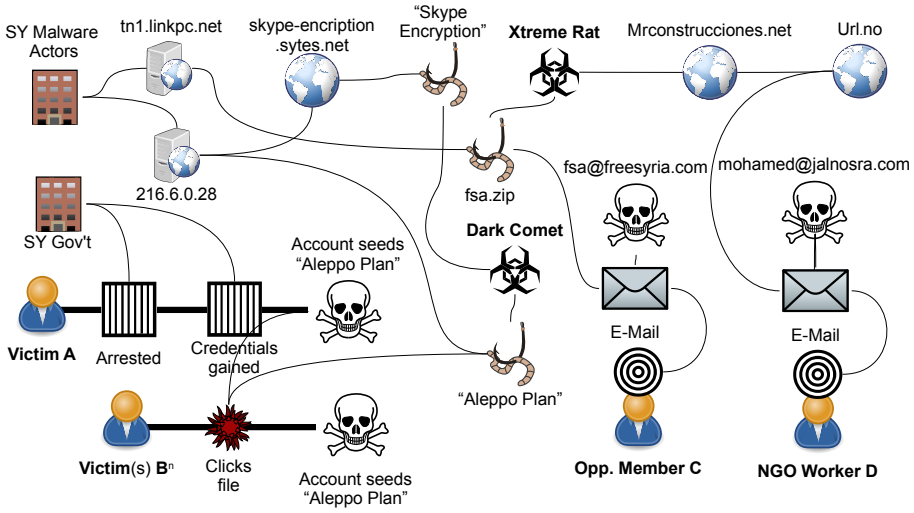

Figure 3: A sample from the ecosystem of Syrian malware campaigns.

events in the ongoing conflict. For example, campaigns dwindled and then rebounded within hours after Syria's 2012 Internet shutdown [48]. Similarly, activity observed by the authors also dwindled prior to expectation of US-led military action against Syrian government targets in September 2013. Once this option appeared to be off the table, the volume of new samples and campaigns we observed again increased, including the recent targeting of NGO workers per Figure 3. We are aware of only a negligible number of cases of the opposition using similar RATs against Syrian Government supporters, although evidence exists of other kinds of electronic attacks by third parties.

Real world consequences. The logistics and activities of Syria's numerous opposition groups are intentionally concealed from public view to protect both their efficacy, and the lives of people participating in them. Nevertheless, Syrian opposition members are generally familiar with stories off digital compromises of high-profile figures, including those entrusted with the most sensitive roles, as well as rank-and-file members. Compromise of operational security poses a documented threat to life both for victims of electronic compromise, and to family members and associates.

The Syrian conflict is ongoing, making it difficult to assem-

Figure 4: The fake Skype program distracts the victim with the promise of encrypted communications while infecting their machine with DarkComet.

ble comprehensive evidence of linkages between government actors and malware campaigns. Moreover, many individuals whose identities have been compromised are in prison or otherwise disappeared, and thus unable to relate the evidence presented to them during interrogation. Still, strong circumstantial evidence links the use of RATs, phishing, and government activity, which we briefly summarize here: (1) many Syrians have recounted to journalists and the authors how interrogators confronted them with material from their computers. For example:

> The policeman told me, "Do you remember when you were talking to your friend and you told him you had something wrong [sic] and paid a lot of money? At that time we were taking information from your laptop." [41]

(2) Syrian activists have supplied cases to international journalists [41], where arrests are quickly followed by the social media accounts of detained individuals seeding malware to contact lists (Figure 3). (3) Finally, despite the notoriety of the attack campaigns, including mention of C&C IPs in international media [45], the Syrian government has made no public statements about these campaigns nor acted to shut down the servers.

Beyond the ongoing challenges of attribution, these malware campaigns have a tangible impact on the Syrian opposition, and generally align with the interests of the Syrian government's propaganda operations. The case of Abdul Razzaq Tlass, a leader in the Free Syrian Army, is illustrative of the potential uses of such campaigns. In 2012 a string of videos emerged showing Tlass sexting and engaged in lewd activity in front of a webcam [49]. While he denied the videos, the harm to his reputation was substantial and he was eventually replaced [50].

4.3 UAE

While the UAE has experienced no recent uprising or political unrest, it has nevertheless cracked down on its opposition, concurrent with the Arab Spring.

The first attacks we observed in the UAE involved a government-grade "lawful interception" trojan known as *Remote Control System* (RCS), sold by the Italian company Hacking Team. The associated C&C server indicated direct UAE government involvement. Over time, we stopped receiving RCS samples from UAE targets, and instead observed a shift to the use of off-the-shelf RATs, and possible involvement of cyber-mercenary groups. However, poor attacker operational security allowed us to link most observed attacks together.

RCS. UAE activist **Ahmed** Mansoor (per Figure 5), imprisoned from April to November 2011 after signing an online pro-democracy petition [51], received an e-mail purportedly from "Arabic Wikileaks" in July 2012. He opened the associated attachment, "veryimportant.doc," and saw what he described as "scrambled letters". He forwarded us the e-mail for investigation.

The attachment exploited CVE-2010-3333, an RTF parsing vulnerability in Microsoft Office. The document did not contain any bait content, and part of the malformed RTF that triggered the exploit was displayed in the document. The exploit loaded shellcode that downloaded a second stage

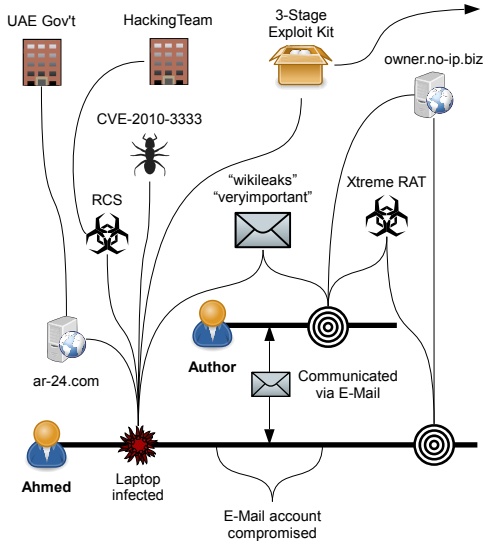

Figure 5: Part of the ecosystem of UAE surveillance attacks.

from `ar-24.com`, which in turn downloaded spyware from `ar-24.com`. We denote this combination as the **3-Stage Exploit Kit** in Figure 5.

The C&C server also ran on `ar-24.com`. When we obtained the sample in July 2012, `ar-24.com` resolved to an IP address on Linode, a hosting provider. Three months later, it resolved to a UAE address belonging to the Royal Group [52], an organization linked to the UAE government; it is chaired by Sheikh Tahnoon bin Zayed Al-Nayhan, a member of the UAE ruling family and a son of the founder of the UAE.

Identification as RCS: We identified strings in memory that matched those in a Symantec analysis [53] of RCS (also known as *DaVinci* or *Crisis*), a product of the Italian company Hacking Team [54]. We also located a structurally similar Word document via VirusTotal. The document used the same exploit and attempted to download a second stage from `rcs-demo.hackingteam.it`, which was unavailable at the time of testing.

Analysis of capabilities: RCS has a suite of functionality largely similar to FinSpy. One difference was in the vectors used to install the spyware. We located additional samples (see § 5), some of which were embedded in a `.jar` file that installs an OS-appropriate version of RCS (Windows or OSX), optionally using an exploit. If embedded as an applet, and no exploit is present, Java displays a security warning and asks the user whether they authorize the installation. We also saw instances of the **3-Stage Exploit Kit** where the first stage contained a Flash exploit; in some cases, we could obtain all stages and confirm that these installed RCS. Some samples were packed with the MPress packer [55], and some Windows samples were obfuscated to look like the `PuTTY` SSH client.

Another difference is in persistence. For example, the RCS sample sent to Ahmed adds a `Run` registry key, whereas the FinSpy samples used in Bahrain overwrite the hard disk's boot sector to modify the boot process; the spyware is loaded be-

fore the OS, and injects itself into OS processes as they start. The RCS samples we examined also had the ability to propagate to other devices, including into inactive VMWare virtual machines by modifying the disk image, onto USB flash drives, and onto Windows Mobile phones. We did not observe similar capabilities in the FinSpy samples we examined.

Exploitation of captured data: When Ahmed Mansoor received the RCS document, he opened it, infecting his computer (Figure 5). Ahmed subsequently noted several suspicious accesses to his GMail account using IMAP. Even after he changed his password, the accesses continued. While corresponding with Ahmed on his compromised account, an author of this paper discovered that the attackers had installed an *application-specific password* [56] in Ahmed's GMail account, a secondary password that they apparently used to access his account even after he changed his main password. The suspicious accesses stopped after removal of the application-specific password.

Two weeks after this correspondence with Ahmed, one of us (**Author** in Figure 5) received a targeted e-mail with a link to a file hosted on Google Docs containing a commercial off-the-shelf RAT, Xtreme RAT. The e-mail was sent from the UAE's timezone (as well as of other countries) and contained the terms "veryimportant" and "wikileaks", just like in the e-mail received by Ahmed.

The instance of Xtreme RAT sent to **Author** used `owner.no-ip.biz` for its C&C, one of the domains mentioned in a report published by Norman about a year-long campaign of cyberattacks on Israeli and Palestinian targets carried out by a group that Norman was unable to identify [57]. Three months after **Author** was targeted, Ahmed received an e-mail containing an attachment with Xtreme RAT that talked to the same C&C server (Figure 5), suggesting that the attackers who infected Ahmed with RCS may have provided a list of interesting e-mail addresses to another group for further targeting.

Possible consequences: Shortly after he was targeted, Ahmed says he was physically assaulted twice by an attacker who appeared able to track Ahmed's location [58]. He also reports that his car was stolen, a large sum of money disappeared from his bank account, and his passport was confiscated [59]. He believes these consequences are part of a government intimidation campaign against him, but we did not uncover any direct links to his infection. (Interestingly, spyware subsequently sent to others has used bait content about Ahmed.)

Further attacks: In October 2012, UAE **Journalist A** and **H**uman **R**ights **activist B** (per Figure 6) forwarded us suspicious e-mails they had received that contained a Word document corresponding to the first stage of **3-Stage Exploit Kit** (Figure 5). The attachment contained an embedded Flash file that exploited a vulnerability fixed in Adobe Flash 11.4, loading shell code to download a second stage from `faddeha.com`. We were unable to obtain the second stage or the ultimate payload, as the website was unavailable at the time of testing. However, the exploit kit appears indicative of Hacking Team involvement. A page on `faddeha.com` found in Google's cache contained an embedded `.jar` with the same applet class (*WebEnhancer*) as those observed in other `.jar` files that we found to contain RCS.

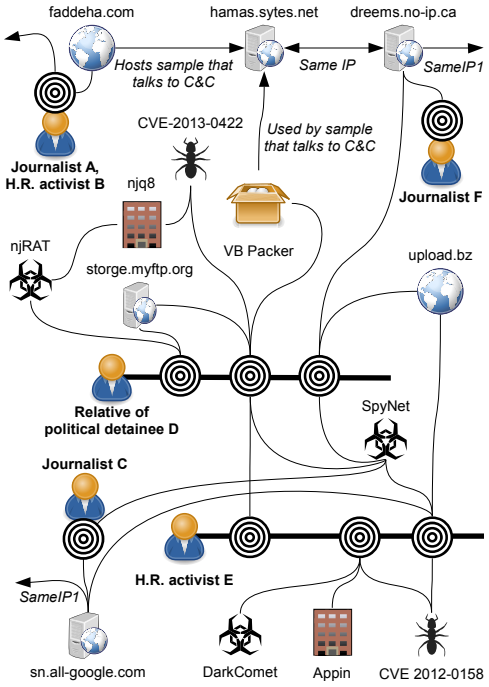

Figure 6: Another part of the ecosystem of UAE surveillance attacks.

Off-the-shelf RATs. We found a file that VirusTotal had downloaded from `faddeha.com`, which appeared to be a remote access toolkit known as *SpyNet*, available for general purchase for 50 Euros [60]. The SpyNet sample communicated with the C&C `hamas.sytes.net`.

SpyNet Packing: We found another instance of the first stage of the **3-Stage Exploit Kit** on VirusTotal. The exploit downloaded a second stage, which in turn downloaded a sample of SpyNet from `maile-s.com`. This sample of SpyNet communicated with the same C&C `hamas.sytes.net`. The sample was packed using *ASProtect* [61]. When run, the sample unpacks a compiled Visual Basic project that loads, via the `RunPE` method [62], an executable packed with *UPX* [63]. Finally, this executable unpacks SpyNet. SpyNet's GUI only offers an option to pack with UPX, suggesting that the attackers specially added the other layers of packing. In some cases, the Visual Basic project bears the name *NoWayTech*, which appears to be an underground `RunPE` tool, while others are named *SpyVisual*, which we have been unable to trace to any public underground tools, and thus also may reflect customization by the attacker. The *SpyVisual* projects contain the string `c:\Users\Zain\AppData\Local\Temp\OLE1EmbedStrm.wav`, which we used as the fingerprint **VB Packer** in Figure 6.

Cedar Key attack: The same **VB Packer** was used in an attack on **Relative of political detainee D** and **H.R. activist E** in Figure 6. These individuals received e-mails containing a link to a web page hosted on `cedarkeyrv.com` impersonating YouTube. Loading the page greeted the target with "*Video loading please wait ...*" The page redirected to a YouTube video a few seconds later, but first loaded a Java exploit [64]—a

known vulnerability with no patch at the time that the e-mails were sent. Oracle released a patch 12 hours after activists began receiving these links.

The cedarkeyrv.com domain is associated with an RV park in Cedar Key, Florida. The website's hosting company told us that the site had apparently suffered a compromise, but did not have further details.

The exploit used in the attack appears to have been originally posted by a Kuwaiti user, *njq8*, on an Arabic-language exploit sharing site [65]. We contacted *njq8*, who told us that he had obtained the exploit elsewhere and modified it prior to posting. The attack downloaded an instance of SpyNet from isteeler.com (which from our inspection did not appear to have any legitimate content), which used the C&C storge.myftp.org. This same C&C occurred in another attack (Figure 6) targeting **Relative of political detainee D**; in that case, the payload was a freely-available RAT known as *njRAT*, written by the same *njq8* as the exploit-poster discussed above. However, we did not find any other evidence suggesting *njq8*'s involvement in either attack.

More SpyNet attacks: The domain hamas.sytes.net, which we previously saw used by two SpyNet samples, resolved to 67.205.79.177. Historically, dreems.no-ip.ca also resolved to this address. An unidentified dropper using this C&C targeted **Journalist F**; a SpyNet attack on **Relative of political detainee D** also used this C&C. In that latter case, the sample arrived via e-mail in a .rar attachment that contained an .scr file disguised as a Word document. The .scr file was a self-extracting archive that decompressed and ran both the bait document and the payload. The SMTP source of the e-mail was webmail.upload.bz.

Appin: In early 2013 UAE **H.R. activist E** forwarded numerous documents that included a particular CVE-2012-0158 exploit for Microsoft Word. In all, these totaled 17 distinct hashes of documents, and 10 distinct hashes of payloads (some documents that differed in their hash downloaded the same payload). The exploits primarily downloaded instances of SpyNet from upload.bz, which for the most part communicated with C&C at sn.all-google.com. This domain was also used for C&C in other attacks, including that on **Journalist C**.

Two of the other CVE-2012-0158 exploits downloaded DarkComet from www.getmedia.us and www.technopenta.com after posting system information to random123.site11.com. All three domains match those used by an Indian cybermercenary group said to be linked to Appin Security Group [66]. The former two domains hosted content other than spyware (i.e., they may have been compromised). We alerted the owner of www.getmedia.us, who removed the payloads.

5 Empirical characterization

The samples we received afforded us an opportunity to empirically characterize the use of FinFisher and Hacking Team around the world, enabling us to assess their prevalence, and identify other country cases that may warrant future investigation. We analyzed the samples and the behavior of their C&C servers to develop indicators (fingerprints) for how the servers respond to certain types of requests. We then scanned the full Internet IPv4 address space ("/0") for these, along with probing results found by past scans. In many cases we do not release the full details of our fingerprints to avoid compromising what may be legitimate investigations.

5.1 FinSpy

Identifying and linking servers: We developed a number of fingerprints for identifying FinSpy servers using HTTP-based probing as well as FinSpy's custom TLV-based protocol. We leveraged quirks such as specific non-compliance with RFC 2616, responses to certain types of invalid data, and the presence of signatures such as the bizarre "Hallo Steffi" that Guarnieri identified from Bahraini FinSpy C&C servers [67, 68]. See Appendix A for details. We then exhaustively scanned the Internet looking for matches to these fingerprints.

Gamma documentation advertises that an operator of FinSpy can obscure the location of the C&C server (called the *master*) by setting up a proxy known as a *relay*. In Spring 2013 we noticed FinSpy servers now issuing 302 Redirects to google.com. However, we noticed anomalies: for example, servers in India were redirecting to the Latvian version of Google google.lv. We suspect that the server in India was a relay forwarding to a master in Latvia. Because the master served as a proxy for Google, we could uncover its IP address using a Google feature that prints a user's IP address for the query "IP address." We created an additional fingerprint based on the proxying behavior and issued GET /search?q=ip+address&nord=1 requests to servers We note some interesting master locations in Table 4.

Server locations: In all, our fingerprints matched 92 distinct IP addresses in 35 different countries. Probing these on 8/8/13 revealed 22 distinct addresses still responding, sited in: Bahrain, Bangladesh, Bosnia and Herzegovina, Estonia, Ethiopia, Germany, Hong Kong, Indonesia, Macedonia, Mexico, Romania, Serbia, Turkmenistan, and the United States. We found servers responding to a number of our fingerprints, suggesting either that some servers lag in their updates, or a concerted effort to vary the behavior of FinSpy servers to make detection harder.

We found: **(1)** 3 IP addresses in ranges registered to Gamma. **(2)** Servers in 3 IP ranges explicitly registered to government agencies: Turkmenistan's Ministry of Communications, Qatar's State Security Bureau, and the Bulgarian Council of Ministers. **(3)** 3 additional IP addresses in Bahrain, all in Batelco. **(4)** Servers in 7 countries with governments classified as "authoritarian regimes" by *The Economist* [69]: Bahrain, Ethiopia, Nigeria, Qatar, Turkmenistan, UAE, Vietnam.

Additional FinSpy samples: In parallel to our scanning, we obtained 9 samples of FinSpy by writing YARA [70] rules for the "malware hunting" feature of VirusTotal Intelligence. This feature sends us all newly-submitted samples that match our signatures. We located a version of FinSpy that does not use the normal FinSpy handshake, but instead uses a protocol based on HTTP POST requests for communication with the C&C server. This did not appear to be an older or newer ver-

Relay IP	Relay Block Assignment	Relay Country	Master IP	Master Block Assignment	Master Country
5.199.xxx.xxx	SynWebHost	Lithuania	188.219.xxx.xx	Vodafone	Italy
46.23.xxx.xxx	UK2 VPS.net	UK	78.100.xxx.xxx	State Security Building	Qatar
119.18.xxx.xxx	HostGator	India	81.198.xxx.xxx	Statoil DSL	Latvia
180.235.xxx.xxx	Asia Web Services	Hong Kong	80.95.xxx.xxx	T-Systems	Czech Republic
182.54.xxx.xxx	GPLHost	Australia	180.250.xxx.xxx	PT Telekom	Indonesia
206.190.xxx.xxx	WestHost	USA	112.78.xxx.xxx	Biznet ISP	Indonesia

Table 4: Deproxifying FinSpy (mapping initial C&C IP addresses to the masters to which they forward).

sion of the protocol, suggesting that our scan results may not reveal the full scope of FinSpy C&C servers. Perhaps, the `HTTP POST` protocol was only delivered to a specific Gamma customer to meet a requirement.

5.2 Remote Control System (RCS)

We began by analyzing the UAE RCS sample from Ahmed and 6 samples obtained from VirusTotal by searching for AV results containing the strings "DaVinci" and "RCS." At the time, several AV vendors had added detection for RCS based on a sample analyzed by Dr. Web [71] and the UAE RCS sample sent to Ahmed. We also similarly obtained and analyzed samples of FSBSpy [72], a piece of malware that can report system information, upload screenshots, and drop and execute more malware, Based on these samples, we devised YARA signatures that yielded 23 additional samples of structurally similar malware.

Fingerprints: We probed the C&C servers of the RCS and FSBSpy samples, and found that they responded in a distinctive way to HTTP requests, and returned distinctive SSL certificates.

We searched sources including Shodan, 5 Internet Census service probes [73], and Critical.IO scanning data [68] for the observed distinctive HTTP behavior. We searched for the distinctive SSL certificates in two Internet Census service probes, and SSL certificate scans from ZMap [74]. We also contacted a team at TU Munich [75], who applied our fingerprints to their SSL scanning data. Across all of these sources, we obtained 31,345 indicator hits reflecting 555 IP addresses in 48 countries.

One SSL certificate returned by 175 of the servers was issued by "/CN=RCS Certification Authority /O=HT srl," apparently referring to the name of the spyware and the company. Servers for 5 of our FSBSpy samples and 2 of our RCS samples responded with this type of certificate.

Some servers returned these certificates in chains that included another distinctive certificate. We found 175 distinct IP addresses (including the C&C's for 5 of our FSBSpy samples and 2 of our RCS samples) responded with this second type of certificate.

We devised two more indicators: one that matched 125 IP addresses, including 7 of our FSBSpy samples' C&C's, and one that matched 2 IP addresses, in Italy and Kazakhstan.

Server locations: On 11/4/13 we probed all of the IP addresses that we collected, finding 166 active addresses matching one of our fingerprints in 29 different countries. We summarize the top providers and countries in Table 5.

Country	IPs
United States	61
United Kingdom	18
Italy	16
Japan	10
Morocco	7

Provider	IPs
Linode	42
NOC4Hosts	16
Telecom Italia	9
Maroc Telecom	7
InfoLink	6

Table 5: Top countries and hosting providers for RCS servers active on 11/4/13.

The prevalence of active servers either located in the USA or hosted by Linode is striking,[8] and seems to indicate a pervasive use of out-of-country web hosting and VPS services.

In addition, we found: **(1)** 3 IP addresses on a `/28` named "HT public subnet" that is registered to the CFO of Hacking Team [76]. The domain `hackingteam.it` resolves to an address in this range. **(2)** An address belonging to Omantel, a majority-state-owned telecom in Oman. This address was unreachable when we probed it; a researcher pointed us to an FSBSpy sample that contained an Arabic-language bait document about Omani poetry, which talked to a C&C in the UK. **(3)** 7 IP addresses belonging to Maroc Telecom. Moroccan journalists at Mamfakinch.com were previously targeted by RCS in 2012 [77]. **(4)** Overall, servers in 8 countries with governments deemed "authoritarian regimes" [69]: Azerbaijan, Kazakhstan, Nigeria, Oman, Saudi Arabia, Sudan, UAE, Uzbekistan.

Link to Hacking Team: All active servers matching one of our signatures also responded peculiarly when queried with particular ill-formed HTTP requests, responding with "`HTTP1/1 400 Bad request`" (should be "`HTTP/1.1`") and a body of "`Detected error: HTTP code 400`". Googling for this response yielded a GitHub project `em-http-server` [78], a Ruby-based webserver. The project's author is listed as Alberto Ornaghi, a software architect at Hacking Team. We suspect that the Hacking Team C&C server code may incorporate code from this project.

Links between servers: We identified many cases where several servers hosted by different providers, and in different countries, returned identical SSL certificates matching our fingerprints. We also observed 30 active servers used a global IPID. Only one active server had neither a global IPID nor

[8] 19 of the 42 Linode servers were hosted in the USA, so the two patterns of prevalence are mostly distinct.

an SSL certificate matching our fingerprints. We assessed whether servers returning SSL certificates were forwarding to the servers with global IPIDs by inducing bursts of traffic at the former and monitoring the IPID at the latter. For 11 servers, we found that the server's activity correlated to bursts sent to other servers We grouped servers by the SSL certificates they returned, and found that each group forwarded to only a single server, except for one case where a group forwarded to two different IPs (both in Morocco). We also found two groups that forwarded to the same address. There was a 1:1 mapping between the remaining 8 addresses and groups. We refer to a group along with the server(s) it forwards to as a *server group*. We identified several server groups that may be associated with victims or operators in a certain country. Some of these suggest possible further investigation:

Turkey: We identified a group containing 20 servers in 9 countries. Two RCS and 5 FSBSpy samples from VirusTotal communicated with various servers in the group. The RCS samples also communicated with domains with lapsed registrations, so we registered them to observe incoming traffic. We exclusively received RCS traffic from Turkish IP addresses. (RCS traffic is identifiable based on a distinctive user agent and URL in `POST` requests.) A sample of FSBSpy apparently installed from an exploit on a Turkish server talked to one of the servers in this group.[79]

We also found server groups containing servers in **Uzbekistan** and **Kazakhstan**; we found FSBSpy samples on VirusTotal uploaded from these countries that communicated with servers in these groups.

In the above cases, save Turkey, the country we have identified is classified as an "authoritarian regime," and may be using Hacking Team products against the types of targets we profile in this paper. In the case of Turkey, there are hints that the tool may be employed against dissidents [80].

6 Summary

Targeted surveillance of individuals conducted by nation-states poses an exceptionally challenging security problem, given the great imbalance of resources and expertise between the victims and the attackers. We have sketched the nature of this problem space as reported to us by targeted individuals in three Middle Eastern countries. The attacks include spyware for ongoing monitoring and the use of "IP spy" links to deanonymize those who voice dissent.

The attacks, while sometimes incorporating effective social engineering, in general lack novel technical elements. Instead, they employ prepackaged tools developed by vendors or acquired from the cybercrime underground. This technology sometimes suffers from what strike us as amateurish mistakes (multiple serious errors implementing cryptography, broken protocol messages), as does the attackers' employment of it (identifying-information embedded in binaries, C&C servers discoverable via scanning or "Google hacking", clusters of attack accounts tied by common activity). Some of these errors assisted our efforts to assemble strong circumstantial evidence of governmental origins. In addition, we mapped out the global use of two "governmental" hacking suites, including identifying 11 cases in which they appeared to be used in countries governed by "authoritarian regimes."

We aim with this work to inspire additional research efforts addressing the difficult problem of how to adequately protect individuals with very limited resources facing very powerful adversaries. Open questions include robust, practical detection of targeted attacks designed to exfiltrate data from a victim's computer, as well as detection of and defense against novel attack vectors, like tampering with Internet connections to insert malware.

The task is highly challenging, but the potential stakes are likewise very high. An opposition member, reflecting on government hacking in Libya, speculated as to why some users would execute files even while recognizing them as potentially malicious [2]: "*If we were vulnerable we couldn't care less … we were desperate to get our voices out … it was a matter of life or death … it was just vital to get this information out.*"

A FinSpy fingerprints

Previous work by Guarnieri on scanning for FinSpy servers found that in response to a request such as `GET /`, the Bahraini FinSpy C&C server returns a response with the string "`Hallo Steffi`" [67]. Guarnieri searched a database of such responses compiled by the Critical.IO Internet scanning project [68], locating 11 additional servers in 10 countries [67]. We refer to this fingerprint as α_1. Concurrent with this effort, we devised our own fingerprint β_1 that tested three aspects of the handshake between a FinSpy infectee and a FinSpy C&C server, which follows a custom TLV-based protocol running on ports such as 22, 53, 80, and 443. We conducted targeted scanning of several countries using β_1, and also confirmed Guarnieri's findings for those servers still reachable after he published his findings.

We observed a trend: changes in HTTP response behavior by FinFisher after publication of findings about the software. In July 2012, for example, after a post about Bahraini FinSpy samples [81], servers closed the TCP connection in response to a `GET /` or `HEAD /` request (although servers continued to behave consistently with β_1. Other changes followed later in 2012, including a new response to `GET /` requests that included an imperfect copy of an Apache server's HTTP response (the `Date` header used `UTC` rather than `GMT`). We fingerprinted this error as α_2, and later in 2012 fingerprinted other distinctive behavior in response to `GET /` requests as α_3.

Subsequent scans of `/0` for α_2 and α_3, and five service probes of the Internet Census for α_1 through α_3, located several additional servers. In Feburary 2013 we identified and fingerprinted new HTTP response behavior with α_4 and modified β_1 to produce β_2, which tests only two of the three aspects of the FinSpy handshake (the third test of β_1 was broken when FinSpy servers were updated to accept types of invalid data they had previously rejected).

As of 3/13/13, all servers that matched any α fingerprint matched β_2.

Targeted Threat Index: Characterizing and Quantifying Politically-Motivated Targeted Malware

Abstract

Targeted attacks on civil society and non-governmental organizations have gone underreported despite the fact that these organizations have been shown to be frequent targets of these attacks. In this paper, we shed light on targeted malware attacks faced by these organizations by studying malicious e-mails received by 10 civil society organizations (the majority of which are from groups related to China and Tibet issues) over a period of 4 years.

Our study highlights important properties of malware threats faced by these organizations with implications on how these organizations defend themselves and how we quantify these threats. We find that the technical sophistication of malware we observe is fairly low, with more effort placed on socially engineering the e-mail content. Based on this observation, we develop the Targeted Threat Index (TTI), a metric which incorporates both social engineering and technical sophistication when assessing the risk of malware threats. We demonstrate that this metric is more effective than simple technical sophistication for identifying malware threats with the highest potential to successfully compromise victims. We also discuss how education efforts focused on changing user behaviour can help prevent compromise. For two of the three Tibetan groups in our study simple steps such as avoiding the use of email attachments could cut document-based malware threats delivered through e-mail that we observed by up to 95%.

1 Introduction

Civil society organizations (CSOs), working on human rights issues around the globe, face a spectrum of politically-motivated information security threats that seek to deny (e.g. Internet filtering, denial-of-service attacks), manipulate (e.g. website defacements) or monitor (e.g. targeted malware) information related to their work. Targeted malware attacks in particular are an increasing problem for CSOs. These attacks are not isolated incidents, but waves of attacks organized in campaigns that persistently attempt to compromise systems and gain access to networks over long periods of time while remaining undetected. These campaigns are custom designed for specific targets and are conducted by highly motivated attackers. The objective of these campaigns is to extract information from compromised systems and monitor user activity and is best understood as a form of espionage. CSOs can be particularly susceptible to these threats due to limited resources and lack of security awareness. Targeted malware is an active research area, particularly in private industry. However, focused studies on targeted attacks against CSOs are relatively limited despite the persistent threats they face and the vulnerability of these groups.

In this study, we work with 10 CSOs for a period of 4 years to characterize and track targeted malware campaigns against these groups. With the exception of two groups that work on human rights in multiple countries, the remaining eight groups focus on China and Tibet-related human rights issues. We focus on targeted malware typically delivered via e-mail that is specifically tailored to these groups as opposed to conventional spam which has been well characterized in numerous previous works [27, 42, 45, 52, 70, 71]. We consider the threats to these groups along two axes: the technical sophistication of the malware as well as sophistication of the social engineering used to deliver the malicious payload. We combine these two metrics to form an overall threat ranking that we call the Targeted Threat Index (TTI). While other scoring systems exist for characterizing the level of severity and danger of a technical vulnerability [7, 17, 41, 50], no common system exists for ranking the sophistication of targeted e-mail attacks. TTI allows us to gain insights into the relative sophistication of social engineering and malware leveraged against CSOs.

A key to the success of our study is a unique methodology, combining qualitative and technical analysis of

e-mails and their attachments with fieldwork (e.g. site visits) and interviews with affected CSOs. This methodology, which we describe in more detail in Section 3, allows us to both accurately rate the level of targeting of e-mail messages by interfacing with CSOs participating in our study (Section 4.2), and understand the relative technical sophistication of different malware families used in the attacks (Section 4.3). By combining the strengths of our qualitative and quantitative analysis, we are able to accurately understand trends in terms of social engineering and technical sophistication of politically-motivated targeted malware threats faced by CSOs.

Our study makes the following observations, which have implications for security strategies that CSOs can employ to protect themselves from targeted malware:

Attachments are the primary vector for email based targeted malware. More than 80% of malware delivered to Tibet-related organizations in our study and submitted to us is contained in an e-mail attachment. Further, for 2 of the 3 Tibetan organizations in our study (with at least 40 submitted e-mails), simply not opening attachments would mitigate more than 95% of targeted malware threats that use email as a vector.

Targeted malware technical sophistication is low. Social engineering sophistication is high We find that the technical sophistication of targeted malware delivered to CSOs in our study is relatively low (*e.g.,* relative to commercial malware that has been found targeting CSOs and journalists [35,36,38] and conventional financially motivated malware), with much more effort given to socially engineering messages to mislead users. This finding highlights the potential for education efforts focused on changing user behaviours rather than high-cost technical security solutions to help protect CSOs.

CSOs face persistent and highly motivated actors. For numerous malware samples in our study we observe several versions of the software appearing over the course of our four year study. These multiple versions show evidence of technical improvements to complement existing social engineering techniques.

Since the start of our study we have participated in a series of workshops with the participating Tibetan organizations to translate these results into a training curriculum. Specifically, we have educated them about how to identify suspicious e-mail headers to identify spoofed senders and demonstrated tools that can be used to check e-mailed links for malware and drive-by-downloads.

The rest of the paper is structured as follows. Section 2 presents relevant background on targeted malware and attacks on CSOs. Our data collection methodology is described in Section 3. We describe our targeting and technical sophistication metrics as well as how we combine them to produce the Targeted Threat Index (TTI) in Section 4. Training and outreach implications of our work are discussed in Section 5. We present related work in Section 6 and conclude in Section 7.

2 Background

2.1 Targeted Malware Overview

Targeted malware are a category of attacks that are distinct from common spam, phishing, and financially motivated malware. Spam and mass phishing attacks are indiscriminate in the selection of targets and are directed to the largest number of users possible. Similarly, financially motivated malware such as banking trojans seek to compromise as many users as possible to maximize the potential profits that can be made. The social engineering tactics and themes used by these kinds of attacks are generic and the attack vectors are sent in high volumes. By contrast targeted malware attacks are designed for specific targets, sent in lower volumes, and are motivated by the objective of stealing specific sensitive data from a target.

Targeted malware attacks typically involve the following stages [24, 66]:

Reconnaissance: During this stage attackers conduct research on targets including profiling systems, software, and information security defenses used to identify possible vulnerabilities and contextual information on personnel and activities to aid social engineering.

Delivery: During this stage a vector for delivering the attack is selected. Common vectors include e-mails with malicious documents or links, or contacting targets through instant messaging services and using social engineering to send malware to them. Typically, a target of such an attack receives an e-mail, possibly appearing to be from someone they know, containing text that urges the user to open an attached document (or visit a website).

Compromise: During this stage malicious code is executed on a target machine typically after a user initiated action such as opening a malicious document or link.

Command and Control: During this stage the infected host system establishes a communications channel to a command and control (C&C) server operated by the attackers. Once this channel has been established the attackers can issue commands and download further malware on to the system

Additional attacker actions: After a successful compromise is established, attackers can conduct a number of actions including ex-filtrating data from the infected host and transmitting it back to attackers through a process of encrypting, compressing, and transferring to a server

operated by the attackers. Attackers may also use peripherals such as webcams and microphones to monitor users in real time. The infected host may also serve as a starting point to infect other machines on the network and seek out specific information or credentials.

2.2 Targeted Malware and CSOs

Targeted malware has become recognized by governments and businesses around the world as a serious political and corporate espionage threat. The United States government has been particularly vocal on the threat targeted malware enabled espionage poses. General Keith Alexander, current Director of the National Security Agency and Commander of United States Cyber Command has stated that the theft of US intellectual property through cyber espionage constitutes the "greatest transfer of wealth in history" [47]. Recent widely publicized targeted malware intrusions against Google, RSA, the New York Times and other high profile targets have raised public awareness around these attacks [20, 44, 48]

Despite this increased attention, targeted malware is not a new problem, with over a decade of public reports on these kinds of attacks [66]. However, the majority of research on targeted malware is conducted by private security companies who typically focus on campaigns against industry and government entities. As a result, targeted attacks on civil society and non-governmental organizations have gone underreported despite the fact that these organizations have been shown to be frequently targeted by cyber espionage campaigns. In particular, communities related to ethnic minority groups in China including Tibetans, Uyghurs, and religious groups such as Falun Gong have been frequent targets of cyber espionage campaigns with reports dating back to at least 2002 [61].

In some cases, the same actors have been revealed to be targeting civil society groups, government and industry entities. A notable example of this was the 2009 report by the Citizen Lab, a research group at the University of Toronto, which uncovered the "GhostNet" cyber espionage network. GhostNet successfully compromised prominent organizations in the Tibetan community in addition to 1,295 hosts in 103 countries, including ministries of foreign affairs, embassies, international organizations, and news media [25]. The GhostNet case is not an isolated example, as other reports have shown CSOs (commonly Tibetan organizations) included as targets in campaigns that are also directed to a range of government and industry entities [8, 26, 28, 29, 54–56] Some of these reports include technical details on the CSO specific attacks [26, 28, 54, 55] while others note them as a target but do not address in detail [8, 29, 56].

While the majority of documented targeted malware campaigns against CSOs involve China and Tibet-related groups and potentially China-related attack operators [9–11, 23, 25, 26, 32, 61–65, 67, 68] , these kinds of attacks go beyond China. Recent research and news media have reported attacks against large human rights groups focused on multiple issues and countries [31, 46], and communities related to Syria [18] and Iran [37]. Researchers have also uncovered the use of commercial network intrusion products used to target activists from Bahrain [38], the United Arab Emirates [36], and journalists from Ethiopia [35].

3 Data collection

Since our study involves dealing with e-mail messages which may contain personally identifiable information (PII) and collection of information from CSOs who need to maintain privacy of their data, we consulted with our institutional research ethics board during the design of our study. The methods described below have been submitted to and approved by this board.

3.1 Study Participants

We recruited participants via three main channels: (1) an open call on our Web site, (2) outreach to organizations we had prior relationship with and (3) referrals from participating groups. As part of the study these groups agreed to share technical data (e.g., e-mails with suspicious attachments) and participate in interviews at the onset and end of the study. Their identity and any PII shared with us were kept strictly confidential.

For the purposes of our study, we focused on organizations with missions concerning the promotion or protection of human rights. For purposes of this study, "human rights" means any or all of the rights enumerated under the *Universal Declaration of Human Rights* [60], *the International Covenant on Civil and Political Rights* [58], and the *International Covenant on Economic, Social and Cultural Rights* [59]. We also considered organizations on a case by case basis that have a mission that does not directly implicate human rights, but who may nonetheless be targeted by politically motivated digital attacks because of work related to human rights issues (e.g., media organizations that report on human rights violations).

In total, 10 organizations participated in the study (summarized in Table 1). The majority of these groups work on China-related rights issues and five of these organizations focus specifically on Tibetan rights. The high rate of participation from China and Tibet-related human rights issues is due in part to our previous relationships with these communities and a significant interest and enthusiasm expressed by the groups. In addition to the China and Tibet-related groups, our study also includes

two groups, Rights Group 1 and 2 that work on multiple human rights related issues in various countries.

The majority of organizations operate from small offices with less than 20 employees. Some organizations (China Group 2, Tibet Group 2) have no physical office and consist of small virtual teams collaborating remotely, often from home offices. Of these groups only two (China Group 1, China Group 3) have a dedicated system administrator on staff. Other groups (Tibet Groups 1-5; China Group 2) rely on volunteers or staff with related technical skills (e.g. Web development) to provide technical support. Rights Group 1 and Rights Group 2 are much larger organizations relative to the others in our sample. Both organizations have over 100 employees, multiple offices, dedicated IT teams, and enterprise level computing infrastructures.

3.2 Data Sources

We collect the following pieces of information from the participant groups in order to understand the malware threats they face:

User-submitted e-mail messages. Our primary data source is a collection of e-mails identified by participants as suspicious which were forwarded to a dedicated e-mail server administered by our research team. When available these submissions included full headers, file attachments and / or links. There are three key limitations to relying on user-submitted e-mails for our analysis. First, we are only able to study e-mails identified by participants as suspicious, which may bias our results to only reporting threats that have been flagged by users. Further, individuals may forget to forward e-mails in some cases. Relying on self-reporting also creates bias between groups as individuals at different organizations may have different thresholds for reporting, which creates difficulties in accurately comparing submission rates between groups. Thus the amount of threat behaviour we see should be considered a lower bound on what occurs in practice. Second, having participants forward us e-mails does not allow us to verify if the targeted organization was successfully compromised by the attack (*e.g.,* if another member of the organization open and executed malware on their machine) and what the scope of the attack was. Finally, e-mail is only one vector that may be used to target organizations. Other vectors include waterhole attacks [21], denial of service attacks, or any other vectors (*e.g.,* physical threats like infected USB sticks). These limitations mean that it is possible that we did not comprehensively observe all attacks experienced by our study groups and some more advanced attacks may have gone unreported.

Recognizing the limitations of e-mail submissions, we complement user submitted emails with data from Network Intrusion Detection System (NIDS) alerts, website monitoring, and interviews. Also, upon request of study groups who were concerned of possible infection we analyzed packet capture data from suspect machines. Through the course of this supplementary analysis we did not find indications of malware compromise that used samples that were not included in our pool of user-submitted emails. In this paper we focus on reporting results from analyzing the user submitted emails through the TTI. The NIDS and website monitoring components were added later in our study and do not significantly contribute to TTI analysis. [1]

Table 2: Breakdown of e-mails submitted per group.

Organization Code	# of e-mails
China Group 1	53
China Group 2	18
China Group 3	58
Rights Group 1	28
Rights Group 2	2
Tibet Group 1	365
Tibet Group 2	177
Tibet Group 3	2
Tibet Group 4	97
Tibet Group 5	4

3.3 Overview of User-Submitted E-mails

The e-mails examined in this study span over four years, from October 14, 2009 to December 31, 2013. Data collection began on November 28, 2011, but China Group 3 and Tibet Group 1 forwarded us their pre-existing archives of suspicious emails, resulting in e-mail samples dating back to October 14, 2009. In total, we received 817 e-mails from the 10 groups participating in our study. Table 2 breaks down the submissions from each groups and illustrates that submissions were highly non-uniform across the groups. Thus, in general, we focus on the groups with at least 50 e-mail submissions for our analysis.

Figure 1 shows the cumulative number of e-mail submissions per month over the course of the study. For example, China Group 3 shared a set of e-mails received in 2010 by a highly targeted member of the organization, which can be observed in Figure 1. Tibet Group 1 accounts for the highest number of submissions relative to the other groups due to being one of the first groups in the study and being persistently targeted by politically motivated malware. Tibetan Groups 2 and 4, who joined the study later (in April 2012) show a similar submission rate to original Tibetan Group 1, suggesting these groups are targeted at a similar rate. In Section 4.2, we investi-

Table 1: Summary of groups participating in our study.

Organization Code	Description	Organization size
China Group 1	Human rights organization focused on rights and social justice issues related to China	Small (1-20 employees)
China Group 2	Independent news organization reporting on China	Small (1-20 employees)
China Group 3	Human rights organization focused on rights and social justice issues related to China	Small (1-20 employees)
Rights Group 1	Human rights organization focused on multiple issues and countries	Large (over 100 employees)
Rights Group 2	Human rights organization focused on multiple issues and countries	Large (over 100 employees)
Tibet Group 1	Human rights organization focused on Tibet	Small (1-20 employees)
Tibet Group 2	Human rights organization focused on Tibet	Small (1-20 employees)
Tibet Group 3	Independent news organization reporting on Tibet	Small (1-20 employees)
Tibet Group 4	Human rights organization focused on Tibet	Small (1-20 employees)
Tibet Group 5	Human rights organization focused on Tibet	Small (1-20 employees)

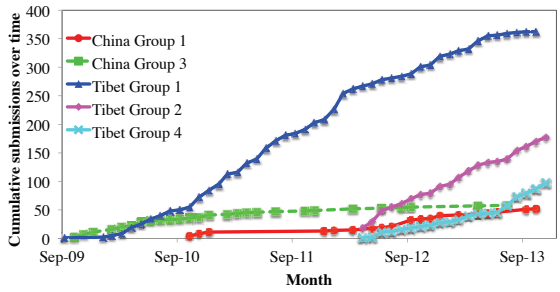

Figure 1: Cumulative number of messages per group over the course of our study for groups that submitted at least 50 e-mail messages.

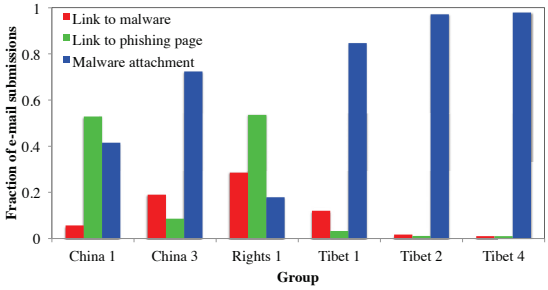

Figure 2: Breakdown of malicious e-mails based on whether they deliver malware as an attachment, refer the use to a link with a malicious file, or attempt to phish data from the user.

gate commonalities in targeting of these groups.

We further classify e-mails as malicious if they include attached malware, a direct link to malware or a site with a drive-by download, or a link to a phishing page. Figure 2 shows the amount of e-mails of each type for the groups that submitted at least 25 e-mails to our system. The most common approach employed in these e-mails was attaching a malicious payload to the e-mail itself. However, we notice a higher rate of phishing attacks on the China-related groups and the rights groups working on multiple international human rights issues. In particular, 46% of the e-mails submitted by China Group 1, and 50% of the e-mails submitted by Rights Group 1, direct the user to a phishing Web site. In the case of China Group 1, this large proportion of phishing sites is observed because this group configured their spam filter to forward e-mails to our system, resulting in us receiving a large number of generic, non-targeted spam. In contrast, the phishing observed for Rights Group 1, while low in volume (13 out of 26 messages) is targeted. We delve more into how we rate the targeting of e-mails in Section 4.2.

The rate of submissions to our project meant that it was feasible to manually analyze e-mail attachments for malware as they were submitted. This analysis gives us higher confidence in our results because AV signatures are frequently unable to detect new or modified threats, and can overlook the presence of a malicious payload that can be easily identified upon manual inspection (e.g. shellcode in an RTF exploit). In total, we analyzed 3,617 payload files and found 2,814 (78%) of them to be malicious. Section 4.3 describes our analysis methodology in more detail.

4 Targeted Threat Index

Our dataset includes a wide range of targeted malware threats varying in level of both social engineering and technical complexity. This range presents a challenge in ranking the relative sophistication of the malware and targeting tactics used by attackers.

While scoring systems such as the Common Vulnerability Scoring System [17] exist for the purpose of communicating the level of severity and danger of a vulnerability, there is no standardized system for ranking

the sophistication of targeted email attacks. This gap is likely because evaluating the sophistication of the targeting is non-technical, and cannot be automated due to the requirement of a strong familiarity with the underlying subject material.

To address this gap we developed the Targeted Threat Index (TTI) to assign a ranking score to the targeted malicious emails in our dataset. The TTI score is intended for use in prioritizing the analysis of incoming threats, as well as for getting an overall idea of how severely an organization is threatened.

The TTI score is calculated by taking a base value determined by the sophistication of the targeting method, which is then multiplied by a value for the technical sophistication of the malware. The base score can be used independently to compare emails, and the combined score gives an indication of the level of effort an attacker has put into individual threats.

4.1 TTI Metric

The TTI score is calculated in two parts:

(*Social Engineering Sophistication Base Value*)
$\times$(*Technical Sophistication Multiplier*) = *TTI Score*

TTI scores range from 1 to 10, where 10 is the most sophisticated attack. Scores of 0 are reserved for threats that are not targeted, even if they are malicious. For example, spam using an attached PDF or XLS to bypass anti-spam filters, and highly sophisticated financially motivated malware, would both score 0.

This section overviews how we compute the *Social Engineering Sophistication Base Value* (Section 4.2) and the *Technical Sophistication Multiplier* (Section 4.3). In Section 4.4, we present the results of computing and analyzing the TTI value of threats observed by the organizations in our study. We also discuss implications and limitations of the metric.

4.2 Social Engineering Tactics

We leverage a manual coding approach to measure the sophistication of social engineering tactics used in the attacks observed by the organizations in our study. While automated approaches may be explored in the future, this manual analysis allows us to have high confidence in our results, especially since understanding the social engineering often required contextual information provided by the organizations in our study. To quantify the level of sophistication, we manually analyse the e-mail subject line, body, attachments and header fields. We perform an initial content analysis by coding the e-mails based on their semantic content, and then use these results to generate a numerical metric quantifying the level of targeting used.

4.2.1 Content coding and analysis results

We code the e-mails based on their subject line, body, attachments and headers using the following methodology:

Subject line, body, and attachments. The content of the subject line, body and attachments for each submitted e-mail were content coded into 8 themes, each containing categories for specific instances of the theme: Country / Region (referring to a specific geographical country or region); Ethnic Groups (referring to a specific ethnic group); Event (referring to a specific event); Organizations (referring to specific organizations); People (referring to specific persons), Political (reference to specific political issues), Technology (reference to technical support), Miscellaneous (content without clear context or categories that do not fall into one of the other themes). Table 3 summarizes the themes and provides examples of categories within each theme.

E-mail headers. The header of each e-mail was analyzed to determine if the sending e-mail address was spoofed or the e-mail address was otherwise designed to appear to come from a real person and / or organization (e.g. by registering an e-mail account that resembles a person and / or organization's name from a free mail provider). We divide the results based on whether they attempted to spoof an organization or a specific person.

Using this manual analysis, we perform a content analysis of e-mails submitted by the organizations. Results of this analysis confirm that social engineering is an important tool in the arsenal of adversaries who aim to deliver targeted malware. Specifically, 95% and 97% of e-mails to Chinese and Tibetan groups, respectively, included reference to relevant regional issues. Spoofing of specific senders and organizations was also prevalent with 52% of e-mails to Tibetan groups designed to appear to come from real organizations, often from within the Tibetan community. For example, a common target of spoofing was the Central Tibetan Administration (CTA), referenced in 21% of the spoofed e-mails, which administers programs for Tibetan refugees living in India and advocates for human rights in Tibet. While the number of e-mail submissions were lower for the general human rights groups, we observe similar trends there with 92% of e-mails submitted by Rights Group 1 appearing to come from individuals in the group (as a result of spoofing).

In some cases we even observed the same attackers targeting multiple CSOs with customized e-mail lures. For example, we tracked a campaign that targeted China Groups 1 and 2, and Tibet Group 1 with a remote access

Table 3: Overview of themes and categories within the themes for grouping targeted e-mail messages.

Theme	Total Categories	Example Categories
Country/Region	26	China, US, European Union
Ethnic Groups	2	Tibetan, Uyghur
Event	31	self immolation, Communist Party of China, 18th National Party Congress
Organizations	32	United Nations, Central Tibetan Administration
People	31	His Holiness the Dalai Lama, Hu Jintao
Political	6	human rights, terrorism
Technology	5	software updates, virtual private servers
Miscellaneous	1	content without clear context which falls outside of the other themes

trojan we call IEXPL0RE [22] China Group 1 received the malware in e-mails claiming to be from personal friends whereas China Group 2 received the malware in an e-mail containing a story about a high-rise apartment building fire in China. In contrast, Tibet Group 1 received the malware embedded into a video of a speech by the Dalai Lama, attached to an e-mail about a year in review of Tibetan human rights issues.

4.2.2 Social Engineering Sophistication Base Value

While the content analysis results clearly show attacks tailored to the interests of targeted groups, content coding alone does not give a relative score of the sophistication used in the attacks. We now describe how we assign the "social engineering sophistication base value" to e-mails based on their level of social engineering.

To measure the targeting sophistication we assign a score that ranges from 0-5 that rates the social engineering techniques used to get the victim to open the attachment. This score considers the content and presentation of the e-mail message as well as the claimed sender identity. This determination also includes the content of any associated files, as malware is often implanted into legitimate relevant documents to evade suspicion from users when the malicious documents are opened.

The Social Engineering Sophistication Base Value is assigned based on the following criteria:

0 Not Targeted: Recipient does not appear to be a specific target. Content is not relevant to the recipient. The e-mail is likely spam or a non-targeted phishing attempt.

1 Targeted Not Customized: Recipient is a specific target. Content is not relevant to the recipient or contains information that is obviously false with little to no validation required by the recipient. The e-mail header and/or signature do not reference a real person or organization.

2 Targeted Poorly Customized: Recipient is a specific target. Content is generally relevant to the target but has attributes that make it appear questionable (e.g. incomplete text, poor spelling and grammar, incorrect addressing). The e-mail header and / or signature may reference a real person or organization.

3 Targeted Customized: Recipient is a specific target. Content is relevant to the target and may repurpose legitimate information (such as a news article, press release, conference or event website) and can be externally verified (e.g. message references information that can be found on a website). Or, the e-mail text appears to repurpose legitimate e-mail messages that may have been collected from public mailing lists or from compromised accounts. The e-mail header and / or signature references a real person or organization.

4 Targeted Personalized: Recipient is a specific target. The e-mail message is personalized for the recipient or target organization (e.g. specifically addressed or referring to individual and / or organization by name). Content is relevant to the target and may repurpose legitimate information that can be externally verified or appears to repurpose legitimate messages. The e-mail header and / or signature references a real person or organization.

5 Targeted Highly Personalized: Recipient is a specific target. The e-mail message is individually personalized and customized for the recipient and references confidential / sensitive information that is directly relevant to the target (e.g. internal meeting minutes, compromised communications from the organization). The e-mail header and / or signature references a real person or organization.

Content coding of emails and determinations of social engineering ratings for the TTI were performed by five independent coders who were given a code book for content categories and the TTI social engineering scale with examples to guide analysis. We performed regular inter-rater reliability checks and flagged any potential edge cases and inconsistencies for discussion and re-evaluation. Following completion of this analysis, two of the authors reviewed the social engineering base value scores to ensure consistency and conformity to the scale. We provide specific examples of each of these targeting values in Appendix A.

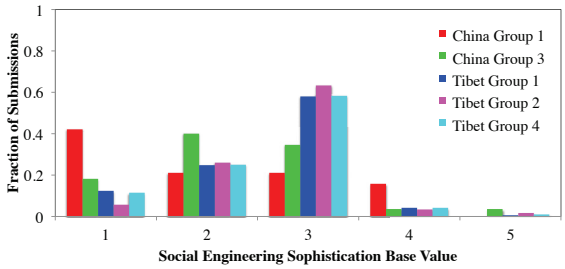

Figure 3: Social engineering sophistication base value assigned to e-mail submissions from groups that submitted at least 50 e-mails.

4.2.3 Summary of Social Engineering Sophistication Base Value

Figure 3 shows the targeting score for organizations in our study who submitted at least 50 e-mails. We can see that actors targeting these groups put significant effort into targeting their messages, in particular the three Tibetan groups included in Figure 3 observe more than half of their messages with a targeting score of 3 or higher. This result means adversaries are taking care to make the e-mail appear to come from a legitimate individual or organization, and include relevant information (*e.g.,* news reports or exchanges from public mailing lists). Higher targeting scores, which result from actions such as personalizing lures to an individual in the group, or including information that requires prior reconnaissance tend to be more rare, but we do observe instances of them. For example, in the case of China Group 3, we observed an e-mail which received a social engineering score of 5, which claimed to be from the group's funder and referenced a specific meeting they had planned that was not public knowledge.

4.3 Technical Sophistication

We manually analyzed all submitted emails and attachments to determine whether they contained politically-motivated malware. The malware is then analyzed in detail to extract information such as the vulnerability, C&C server (if present), and technical sophistication of the exploit.

4.3.1 Assessment methodology

The first step in our analysis pipeline is determining whether the email contains politically motivated malware or not. This process involves an initial inspection for social engineering of the email message and attachment (e.g., an executable pretending to be a document). We also correlate with other emails received as part of this project to identify already-known malware. Well-known malware attacks (*e.g.,* the Zeus trojan masquerading as an email from the ACH credit card payment processor, or Bredolab malware pretending to be from the DHL courier service) are not considered targeted attacks in our study, but are still kept for potential review.

Once we have identified emails which we suspect of containing politically-motivated malware, we perform the following analysis steps on any attachments to verify that they indeed contain malware. First, we run the attachment in a sandboxed VM to look for malicious activity *e.g.,* an Office document writing files to disk or trying to connect to a C&C server. We also check the MD5 hash of the attachment against the Virus Total database to see if it matches existing viruses. We also manually examine the attached file for signs of malicious intent (*e.g.,* executable payload in a PDF, shellcode or Javascript). We exclude any graphics attached to the email which are used for social engineering (and do not contain malicious payload) from our analysis.

We follow this initial analysis with more detailed technical analysis of the attachments which we confirm contain malware. First, we manually verify the file type of the attachment for overview statistics. This manual analysis is necessary as the Unix file command may be misled by methods of manipulating important bytes in the file (*e.g.,* replacing \rtf1 with \rtf[null]). We then identify if the vulnerability included in the malware already exists in a corpus of vulnerabilities, such as the Common Vulnerabilities and Exposures (CVE) naming system. We also perform analysis of network traffic from the attachment to identify the C&C server the malware attempts to contact. In cases where the malware does not execute in our controlled environment we manually examine the file to extract the relevant information.

On a case-by-case basis we use additional tools such as IDA [1] and OllyDbg [3] for detailed static and dynamic analysis, respectively. Our goal in this analysis is to identify relationships between malware campaigns between organizations, or instances of the same malware family repeatedly targeting a given organization. By observing overlapping C&C servers, or mapping malware to common exploits identified by anti virus/security companies we can cluster attacks that we believe come from the same malware family and potentially the same adversary.

4.3.2 Technical Sophistication Multiplier

While the previous analysis is useful for understanding the nature of threats, we also score threats numerically to aid in understanding the relative technical sophistication of their approaches. Each malware sample is assigned one of the following values:

1 Not Protected - The sample contains no code protec-

tion such as packing, obfuscation (e.g. simple rotation of interesting or identifying strings), or anti-reversing tricks.

1.25 Minor Protection - The sample contains a simple method of protection, such as one of the following: code protection using publicly available tools where the reverse method is available, such as UPX packing; simple anti-reversing techniques such as not using import tables, or a call to IsDebuggerPresent(); self-disabling in the presence of AV software.

1.5 Multiple Minor Protection Techniques - The sample contains multiple distinct minor code protection techniques (anti-reversing tricks, packing, VM / reversing tools detection) that require some low-level knowledge. This level includes malware where code that contains the core functionality of the program is decrypted only in memory.

1.75 Advanced Protection - The sample contains minor code protection techniques along with at least one advanced protection method such as rootkit functionality or a custom virtualized packer.

2 Multiple Advanced Protection Techniques - The sample contains multiple distinct advanced protection techniques, e.g. rootkit capability, virtualized packer, multiple anti-reversing techniques, and is clearly designed by a professional software engineering team.

The purpose of the technical sophistication multiplier is to measure how well the payload of the malware can conceal its presence on a compromised machine. We use a multiplier because advanced malware requires significantly more time and effort (or money, in the case of commercial solutions) to customize for a particular target.

We focus on the level of obfuscation used to hide program functionality and avoid detection for the following reasons: (1) It allows the compromised system to remain infected for a longer period; (2) it hinders analysts from dissecting a sample and developing instructions to detect the malware and disinfect a compromised system; (3) since most common used remote access trojans (RATs) have the same core functionality (e.g. keylogging, running commands, exfiltrating data, controlling microphones and webcams, etc.) the level of obfuscation used to conceal what the malware is doing can be used to distinguish one RAT from another.

4.3.3 Summary of Technical Sophistication Multiplier Value

Figure 4 shows the technical sophistication multiplier values for e-mails submitted by the different organizations in our study. One key observation we make here is that the email-based targeted malware that was self-reported by our study groups is relatively simple. The highest multiplier value we see is 1.5 and even that value is seen infrequently. The majority of malware observed is rated either 1 or 1.25 according to our technical scoring criteria, with Tibetan Groups observing a higher fraction of malware rated 1.25 and Chinese groups observing a higher fraction rated 1.

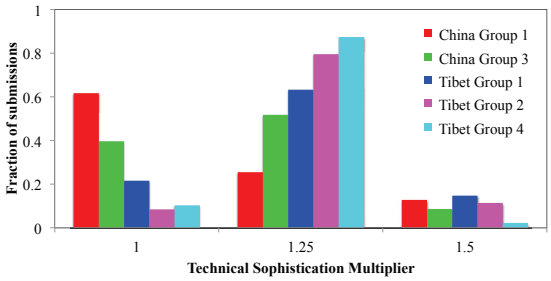

Figure 4: Technical sophistication multiplier assigned to e-mail submissions from groups that submitted at least 50 e-mails.

The technical sophistication multiplier value is also useful for assessing the technical evolution of threats in our study. When we group malware into different family groups we can see some of these groups are under active development. For example, we observe multiple versions of the Enfal [40, 49], Mongal [14], and Gh0st RAT [15] families with increasing levels of sophistication and defenses in place to protect the malware code (resulting in an increase in technical multiplier from 1 to 1.25 for these families). Since our technical multiplier value focuses on how well malware code defends and disguises itself, changes to other aspects of the code may not result in an increase in value (*e.g.,* we observe multiple versions of the IMuler.A/Revir.A malware which all receive a score of 1). Interestingly, when we observe both a Windows and Mac version of a given malware family, the technical score for the Mac version tended to be lower with the Mac version being relatively primitive relative to the Windows variant.

4.4 TTI Results

We now show how the TTI metric can help us better characterize the relative threat posed by targeted malware. Figure 5 shows the technical sophistication multiplier and maximum/minimum TTI scores for malware families observed in our dataset. Since we primarily observe simple malware, with a technical sophistication multiplier of 1 or 1.25, this value does a poor job of differentiating the threat posed by the different malware families to the CSOs. However, by incorporating both the technical sophistication and targeting base value into the TTI metric we can gain more insights into how effective these

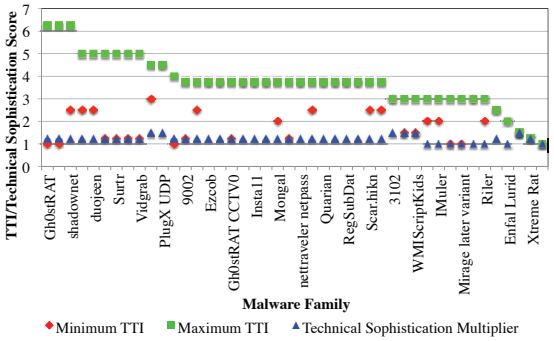

Figure 5: Comparison of the maximum and minimum TTI score and technical sophistication multiplied for malware families observed in our data (sorted in decreasing order of maximum TTI).

Table 4: Top malware families in our data set in terms of technical sophistication multiplier and in terms of final TTI score.

Technical Sophistication		
Family	TTI	Tech. Soph.
3102	3	1.5
nAspyUpdate	1.5	1.5
PlugX	4.5	1.5
PoisonIvy	3	1.5
WMIScriptKids	3	1.5
TTI		
Family	TTI	Tech. Soph. .
Gh0stRAT LURK0	6.25	1.25
shadownet	6.25	1.25
conime	5	1.25
duojeen	5	1.25
iexpl0re	5	1.25

threats may be in practice.

The impact of using TTI is especially apparent when trying to gain insights into the targeted malware that poses the biggest risk to CSOs. Table 4 shows the top 5 malware families we observe in terms of technical sophistication and in terms of TTI score. If we consider the malware families with the highest technical sophistication, we can see that their TTI values are relatively low, with maximums ranging from 1.5 to 4.5. These tend to be malware families that are familiar to researchers. In particular, PlugX and PoisonIvy have been used in targeted attacks together [43] and PlugX is still actively used and under constant development [16]. Despite technical sophistication, the social engineering lures of these threats are not well crafted and pose less of a risk to the CSOs whose members may be able to identify and avoid these threats.

In contrast, the top 5 malware families in terms of TTI have lower technical sophistication (1.25) but much higher levels of social engineering. It is no surprise that threats which score the highest TTI use well known malware that have been extensively documented in attacks against a variety of targets. For example, the TTI scores reflect that Gh0st RAT continues to be seen in higher risk attacks due to its popularity amongst attackers even though it is an older and not particularly advanced tool. Since there is no direct connection between the technical sophistication of threats and the level of social engineering used to target CSOs, it is likely that different threat actors, with a different focus, are at work here. Indeed, Gh0st RAT was discovered by the Citizen Lab in their analysis of GhostNet [25] and IEXPL0RE RAT was discovered and named for the first time in our work.

Another observation is that commercial malware such as FinFisher and DaVinci RCS, while being of much higher technical sophistication (relative to the samples in our study), do not necessarily score higher on TTI than a targeted attack with advanced social engineering and more basic malware. For example, analyzing a FinFisher sample targeted against Bahraini activists [38] with the TTI, produces an overall TTI score that is dependent on the social targeting aspect, even though the malware is very technically advanced. In this case, the FinFisher attack scores 4.0 on the TTI (base targeting score of 2 with a technical multiplier of 2). Although the email used in the attack references the name and organization of a real journalist, the content is poorly customized, and has attributes that look questionable. However, the technical sophistication of the malware is advanced earning it a score of 2 due to multiple advanced protection techniques, including a custom-written virtualized packer, MBR modification, and rootkit functionality. The sample also uses multiple minor forms of protection, including at least half a dozen anti-debugging tricks. Even though the technical multiplier is the maximum value, the overall TTI score is only 4.0 due to the low targeting base value. FinFisher is only effective if it is surreptitiously installed on a users' computer. If the malware is delivered through an email attachment, infection is only successful if the user opens the malicious file. The advanced nature of this malware will cause the overall score to increase quickly with improved targeting, but as it still requires user intervention, this threat scores lower overall than attacks with highly targeted social engineering using less sophisticated malware.

Similar findings can also be observed in attacks using DaVinci RCS developed by Italy-based company Hacking Team against activists and independent media groups from the United Arab Emirates and Morocco [36]. While the malware used in these publicly reported attacks is

technically sophisticated, the social engineering lures employed are poorly customized for the targets resulting in a 4.0 TTI score (targeting base value 2, technical multiplier 2).

These results support the idea that different threat actors have varying focuses and levels of resources, and as a result, different methodologies for attacks. For example, the majority of malware submitted by our study groups appear to be from adversaries that have in-house malware development capabilities and the capacity to organize and implement targeted malware campaigns. These adversaries are spending significant effort on social engineering, but generally do not use technically advanced malware. Conversely, the adversaries using FinFisher and DaVinci RCS have bought these products rather than develop malware themselves. However, while the FinFisher and RCS samples are technically sophisticated pieces of malware, the attacks we analyzed are not sophisticated in terms of social engineering tactics.

4.5 Limitations of TTI

While the Targeted Threat Index gives insight into the distribution of how sophisticated threats are, we are still in the process of evaluating and refining it through interactions with the groups in our study and inclusion of more sophisticated threats observed in related investigations in our lab. Average TTI scores in our dataset may be skewed due to the self-reporting method we use in the study. Very good threats are less likely to be noticed and reported while being sent to far fewer people, and low-quality emails are much more likely to be sent in bulk and stand out. It is also possible that individuals in different groups may be more diligent in submitting samples, which could affect between group comparisons. We are more interested, however, in worst-case (highest) scores and not in comparing the average threat severity between organizations.

Finally, this metric is calculated based on the technical sophistication of the payload, not on the specific exploit. There is currently no method to modify the TTI score in a way similar to the temporal metrics used by the CVSS metric. A temporal metric could be added to increase the final TTI value for 0-day vulnerabilities, or possibly to reduce the score for exploits that are easily detectable due to a public and well-known generation script, e.g. Metasploit [2].

5 Implications

Our study primarily focuses on threats that groups working on human rights issues related to Tibet or China are currently facing. While our dataset is concentrated on these types of groups, our results have implications for how CSOs can protect themselves against email-based targeted malware.

Specifically, we find that moving towards cloud-based platforms (*e.g.,* Google Docs) instead of relying on e-mail attachments would prevent more than 95% of the e-mail malware seen by 2 out of 3 Tibetan groups that had more than 50 e-mail submissions.

Further, our results highlight the potential for lower-cost user education initiatives to guard against sophisticated social engineering attacks, rather than high cost technical solutions. This observation stems from the fact that much of the malware we observe is not technically sophisticated, but rather relies on social engineering to deliver its payload by convincing users to open malicious attachments or links. Other studies [35, 36, 38] that have revealed the use of commercial malware products against CSOs and journalists have shown that many of these cases also rely on duping users into opening malicious e-mail attachments or social engineered instant messaging conversations. These incidents show that even advanced targeted malware requires successful exploitation of users through social engineering tactics.

User education can be a powerful tool against the kinds of targeted attacks we observed in this study. Indeed, the Tibetan community has taken an active approach with campaigns that urge Tibetan users to not send or open attachments and suggests alternative cloud based options such as Google Docs and Dropbox for sharing documents [53]. We have also engaged the Tibetan groups in a series of workshops to introduce training curriculum which draws on examples submitted by organizations participating in our study. We have also provided them with technical background to identify suspicious e-mail headers and how to use free services to check the validity of suspicious links in e-mail messages.

The mitigation strategies presented here are focused on email vectors and do not consider all of the possible attacks these groups may face. We highlight these strategies in particular because the majority of groups in our study identified document-based targeted malware as a high priority information security concern. The adversaries behind these attacks are highly motivated and will likely adapt their tactics as users change their behaviors. For example, it is plausible that if every user in a particular community began to avoid opening attachments and document-based malware infected fewer targets, attackers may move on to vectors such as waterhole attacks or attacks on cloud document platforms to fill the gap. User education and awareness raising activities need to be ongoing efforts that are informed by current research on the state of threats particular communities are experiencing. Evaluation of the effectiveness of user education efforts in at risk communities and corresponding reactions from attackers is required to understand the dynamics between

these processes.

6 Related Work

There is a wide body of literature on filtering and detection methods for spam [27,42,45,52,70,71] and phishing emails and websites [12, 34, 39, 69]. Attention has also been given to evaluating user behavior around phishing attacks and techniques for evading them [6, 30, 33]. By comparison research on detecting email vectors used for targeted malware attacks is limited. A notable exception is [4, 5], which uses threat and recipient features with a random forest classifier to detect targeted malicious emails in a dataset from a large Fortune 500 company. Other work has focused on imporoving detection of documents (e.g. PDF, Microsoft Office) with embedded malicious code [13, 51, 57]

Another area of research explores methods for modeling the stages of targeted attacks and using these models to develop defenses. Guira and Wang [19] propose a conceptual attack model called the attack pyramid to model targeted attacks and identify features that can be detected at the various stages. Hutchins, Cloppert and Amin, [24] use a kill chain model to track targeted attack campaigns and inform defensive strategies.

Metrics have been developed to characterize security vulnerabilities and their severity [7, 41, 50]. The industry standard is the Common Vulnerability Scoring System (CVSS) [17], which uses three metric groups for characterizing vulnerabilities and their impacts. These groups are: base metric group (the intrinsic and fundamental characteristics of a vulnerability that are constant over time and user environments), temporal metric group (characteristics of a vulnerability that change over time but not among user environments) and environmental metric group (characteristics of a vulnerability that are relevant and unique to a particular user's environment). The CVSS is a widely adopted metric, but only rates technical vulnerabilities. Targeted attacks rely on a user action of opening a malicious attachment or visiting a malicious link to successfully compromise a system. Therefore, the sophistication of message lures and other social engineering tactics are an important part of determining the severity of a targeted attack. Systems like the CVSS cannot address this contextual component.

Our study makes the following contributions to the literature. Previous studies of targeted attacks against CSOs usually focus on particular incidents or campaigns and do not include longitudinal observations of attacks against a range of CSO targets. While standards exist for rating the sophistication of technical vulnerabilities and research has been done on detecting targeted malware attacks and modeling campaigns, there is no scoring system that considers both the sophistication of malware and social engineering tactics used in targeted malware attacks. We address this gap through development of the TTI and validate the metric against four years of data collected from 10 CSOs.

7 Conclusions

Our study provides an in-depth look at targeted malware threats faced by CSOs. We find that considering the technical sophistication of these threats alone is insufficient and that educating users about social engineering tactics used by adversaries can be a powerful tool for improving the security of these organizations. Our results point to simple steps groups can take to protect themselves from document-based targeted malware such as shifting to cloud-based document platforms instead of relying on attachments which can contain exploits. Further research is needed to measure the effectiveness of education strategies for changing user behaviour and how effective these efforts are in mitigation of document-based malware for CSOs. Further work is also required in monitoring how attackers adapt tactics in response to observed behavioural changes in targeted communities.

In ongoing work we are continuing our collection of e-mails and NIDS alerts as well as monitoring other attacks against these groups (*e.g.,* waterhole attacks and DoS attacks) to understand how threats vary based on their delivery mechanism. We are also working to extend our methodology to more diverse CSO communities such as those in Latin America, Africa, and other underreported regions to better document the politically motivated digital threats they may be experiencing.

Acknowlegements

This work was supported by the John D. and Catherine T. MacArthur Foundation. We are grateful to Jakub Dalek, Sarah McKune, and Justin Wong for research assistance. We thank the USENIX Security reviewers and our shepherd Prof. J. Alex Halderman for helpful comments and guidance. We are especially grateful to the groups who participated in our study.

Appendix

A Examples of targeted e-mails

In this section, we provide specific examples of e-mails that would be assigned targeting scores described in Section 4.2.2.

Targeting Score 1 (Targeted Not customized). The e-mail in Figure 6 was sent to Tibet group 1. The message content and sender are vague and do not relate to the interest of the group. The attachment is a word document implanted with malware. The lack of relevant information in this message gives it a score of 1 (targeted, not customized).

Targeting Score 2 (Targeted, Poorly Customized). The e-mail in Figure 7 was sent to Tibet group 1. It references Tibetan self-immolations which is an issue of interest to the group. However, the sender does not appear to be from a real person or organization. The message content is terse and does not referenced information that can be externally validated. Therefore this message scores a 2 (targeted, poorly customized).

xls
```

Figure 9: Example of e-mail with Targeting Score 4

Targeting Score 3 (Targeted Customized). The e-mail in Figure 8 was sent to Tibet group 2. On the surface it appears to be a professional e-mail from "Palden Sangpo" a consultant at the Tibet Career Centre. The e-mail sender address and signature reference accurate contact details that can be easily verified through an Internet search. However, the e-mail headers reveal the purported e-mail sender address is fraudulent and the actual sender was `albano_kuqo@gmx.com`. The e-mail generally addresses the organization rather than the individual recipient. Therefore this message scores a 3 (targeted, customized).

Targeting Score 4 (Targeted Personalized). The e-mail in Figure 9 was sent to Tibet group 1. It is directly addressed to the director of the group and appears to come from Mr. Cheng Li, a prominent China scholar based at the Brookings Institute. The e-mail address is made to appear to be from Mr. Cheng Li, but from an AOL account (chengli.brookings@aol.com) that was registered by the attackers. The message asks the recipient for information on recent Tibetan self-immolations. The level of customization and personalization used in this message gives it a score of 4 (targeted, personalized).

Targeting Score 5 (Targeted Highly Personalized). Targeting scores of 5 (targeted, highly personalized) require reference to internal information to the target organization that could *not be* obtained through open sources. Examples of messages scoring at this level include an e-mail that purported to come from a funder of China Group 3 that provided details of an upcoming meeting the group actually had scheduled with the funder. In another example, Tibet Group 2 and Tibet Group 3 received separate e-mails that contained specific personal details about a South African group's visit to Dharamsala, India that appear to have been repurposed from a real private communication. The malicious attachment contained an authentic travel itinerary, which would be displayed after the user opened the document. The private information used in these messages suggest that the attackers performed significant reconnaissance of these groups and likely obtained the information through prior compromise.

A Look at Targeted Attacks Through the Lense of an NGO

Stevens Le Blond[1] Adina Uritesc[1] Cédric Gilbert[1]

[1]*MPI-SWS* [2]*National Univ. of Singapore* [3]*Northeastern Univ.*

Abstract

We present an empirical analysis of targeted attacks against a human-rights Non-Governmental Organization (NGO) representing a minority living in China. In particular, we analyze the social engineering techniques, attack vectors, and malware employed in malicious emails received by two members of the NGO over a four-year period. We find that both the language and topic of the emails were highly tailored to the victims, and that sender impersonation was commonly used to lure them into opening malicious attachments. We also show that the majority of attacks employed malicious documents with recent but disclosed vulnerabilities that tend to evade common defenses. Finally, we find that the NGO received malware from different families and that over a quarter of the malware can be linked to entities that have been reported to engage in targeted attacks against political and industrial organizations, and Tibetan NGOs.

1 Introduction

In the last few years, a new class of cyber attacks has emerged that is more targeted at individuals and organizations. Unlike their opportunistic, large-scale counterparts, *targeted attacks* aim to compromise a handful of specific, high-value victims. These attacks have received substantial media attention, and have successfully compromised a wide range of targets including critical national infrastructures [19], Fortune 500 companies [23], news agencies [20], and political dissidents [10, 11, 16].

Despite the high stakes involved in these attacks, the ecosystem sustaining them remains poorly understood. The main reason for this lack of understanding is that victims rarely share the details of a high-profile compromise with the public, and they typically do not disclose what sensitive information has been lost to the attackers. According to folk wisdom, attackers carrying out targeted attacks are generally thought to be state-sponsored. Examples of national organizations that have been reported to be engaged in targeted attacks include the NSA's office of Tailored Access Operations (TAO) [3] and the People's Liberation Army's Unit 61398 [15]. Recently, researchers also attributed attacks in the Middle East to the governments of Bahrain, Syria, and the United Arab Emirates [16].

There now exists public evidence that virtually every computer system connected to the internet is susceptible to targeted attacks. The Stuxnet attack even successfully compromised air-gapped Iranian power plants [19] and was able to damage the centrifuges in the facility. More recently, Google, Facebook, the New York Times, and many other global companies have been compromised by targeted attacks. Furthermore, political dissidents and Non-Governmental Organizations (NGOs) are also being targeted [10, 11, 16].

In this paper, we analyze 1,493 suspicious emails collected over a four-year period by two members of the World Uyghur Congress (WUC), an NGO representing an ethnic group of over ten million individuals mainly living in China. WUC volunteers who suspected that they were being specifically targeted by malware shared the suspicious emails that they received with us for analysis. We find that these emails contain 1,176 malicious attachments and target 724 unique email addresses belonging to individuals affiliated with 108 different organizations. This result indicates that, despite their targeted content, these attacks were sent to several related victims (e.g., via Cc). Although the majority of these targeted organizations were NGOs, they also comprised a few high-profile targets such as the New York Times and US embassies.

We leverage this dataset to perform an empirical analysis of targeted attacks in the wild. First, we analyze the engineering techniques and find that the language and topic of the malicious emails were tailored to the mother tongue and level of specialization of the victims. We also find that sender impersonation was common and that some attacks in our dataset originated from compromised email accounts belonging to high-profile ac-

tivists. Second, whereas recent studies report that malicious archives and executables represented the majority of the targeted-attack threat [15, 22], we find that malicious documents were the most common attack vector in our dataset. Although we do not find evidence of zero-day vulnerabilities, we observe that most attacks used recent vulnerabilities, that exploits were quickly replaced to adapt to new defense mechanisms, and that they often bypassed common defenses. Third, we perform an analysis of the first-stage malware delivered over these malicious emails and find that WUC has been targeted with different families of malware over the last year. We find that over a quarter of these malware samples exhibited similarities with those used by entities reported to have carried out targeted attacks.

Our work complements existing reports on targeted attacks such as GhostNet, Mandiant, and Symantec Internet Security Threat (ISTR) 2013 [11, 15, 22]. Whereas the GhostNet and Mandiant reports focus on the attack lifecycle *after* the initial compromise, this study provides an in-depth analysis of the reconnaissance performed *before* the compromise. We note that both approaches have pros and cons and are complementary: While it is hard for the authors of these reports to know *how* a system became compromised in retrospect, it is equally hard for us to know *if* the observed attacks will compromise the targeted system(s). Finally, whereas ISTR provides some numbers about reconnaissance analysis for industrial-espionage attacks [22], we present a thorough and rigorous analysis of the attacks in our dataset.

Finally, to foster research in this area, we release our dataset of targeted malware to the community [4].

Scope. Measuring real-world targeted attacks is challenging and this paper has a number of important biases. First, our dataset contains mainly attacks against the Uyghur and human-rights communities. While the specifics of the social engineering techniques (e.g., use of Uyghur language) will vary from one targeted community to another, we argue that identifying commonly used techniques (e.g., topic, language, senders' impersonation) and their purpose is a necessary step towards designing effective defenses. Another limitation of our dataset is that it captures only targeted attacks carried out over email channels and that were detected by our volunteers. Although malicious emails seem to constitute the majority of targeted attacks, different attack vectors such as targeted drive-by downloads are equally important. Finally, we reiterate that the goal of this study is to understand the reconnaissance phase occurring *before* a compromise. Analyzing second-stage malware, monitoring compromised systems, and determining the purpose of targeted attacks are all outside of the scope of this paper and are the topic of recent related work [10, 16]. We discuss open research challenges in Section 6.

Subject: Invitation Letter of WUC International Conference
To: ...

Dear ...,

I am writing to you from the World Uyghur Congress (WUC) and on behalf
of the Unrepresented Nations and Peoples Organization (UNPO) and the
Society for Threatened Peoples (STP) with financial support from the
National Endowment for Democracy,cordially invites you to attend the
WUC's upcoming Conference which will be held in Geneva between 11th
and13th March 2013.

Attached you can find the invitation letter. We hope you will give a
positive consideration to this invitation, and look forward to meeting
you in Geneva. During your stay in Geneva, travel, accommodation and
food are covered by the WUC.

The WUC is a nonprofit organization granted by the National Endowment
for Democracy in Washington, DC to peacefully promote human rights,
democracy and freedom for the Uyghur people in East Turkestan.

If you have any questions or queries regarding your participation,
please do not hesitate to contact me. Phone: ..., Fax: ..., e-mail:
...

sincerely,
```

Figure 1: Screenshot of a malicious email with an impersonated sender, and a malicious document exploiting Common Vulnerabilities and Exposures (CVE) number 2012-0158 and containing malware. **The email replays an actual announcement about a conference in Geneva and was edited by the attacker to add that all fees would be covered.**

2 Overview

Context. WUC, the NGO from which we have received our dataset, represents the Uyghurs, an ethnic minority concentrated in the Xinjiang region in China. Xinjiang is the largest Chinese administrative division, has abundant natural resources such as oil, and is China's largest natural gas-producing region. WUC frequently engages in advocacy and meeting with politicians and diplomats at the EU and UN, as well as collaborating with a variety of NGOs. Rebiya Kadeer, WUC's current president, was the fifth richest person in China before her imprisonment for dissent in 1996, and is now in exile in the US. Finally, WUC is partly funded by the National Endowment for Democracy (NED), a US NGO itself funded by the US Congress to promote democracy. (We will see below that NED has been targeted with the same malware as WUC.)

WUC has been a regular target of Distributed Denial of Service (DDoS) attacks and telephone disruptions, as well as targeted attacks. For example, the WUC's website became inaccessible from June 28 to July 10, 2011 due to such a DDoS attack. Concurrently to this attack, the professional and private phone lines of WUC employees were flooded with incoming calls, and the WUC's contact email address received 15,000 spam emails in one week.

Data acquisition. In addition to these intermittent threats, WUC employees constantly receive suspicious emails impersonating their colleagues and containing

malicious links and attachments. These emails consistently evade spam and malware defenses deployed by webmail providers and are often relevant to WUC's activities. In fact, our volunteers claim that the emails are often so targeted that they need to confirm their legitimacy with the impersonated sender in person. For example, Figure 1 shows the screenshot of such an email that replays the actual announcement for a conference in Geneva organized by WUC. As a result, WUC members are wary of any emails containing links or attachments, and some of them save these emails for future inspection. We came in contact with two WUC employees who shared the suspicious emails that they had received (with consent from WUC). The authors of this work were not involved in the data collection.

Characteristics of the dataset. The two volunteers shared with us the headers and content of 1,493 suspicious emails that they received over a four-year period. 1,178 (79%) of these emails were sent to the private email addresses of the two NGO employees from whom we obtained the data, 16 via the public email address of the WUC, and the remaining 299 emails were forwarded to them (126 of these by colleagues at WUC). Overall, 89% of these emails were received directly by our volunteers or their colleagues at WUC. As we will see below, they also contain numerous email addresses in the To and Cc fields belonging to individuals that are not affiliated with WUC.

The emails contained 209 links and 1,649 attachments, including 1,176 with malware (247 RAR, 49 ZIP, 144 PDF, and 655 Microsoft Office files, and 81 files in other formats). Our analysis revealed 1,116 *malicious emails* containing malware attachments. (We were not able to verify the maliciousness of the links as most of them were invalid by the time we obtained the data.) In the following, we analyze malicious emails exclusively and we refer to *malicious archives or documents* depending on whether they contained RAR or ZIP, PDF or Microsoft Office documents, respectively. Finally, the volunteers labeled the data wherever necessary, enabling us, for example, to establish that the sender of the emails was impersonated for 84% of the emails. Table 1 summarizes the main characteristics of these malicious emails.

Scope of the dataset. Analyzing the headers of the malicious emails revealed a surprisingly large number of recipients in the To or Cc fields. In particular, we observed that malicious emails had been sent to 1,250 unique email addresses and 157 organizations. A potential explanation for this behavior could be that the attacker tampered with the email headers (e.g., via a compromised SMTP server) as part of social engineering so these emails were only delivered to our volunteers, despite the additional indicated recipients. To test this hypothesis, we considered only those emails received directly by our volunteers, originating from well-known webmail domains (i.e., aol.com, gmx.de, gmx.com, gmail.com, googlemail.com, hotmail.com, outlook.com, and yahoo.com), and verified via Sender Policy Framework (SPF) *and* DomainKeys Identified Mail (DKIM). SPF and DKIM are methods commonly used to authenticate the sending server of an email message. By verifying that these malicious emails originated from well-known webmail servers, we obtain 568 malicious emails whose headers are very unlikely to have been tampered with by the attacker. By repeating our above analysis on these emails only, we obtain 724 unique email addresses and 108 organizations. Other organizations besides WUC include NED (WUC's main source of funding and itself funded by the US congress), the New York Times, and US embassies. In summary, while we obtained our dataset from two volunteers working for a single organization, it offers substantial coverage not only of one NGO, but also of those attacks against multiple NGOs in which attackers target more than one organization with the same email. We show the full list of organizations targeted in our dataset in Appendix A.

What are targeted attacks? There is no precise definition of targeted attacks. In this paper, we loosely define these attacks as *low-volume*, *socially engineered* communication which entices *specific* victims into installing malware. In the dataset we analyze here, the communication is by email, and the mechanism of exploitation is primarily using malicious archives or documents. A targeted victim, in this work, refers to specific individuals, or an organization as a whole. When necessary, we also use the term volunteer(s) to distinguish between our two collaborators and other victims.

The terms targeted attacks and Advanced Persistent Threats (or APTs) are often used interchangeably. As this paper focuses on the reconnaissance phase of targeted attacks (occurring before a compromise), we cannot measure how long attackers would have remained in control of the targeted systems (i.e., their persistency). As a result, we simply refer to these attacks as targeted attacks, and not APTs, throughout the rest of this paper. We discuss specific social engineering characteristics that make targeted attacks difficult to detect by unsuspecting average users in Section 3, the attack vectors used in our dataset in Section 4, and the malware families they install in Section 5. Finally, we will discuss open research challenges in Section 6.

Ethics. The dataset was collected prior to our contacting WUC and for the purpose of future security analysis. Furthermore, WUC approved the disclosure of all the information contained in this paper and requested that the organization's name not be anonymized.

Table 1: Summary of our dataset originating from two volunteers. *Malicious* indicates the fraction of emails containing malware, *Impersonated* the fraction of emails with an impersonated sender, *# recipients* and *# orgs* the number of unique email addresses that were listed in the To and Cc fields of the malicious emails and the corresponding number of organizations, respectively.

	Beginning - end	*Size*	*Malicious*	*Impersonated*	*# recipients*	*# orgs*
1st volunteer	Sept 2012 - Sept 2013	98 MB	154/241 (64%)	141/154 (92%)	124	25
2nd volunteer	Sept 2009 - Jul 2013	818 MB	962/1,252 (77%)	802/962 (83%)	666	102
Total	Sept 2009 - Sept 2013	916 MB	1,116/1,493 (75%)	943/1,116 (84%)	724	108

3 Analysis of social engineering

The GhostNet, Mandiant, ISTR, and other reports [11, 15, 22] mention the use of socially-engineered emails to lure their victims into installing malware, clicking on malicious links, or opening malicious documents. For example, the GhostNet report refers to one spoofed email containing a malicious DOC attachment, and the Mandiant report to one email sent from a webmail account bearing the name of the company's CEO enticing several employees to open malware contained in a ZIP archive. Concurrent work reports the use of careful social engineering against civilians and NGOs in the Middle East [16] and also Tibetan and human-rights NGOs [10]. Despite this anecdotal evidence, we are not aware of any rigorous and thorough analysis of the social engineering techniques employed in targeted attacks. In this section, we seek to answer the following questions in the context of our dataset:

- *What social traits of victims are generally exploited?* Do attackers generally impersonate a sender known to the victim and if so who do they choose to impersonate?
- *Who are the victims?* Are malicious emails sent only to specific individuals, to entire organizations, or communities of users?
- *When are users being targeted?* When do users start being targeted? Are the same users frequently being targeted and for how long? Are several users from the same organization being targeted simultaneously?

3.1 Methodology

The analysis below focuses on 1,116 malicious emails received between 2009 and 2013.

Topics and language. To attempt to understand how well the attacker knows his victims, we manually categorized the emails (coded) by topic and language. (Unless indicated otherwise, the analysis below was performed on emails that were coded by one of the author.) The topic was determined by reading the emails' titles and bodies and, in cases where emails were not written in English, we also used an online translation service. Emails whose topic was still unclear after using the translator were labeled as *Unknown*.

Targeted victims. To determine the targeted victims of these attacks, we searched the email addresses and full names of the senders and receivers for the malicious emails originating from trustworthy SMTP servers. When available, we used their public profiles available on social media websites such as Google, Facebook, and Skype to determine their professional positions and organizations. We assume we have found the social profile of a victim if one of the three following rules applies (in that order): First, if the social profile refers directly to the email address seen in the malicious email; second, if the social profile refers to an organization whose domain matches the victims' email address; or third, if we find contextual evidence that the social profile is linked to WUC, Uyghurs, or the topic of the malicious email. Out of 724 victims' email addresses, we found the profile of 32% (237), 4% (30), and 23% (167) using the first, second, and last rule, respectively.

Organizations and industries. In the following, *WUC* refers to victims directly affiliated with the organization (including our volunteers). Other *Uyghur NGOs* include Australia, Belgium, Canada, Finland, France, Japan, Netherlands, Norway, Sweden, and UK associations. *Other NGOs* include non-profit organizations such as Amnesty International, Reporters Without Borders, and Tibetan NGOs. *Academia*, *Politics*, and *Business* contain victims working in these industries. Finally, *Unknown* corresponds to victims for which we were not able to determine an affiliation.

Ranks. We also translated the professional positions of the victims into one of the three categories: *High*, *Medium*, and *Low* profile. We consider professional leadership positions such as chairpersons, presidents, and executives as high-profile, job positions such as assistants, and IT personnel as medium-profile, and unknown and shared email addresses (e.g., NGO's contact information) as low-profile.

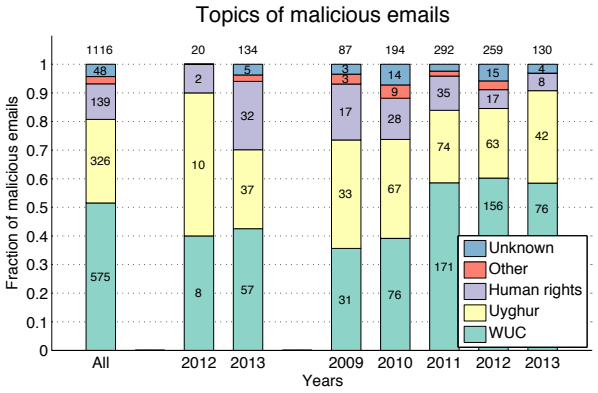

Figure 2: Distribution of the topics of the malicious emails for each year of the dataset shared by our two volunteers. The left bar corresponds to the data shared by both volunteers, and the next two bar groups to each year of the data shared by our first and second volunteer, respectively. **The content of malicious emails is targeted to the victims.**

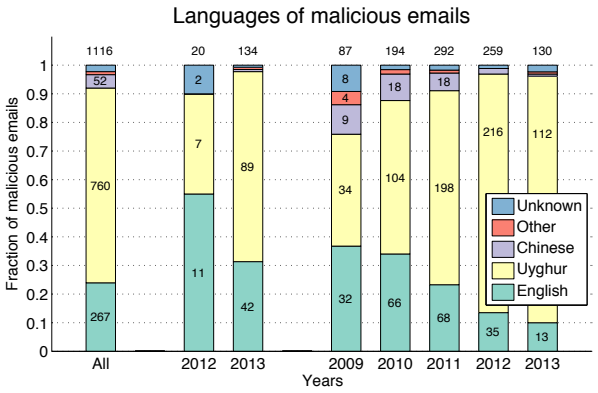

Figure 3: Distribution of languages for each year of our dataset. **Malicious emails employ the language of their victims.**

Impersonation. Finally, to understand the social context of the attack, each of our volunteers coded (based on her experience within the organization) all the email addresses of the senders into one of five categories: *Spoofed*, *Typo*, *Name*, *Suspicious*, or *Unknown*. (Coding was done based exclusively on the personal knowledge of the volunteers.) An email is marked as *Spoofed* if it bears the exact sender email address of a person known to our volunteers, as *Typo* if it resembles a sender email address known to the receiver but is not identical, and as *Name* if the attacker used the full name of a volunteer's contact (with a different email address). Finally, email addresses that look as if they had been generated by a computer program (e.g., uiow839djs93j@yahoo.com) are labeled as *Suspicious* and all remaining emails as *Unknown*. Our assumption is that, because our volunteers received most of the malicious emails directly, they were likely to recognize cases where their contacts were being impersonated. We note that labeling is conservative: Our volunteers may sometimes label *Spoofed* or *Typo* addresses as *Unknown* because they do not know the person impersonated in the attack. This may happen, for example, in cases where they were not the primary target of the attack (e.g., they appeared in Cc).

Limitations. Our dataset originates from WUC and is limited to those victims that were targeted together with that organization. We will see that these victims were often NGOs. As a result, the social engineering techniques observed here may differ from attacks against different entities such as companies, political institutions, or even other NGOs. Despite these limitations, we argue that this analysis is an important first step towards understanding the human factors exploited by targeted attacks.

3.2 Results

In this subsection, we discuss the results of our analysis of the social engineering techniques used in the malicious emails.

Topics and language. The topic of malicious emails in our dataset can generally be classified into one of three categories: WUC, Uyghur, and human-rights. In particular, we observed 51% (575) of malicious emails pertaining to WUC, 29% (326) to Uyghurs, 12% (139) to human-rights, and 3% (28) to other topics. In addition, the native language of the victim is often used in the malicious emails. In fact, 69% (664) of the emails sent to the second volunteer were written in the Uyghur language, and 62% (96) for the first one. These results indicate that attackers invested significant effort to tailor the content of the malicious emails to their victims, as we see in Figure 2 and Figure 3.

Specialized events. In addition to being on topic, we also observed that emails often referred to specific events that would only be of interest to the targeted victims. Throughout our dataset, we found 46% of events (491) related to organizational events (e.g., conferences). We note that these references are generally much more specialized than those used in typical phishing and other profit-motivated attacks. For example, Figure 1 shows a screenshot of an attack that replayed the announcement of a conference on a very specialized topic. The malicious email was edited by the attacker to add that all fees would be covered (probably to raise the target's interest).

Impersonation. We find that attackers used carefully crafted email addresses to impersonate high-profile identities that the victims may directly know. That is, attackers used one of the following four techniques to add legitimacy to a malicious email: First, 41% (465) of the

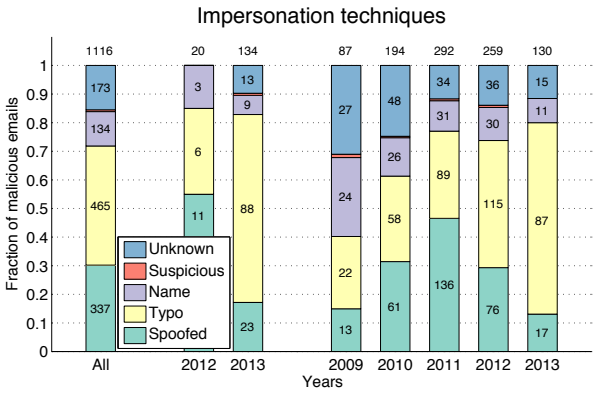

Figure 4: Distribution of senders' impersonation techniques for each year of our dataset. **Malicious emails spoof the email address of a contact of the volunteers, use a very similar address controlled by the attacker, or a contact's full name.**

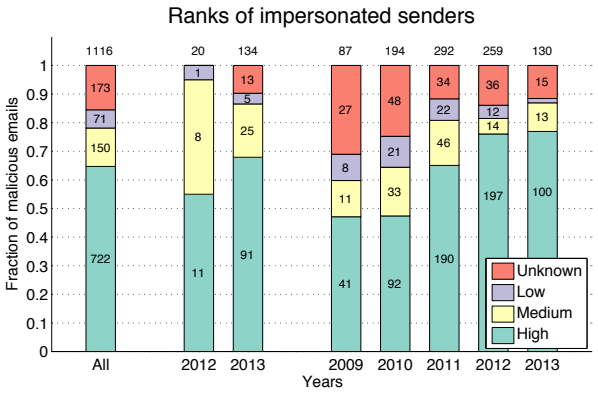

Figure 5: Distribution of impersonated senders' ranks for each year of our dataset. **Malicious emails often impersonate high-profile individuals.**

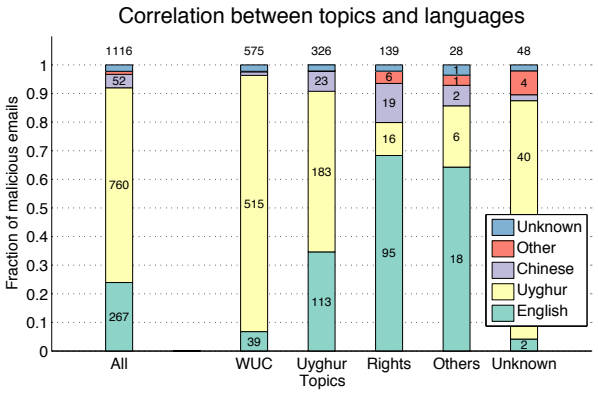

Figure 6: Distribution of languages employed to write about the main topics of malicious emails. **There is a strong correlation between malicious emails' topics and the language in which they are written.**

email addresses have *Typos* (i.e., the email address resembles known sender addresses, but with minor, subtle differences). These email addresses are identical to legitimate ones with the exception of a few characters being swapped, replaced, or added in the username. Second, 12% (134) of the senders' full names corresponded to existing contacts of the volunteers. Third, we find that most email addresses belonged to well-known email providers — Google being the most prominent with 58% of all emails using the Gmail or GoogleMail domains, followed by Yahoo with 16%.

Fourth, we find that 30% (337) of the sender emails were spoofed (i.e., the email was sent from the address of a person that the volunteer knows). This observation suggests that the attacker had knowledge of the victim's social context, and had either spoofed the email header, or compromised the corresponding email account. To identify a subset of compromised email accounts, we consider spoofed emails authenticated by the senders' domains using both SPF and DKIM. To reduce the chances of capturing compromised servers instead of compromised accounts, we also consider only well-known, trustworthy domains such as GMail. This procedure yields malicious emails that were likely sent from the legitimate account of the victims' contacts. We found that three email accounts belonging to prominent activists, including two out of 10 of the WUC leaders, were compromised and being used to send malicious emails. We have alerted these users and are currently working with them to deploy defenses and more comprehensive monitoring techniques, as we will discuss in Section 6.

We show the distributions of malicious emails sent with spoofed, typo, suspicious, or unknown email addresses in Figure 4, and the ranks of the impersonated senders in Figure 5. (We do not show the corresponding ranks for receivers because NGOs generally function with a handful of employees, all playing a key role in the organization.)

Targeted victims. For the analysis below, which leverages other recipients besides our two volunteers, we further filter emails to keep only those originating from well-known domains (as described in Section 2). Doing this leaves us with 568 malicious emails that are likely to have indeed been sent to all the email addresses in the header. We find that the attacks target more organizations than WUC, including 38 *Uyghur NGOs*, 28 *Other NGOs*, as well as 41 *Journalistic*, *Academic*, and *Political* organizations. (See Appendix A for the complete list of targeted organizations.) Interestingly, we find a strong correlation between the topic of an email and the language in which the email was written, as we show in Figure 6. Our results show that English was more and

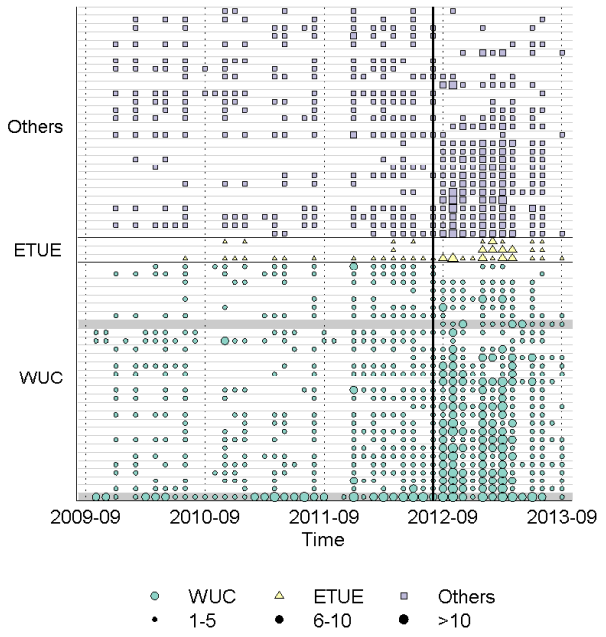

Figure 7: Timeline of attacks, in number of malicious emails per month, against the 60 most targeted victims (our two volunteers' rows are shaded and the vertical line corresponds to one of our volunteer joining WUC). The Y axis represents victims grouped by organization. *ETUE* corresponds to the East Turkestan Union in Europe NGO and *Others* to different organizations. **Each of the top 60 victims has been frequently attacked over the last four years and several victims from the same NGOs were attacked simultaneously.**

more common as the topic became less and less specialized. We hypothesize that attackers may have sent the same email messages to several recipients with similar interests to reduce the costs involved in manually crafting these emails.

Timing. Our dataset shows that the same victims were frequently targeted and that several members of the same organization were routinely targeted simultaneously. This suggests that attackers were using a "spray" strategy, trying to find the weakest links in the targeted organization, and hence, optimizing their chance of success. Spraying is clearly visible in Figure 7 where we see that the top 60 most targeted victims in our dataset received malicious emails often over the last four years. (We note that the dataset shared by one of our volunteers starts on August 2012, explaining why we observe more malicious emails after that date.) We also see that, 31 email accounts from individuals without affiliation to WUC were often targeted simultaneously to the WUC accounts.

Summary of Findings. We now revisit the initial questions posed at the beginning of this section. First, we saw that most emails in our dataset pertained to WUC, Uyghurs, or human-rights, were written in the recipient's mother tongue, and often referred to very specialized events. We also found that sender impersonation was common and that some email accounts belonging to WUC's leadership were compromised and used to spread targeted attacks. (We note that many more accounts may be compromised but remain dormant or do not appear as compromised in our dataset.) Second, we showed that numerous NGOs were being targeted simultaneously with WUC and that the specialization of emails varied depending on the recipient(s). Finally, we observed that the most targeted victims received several malicious emails every month and that attacks were sprayed over several organizations' employees.

4 Analysis of attack vectors

We now analyze the techniques used to execute arbitrary code on the victim's computer. The related work reports the use of malicious links, email attachments, and IP tracking services [10, 16]. Whereas ISTR 2013 reports that EXE are largely used in targeted attacks, and the Mandiant report that ZIP is the predominant format that they have observed in the last several years, we find that these formats represent 0% and 4% (49) of malicious attachments in our dataset, respectively. Instead, we find RAR archives and malicious documents to be the most common attack vectors. Hypotheses that may explain these discrepancies with the Mandiant report include the tuning of attack vectors to adapt to the defenses mechanisms used by different populations of email users (e.g., NGOs vs. corporations); Mandiant's attacker (APT1), mainly using primitive attack vectors such as archives; and/or Mandiant having excluded more advanced attack vectors, such as documents, from its report. However, in the absence of empirical data on APT1's attack vectors, we cannot test these hypotheses. In this section, we perform a quantitative study of the attack vectors employed in our dataset, and also analyze their dynamics. We seek to answer the following questions:

- *What attack vectors are being employed against WUC?* Do they generally rely only on human failures or also on software vulnerabilities? Do they evolve in time and if so, how quickly do they adapt to new defense mechanisms?
- *What is the efficacy of existing countermeasures?* As all malicious documents in our dataset used well-known vulnerabilities, would commercial, state-of-the-art defenses have detected all of them?

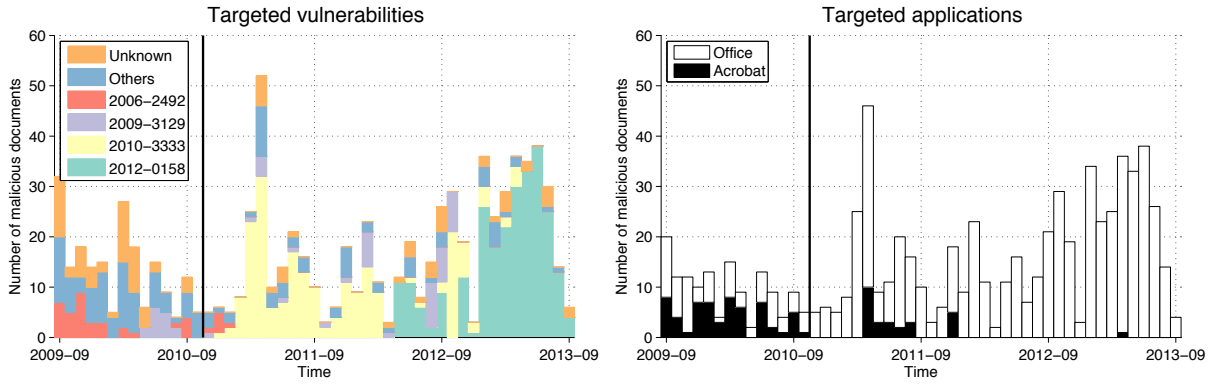

Figure 8: Number of malicious documents containing a given vulnerability (CVE) (left) and target application (right) for each month of our dataset. We represent the top four CVEs in number of attacks over the whole trace individually and *others* are represented in aggregate. The vertical line in November 2010 corresponds to the deployment of sandboxing in Acrobat Reader. **Although Acrobat Reader was the most targeted application until 2010, recent attacks mainly target the Office suite.**

4.1 Methodology

Malicious archives. To analyze the archives' contents, we extracted them in a disconnected VM environment and manually inspected their contents to determine the type of files they contain, independently of their extensions. In the case of EXE files, we also examined them manually to determine whether their Microsoft Windows icons were similar to those used for other file formats (e.g., JPEG) in order to persuade average users that they were not executable.

Malicious documents. We used two methodologies to determine the characteristics of the vulnerabilities being exploited by malicious documents. First, we submitted the documents to VirusTotal [1] for analysis. Each of the 45 Antivirus (AVs) on VirusTotal classified the checked sample as benign or malicious, and attached a "tag" describing the auxiliary information relating to the sample. Often the tag is a Common Vulnerabilities and Exposures (CVE) number, presumably corresponding to the signature that matched, but in some cases, the tag field is not a CVE; it is either tagged as "unknown" or contains a symptomatic description such as the inclusion of a suspicious OLE object. We refer to these three tags as *CVE*, *Unknown*, and *Heuristic*, respectively. Often all AVs reported a *Single* CVE but sometimes, they reported *Multiple*, conflicting CVEs. Once we collected all CVE tags, we then scraped the National Vulnerability Database [18] to obtain the release date and vulnerable applications for each of the CVEs that we found.

Second, we inspected the documents manually to confirm that they contain malware, and also used taint-assisted analysis both to verify the accuracy of the CVEs reported in AV reports and to investigate the presence of zero-day vulnerabilities.[1] The methodological details of our taint-assisted manual analysis are described in Appendix B.

Defenses. We performed a retrospective analysis of the protection offered by common defenses such as AV and webmail providers in the context of our malicious documents. For AV, we used VirusTotal to determine whether a malicious document is detected by the scanning engine of each AV, as described above. For webmail channels, we created an email account on GMail, Hotmail, and Yahoo, and used a dedicated SMTP server to send emails to that account with malicious documents attached. We considered malicious documents delivered without modifications as undetected by the webmail defenses. Otherwise, if an email or its attachment is dropped, or if the attachment's payload is modified, we considered it as detected. The analyses based on webmails and VirusTotal were performed in November 2013 and July 2014, respectively.

Limitations. As with social engineering, our analysis of attack vectors is biased towards NGOs. In addition, the above methodology is limited to the attack vectors captured in our dataset. For example, we miss attacks against the NGOs' web servers unless the corresponding malicious link appears in the suspicious emails.

Second, our taint-assisted analysis of vulnerabilities is limited to those documents for which we were able to analyze the logs manually. For example, we found that opening PDF files in our environment generated log files that were far too large (around 15GB in the median case) for manual analysis. As a result, we were able to manually confirm vulnerabilities only against Microsoft Office. However, despite this limitation, we were also able to determine which PDF documents contained malware through manual inspection.

[1] Hereafter, *zero-day vulnerabilities* refer to vulnerabilities that were not publicly disclosed at the time of the attack.

Table 2: List of well-known vulnerabilities exploited by malicious documents. *Release* corresponds to the release date of the vulnerability and *First* to its first exploitation in our data set (in number of days relative to the release date). *Resolved* corresponds to the number of Microsoft Office vulnerabilities that were mistagged in AV reports but that we were able to resolve using taint-assisted manual analysis.

CVE	*Release*	*First*	*Apps*	*# emails*	*Resolved*
2006-0022	06/13/06	1,191	Office	2	0
2006-2389	07/11/06	1,166	Office	18	16
2006-2492	05/20/06	1,125	Office	59	47
2007-5659	02/12/08	588	Acrobat	3	0
2008-0081	01/16/08	651	Office	1	0
2008-0118	03/11/08	1,010	Office	1	0
2008-4841	12/10/08	824	Office	1	0
2009-0557	06/10/09	405	Office	2	0
2009-0563	06/10/09	880	Office	31	0
2009-0927	03/19/09	180	Acrobat	11	0
2009-1862	07/23/09	68	Acrobat	3	0
2009-3129	11/11/09	188	Office	58	4
2009-4324	12/15/09	4	Acrobat	15	0
2010-0188	02/22/10	28	Acrobat	15	0
2010-1297	06/08/10	0	Acrobat	9	0
2010-2883	09/09/10	7	Acrobat	7	0
2010-3333	11/10/10	49	Office	220	0
2010-3654	10/29/10	0	Office	7	0
2011-0611	04/13/11	0	Acrobat	19	0
2011-0097	04/13/11	224	Office	3	0
2011-2462	12/07/11	2	Acrobat	5	0
2012-0158	04/10/12	37	Office	278	12
2013-0640	02/14/13	68	Acrobat	1	0

Finally, our defense analysis was performed in bulk, after the time of the attacks. As a result of the difference between the times of attack and analysis (up to four years for the first malicious documents), the detection rates reported hereafter should be treated as upper bounds. This is because the AV signatures at the time of the analysis were more up-to-date than they would have been at the time of the attack.

4.2 Results: Attack vectors

4.2.1 Malicious archives

We observed numerous targeted attacks leveraging social engineering and human failure to install malware on the victim's computer. In particular, we found 247 RAR and 49 ZIP containing malicious EXE. In 10 cases, the malicious archives were password protected with the password included in the email's body. We hypothesize that archiving was used as a rudimentary form of packer for the malware to evade detection by the distribution channels. Finally, we found that 20% of all EXEs contained in the archives used an icon that resembled a non-EXE, i.e., a DOC, JPEG, or PDF icon, in 20%, 19%, and 7% of the cases.

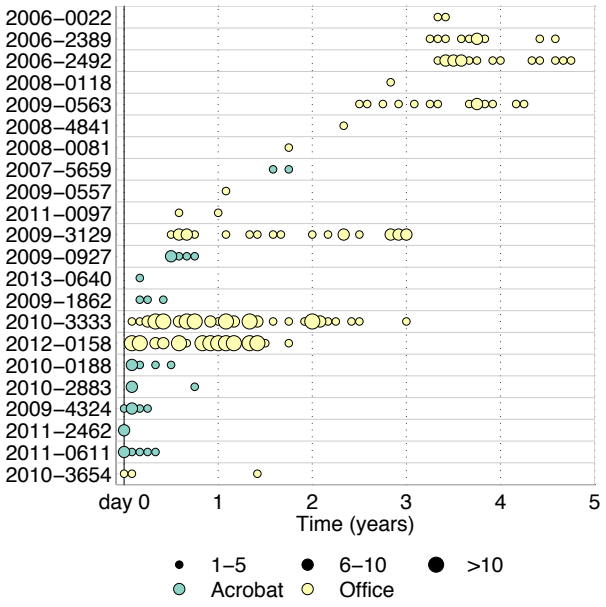

Figure 9: Timeline of the target vulnerabilities. The Y axis corresponds to CVEs and each circle to the number of CVEs seen each month after the public disclosure of the vulnerability (day 0). **All vulnerabilities were first targeted after their public disclosure.**

4.2.2 Malicious documents

We used taint-assisted analysis to resolve the conflicts due to AV mistagging and summarize the CVE information in Table 2. The number of conflicts resolved using taint-assisted manual analysis is reported in the last column *Resolved*. Additional taint-analysis results are reported in Appendix B.

Zero-day versus unpatched vulnerabilities. We find no evidence of the use of zero-day vulnerabilities against our dataset, but several uses of disclosed vulnerabilities within the same week as their public release date. In addition, we see in Figure 9 that vulnerabilities continued to be exploited for years after their disclosure, and this confirms that unpatched vulnerabilities represent a large fraction of attacks in our dataset. To ascertain the CVE being exploited in each sample, we used a combination of the telemetry data available in CVE tags generated by AVs, and a manual analysis to resolve cases where the tag was ambiguous. For each sample, we then recover the public disclosure date for the vulnerability manually, and treat it as the corresponding day-zero. By comparing the time of use in our email dataset, we are able to ascertain the lifetime of vulnerability exploits.

We find several instances of exploits that were used in publicly-reported targeted attacks in our dataset. For

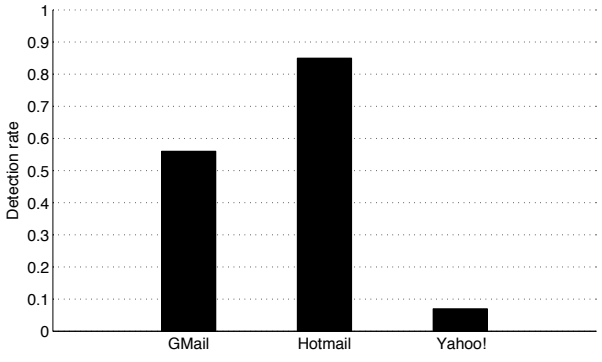

Figure 10: Detection rates of popular webmails for the malicious documents. **The efficacy of webmails to detect malicious documents varies widely.**

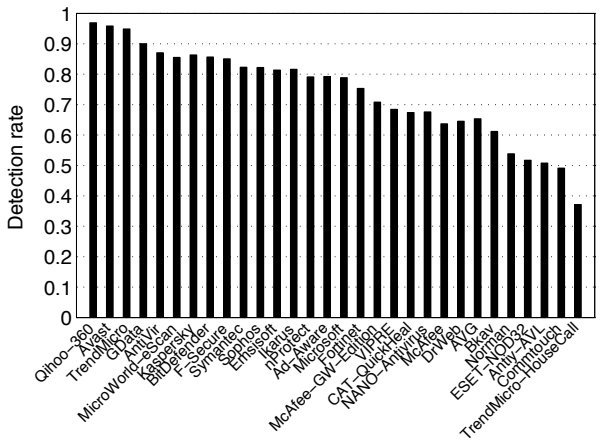

Figure 11: Detection rates of malicious documents for each of the top 30 AVs as reported by VirusTotal. **No single AV detected all malicious documents despite their use of well-known vulnerabilities.**

instance, vulnerabilities such as CVE-2009-4324, CVE-2010-3654, and CVE-2010-2883 have been reported to be zero-day vulnerabilities [6]. However, in our dataset, these vulnerabilities were used after their disclosure.

Evolution of target applications. Our data shows a sudden switch from Adobe Reader to Microsoft Office suite as the primary targeted application as of November 2010, as seen in Figure 8. We find a correlation between the time of this switch and two events: (a) the deployment of sandboxing defenses in Adobe Reader and (b) the disclosure of vulnerabilities in the Office suite. The first version of Acrobat Reader to support sandboxing for Windows (version 10.0) was released on November 15, 2010. Within the same month, a stack buffer overflow against Microsoft Office was released publicly (November 2010), reported as CVE-2010-3333. We see this CVE being massively exploited in our dataset as of January 2011, which is a time lag of two months. We observe the use of CVE-2010-3333 being replaced with CVE-2012-0158 in January 2013. This evidence suggests that attackers adapted their targeted vectors to use newly disclosed vulnerabilities within a few days to a few months of disclosure, and that updates to the security design of software reduces its exploitability in the wild (as one would expect).

4.3 Results: Bypassing common defenses

We now investigate the efficacy of existing defenses against malicious documents.

Email / Webmail Filtering. Despite the retrospective analysis of the malicious documents, we find that the detection rates of malicious documents for GMail, Hotmail, and Yahoo were still relatively low (see Figure 10). We also find that GMail failed to detect most malicious documents sent after March 2012. In particular, while the detection of documents sent before March 2012 was 73%, it is 28% after that date. Interestingly, 71% of the true positives for GMail after March 2012 corresponded to RTF files with all \r\n character sequences substituted with the \n character. While this substitution did not deactivate the malware, we observed that it broke the shellcodes embedded into these documents as they require the document size to remain unchanged to function properly. As a result, the malware was never executed. Although we cannot verify the purpose of this substitution, we note that its appearance coincided with that of the malicious RTF files. We conclude this discussion by pointing out that Yahoo's low detection rate is interesting as it claims to be using Symantec AV for its webmail service [12] — which, as we will see below, has a much higher detection rate.

Signature-based AV Scanning. In Figure 11, we show the detection rates for the top 30 VirusTotal AVs, sorted by decreasing detection rate of the malicious documents. There are two main takeaways from this graph. First, no single vendor detected all original malicious documents, even though we have seen that they used well-known vulnerabilities. For example, Qihoo, the vendor with the overall best efficacy, was unable to detect 3% of the malicious documents based on scanning. Second, we observe large variations among the efficacy of different AV vendors. That is, the detection rate dropped by 30% from the first to the twentieth AV (CAT QuickHeal) and the 15 AVs with the lowest detection rate (not shown) all had a detection rate of less than 35%.

Summary of Findings. We found that malicious documents are the most popular attack vectors in our dataset followed by malicious archives. Malicious documents tended to use newly released vulnerabilities, often within

Table 3: Summary of the malware clusters. For each cluster, we show the malware family (or an ID if we could not determine it), the number of malicious emails containing the malware, the number of Command and Control (C2) servers, the similarities in terms of communication protocols and C2 with malware attributed to known entities (*entity(Com,C2)*). **Our dataset contains several families of first-stage malware previously seen in targeted attacks carried out in the wild.**

Clusters	*1*	*2*	*Surtr*	*4*	*5*	*6*	*7*	*8*	*9*	*TravNet*
# samples	67 (9%)	58 (8%)	51 (7%)	37 (5%)	30 (4%)	22 (3%)	19 (2%)	19 (2%)	18 (2%)	13 (2%)
# C2	6	2	6	18	13	3	8	13	9	4
Similarity	DTL(C2)	—	DTL(C2)	—	—	—	—	—	—	TravNet(Com,C2)

a week, continued to utilize them for several years, and most of them used well-known instead of zero-day vulnerabilities. In particular, our taint-assisted manual analysis of Office documents did not reveal a single zero-day vulnerability in our dataset. This raises the question of whether defense mechanisms deployed in webmails and state-of-the-art commercial defenses are effective in blocking these well-known attacks. Furthermore, we found that malicious archives often contained EXE files that masquerade as pictures or documents.

5 Malware analysis

We now analyze the first-stage malware found in malicious documents. Unlike the Mandiant report, which provides an analysis for malware that targets different organizations and that (they claim) originates from the same group, our analysis focuses on all malware (in our dataset) that has targeted a single organization. By looking at targeted attacks from the perspective of the target rather than the attacker, our analysis enables us to determine whether WUC has been targeted with the same or different malware over the years. We also take a different approach from the authors of the GhostNet report who performed malware analysis on a few compromised systems belonging to different but related organizations. We instead analyze over six hundred malware samples used to establish a foothold on the targeted systems of a single organization. Our analysis differs from the related work in its scale and context [16] or focus [10]. This section aims to answer the following question:

- *Is WUC targeted with the same or different malware?* In the latter case, are there similarities between this first-stage malware and others found in targeted attacks in the wild?

5.1 Methodology

Our analysis below was done on 689 malware samples that we extracted from malicious documents.

Clustering. To make our analysis tractable for 689 malware samples, we started by clustering the malware based on its behavior. To do so, we ran the malicious EXE and DLL files in a disconnected sandboxed environment and hooked the function calls to resolve domain names and establish network communications. In addition, to obtain the TCP port number on which communication is done, we intercepted function calls to `gethostbyname` and returned a dummy routable IP address. As a result, the malware subsequently reveals the port number when it initiates a connection with the returned IP. (See Appendix C for the complete list of Command and Control (C2) domains.) Finally, we generated behavioral profiles for 586 samples, clustered them using an approach similar to [5, 14], and manually verified the accuracy of the resulting clusters.

Malware family and similarities. Similarly to Bailey et al. [5], we found that determining the malware family using AV signature scanning was unproductive. To determine whether our malware shares similarities with other known targeted malware, we relied on several reports on targeted attacks [9, 13]. We extracted the C2 domains and, when available, additional information about the malware (e.g., hashes and behavior) from these reports. Finally, we correlated the domains, IP addresses, hashes, and behavioral profiles with those from the reports in order to find similarities between the different sets of malware. We performed this analysis in February 2014.

Limitations. Our behavioral analysis was performed in a disconnected environment and as a result, it is limited to the first stage of the malware behavior. Studying the behavior of additional payload that would be downloaded after the compromise is beyond the scope of this paper and will be the subject of future work.

5.2 Results

We now analyze the malware clusters and their similarities with other targeted malware found in the wild.

Cluster sizes. We find that 57% of our malware belonged to the ten largest clusters (we show additional information about these clusters in Table 3). In total, five clusters (two in the top ten) used at least one of dtl6.mooo.com, dtl.dnsd.me, or dtl.eatuo.com as their

C2 domains, indicating some operational link between them. In fact, at the time of analysis, these three domains resolved into the same IP address and the malware in each cluster connected to different ports of the same server. Despite these apparent similarities, however, manual analysis of the behavioral logs revealed that their logic differed from one another, explaining their assignment to different clusters. Combined, these five clusters represented 24% of the malware that we analyzed.

Malware family and similarities. We found various degrees of similarities between our clusters and targeted attacks reported in the wild. First, the five clusters above had the same C2 as the DTL group reported by FireEye in November 2013 and that the malware was of the same family as one of these clusters' (*APT.9002,* not shown) [9]. In particular, we found that one of our samples in that cluster had the same MD5 hash as those described in the FireEye report and that eight had identical manifest resources. FireEye claims that this malware has been used in targeted attacks against various governmental and industrial organizations.

Second, malware in the *Surtr* cluster had the same behavioral profile as samples used against the Tibetan community in March 2012 [7]. Although the two sets of samples had different MD5 hashes, they both connected to the same C2 server (shared with *APT.9002*) on the same port number, and exhibited the same behavior to establish persistency on the victim's machine.

Third, our 13 TravNet samples exhibited similar behavior as those used against Indian targets in 2013 [2]. To do so, we obtained the samples used in India, generated their behavioral profiles, and compared them manually with the malware in our *TravNet* cluster. Although both sets connected to different C2 servers and exhibited variations in the way they searched the victims' file system, we found that they both used the same communication protocol with the C2.

Fourth, samples in another cluster communicated with the same C2 server and exhibited the same behavior as a Vidgrab sample found in a malicious document sent to a victim in Hong Kong in August 2013 [8].

Summary of findings. We found that WUC has been targeted with several malware families in the last year. We also showed that the *Surtr* and *APT.9002* clusters corresponded to malware that Citizenlab and FireEye identified as having targeted the Tibetan community, as well as other political and industrial organizations [7, 9]. Furthermore, 24% of our malware (including *Surtr*, *APT.9002* and three other clusters) had at least one C2 domain in common, which was identical to those of the Citizenlab and FireEye reports.

6 Future Work

Several directions for future work arise from this work. We briefly discuss them below.

Attack vectors and generalization. Our analysis is limited to attack vectors used against WUC. Similar studies on a wider range of targets would benefit understanding this emerging threat better. Further, our attack vectors distributed over email channels and have two main limitations. First, it is possible that our volunteers have been attacked via other channels besides email. Second, although we have seen various organizations targeted with the same malware as WUC, it is generally hard to determine with certainty which victims were the primary target of these attacks. Therefore, it is possible that other victims have been targeted with additional attack vectors when the attacks did not involve WUC. Further research is needed to overcome these limitations

Exploring different channels that attackers use for distributing malicious payloads is important. As a step towards this goal, we are currently collaborating with the Safebrowsing team at Google to investigate the emergent threat of watering-hole attacks. These attacks are conceptually very similar to drive-by download attacks with one key difference: They compromise *very specific* websites commonly visited by the targeted community (e.g., a company's website) and wait for victims to visit the website. As compared to spear phishing, watering-hole attacks offer the advantage of potentially targeting a fairly large number of victims (e.g., all employees of a large company) before raising suspicion. We conjecture that the small number of suspicious links in our dataset may be due to the small size of the targeted organizations and the public availability of their employees' email addresses.

Other attack vectors include but are not limited to packets injection to redirect victims to malicious servers (similar to those used in watering-hole attacks) and physical attacks on the victims' devices [3]. Detecting these attacks would require completely different methodologies than the one we used in this paper.

Monitoring. We have seen that a few high-profile members of the Uyghur community were compromised and that their email accounts were being used as stepping stones to carry out targeted attacks. Although it is possible that these email accounts were compromised via targeted attacks, we have not yet confirmed this hypothesis. More generally, we do not know yet what is the specific aim of these targeted attacks. Monitoring the full lifecycle of targeted attacks would require novel measurement systems, deployed at the end users, that can identify compromises without being detected.

Pinpointing the geolocation of attackers carrying out targeted attacks, or *attack attribution*, is another open

monitoring challenge. Marczak et al. were able to attribute targeted attacks to governments in the Middle East by analyzing relationships of cause and effect between compromises and real-world consequences [16]. In contrast to monitoring and attack attribution, this paper has presented a extensive, complementary analysis of the life cycle of targeted attacks *before* the compromise.

Large-scale malware analysis and clustering. We found it challenging to (a) cluster targeted malware and (b) locate similar samples. First, this malware sometimes exhibits significant similarity in its logic and different malware may also use the same Command and Control (C2) infrastructure. As a result, traditional clustering algorithms tend not to work very well. Second, we located similar samples based on a limited set of indicators such as C2, cryptographic hash, or YARA signatures, however, we feel that our current capability in that respect has a lot of room for improvement. We foresee that a search engine that can, for example, locate malware matching certain indicators out of an arbitrarily large corpus would be a useful instrument for researchers working on targeted attacks.

Our analysis of CVEs highlights that telemetry data from commercial AVs is not always reliable. Our analysis complemented with taint-analysis was largely manual and time-intensive. Analysis techniques to quickly diagnose known CVEs directly from given exploits is an open problem and perhaps one of independent interest.

Defenses. Our findings confirm that AVs may miss known CVEs, even years after their release dates. Clearly, known CVEs contribute a large part of the emerging threat of targeted attacks. Understanding why commercial AVs miss known attacks conclusively, for example to tradeoff false positives or performance for security, is an important research direction. Designing effective defenses against targeted attacks is a major research challenge which depends on our ability to understand the threat at hand. As part of future work, one could evaluate the effectiveness of novel defenses based on the findings from this paper. As a small step towards that goal, we plan to soon deploy a webmail plugin that combines metadata and stylometry analysis [17] to detect contact impersonation.

7 Conclusion

We have presented an empirical analysis of a dataset capturing four years of targeted attacks against a human-rights NGO. First, we showed that social engineering was an important component of targeted attacks with significant effort paid in crafting emails that look legitimate in terms of topics, languages, and senders. We also found that victims were targeted often, over the course of several years, and simultaneously with colleagues from the same organization. Second, we found that malicious documents with well-known vulnerabilities were the most common attack vectors in our dataset and that they tended to bypass common defenses deployed in webmails or users' computers. Finally, we provided an analysis of the targeted malware and showed that over a quarter of samples exhibited similarities with entities known to be involved in targeted attacks against a variety of industries. We hope that this paper, together with the public release of our malware dataset, will facilitate future research on targeted attacks and, ultimately, guide the deployment of effective defenses against this threat.

Acknowledgements. The authors would like to thank the anonymous reviewers, our shepherd Stuart Schechter, and Peter Druschel for their useful feedback. We would also like to acknowledge Karmina Aquino (F-Secure), Emiliano Martinez (VirusTotal), Mila Parkour (Contagio), and Nart Villeuneuve (FireEye) for their help locating similar malicious documents. Finally, we thank the Max Planck Society, the Ministry of Education of Singapore under Grant No. R-252-000-495-133, and the NSF under Grant No. CNS-1116777 for partially supporting this work.

B Dynamic taint-assisted analysis of malicious documents

B.1 Methodology

We use BitBlaze [21] to perform dynamic taint-tracking analysis of the targeted applications under the malicious documents as input and configure it to report four kinds of reports: (a) when a tainted Extended Instruction Pointer (EIP) is executed, (b) when a memory fault is triggered in the target program, (c) when a new process is spawned from the target program, or (d) when the analysis "times out" (i.e., runs without interruption for over 15 minutes). To mark malicious documents as a source of taint, we tainted the network inputs and routed the malicious input file using `netcat`. Additionally, we set BitBlaze to exit tracing at the detection of null pointer exceptions, user exceptions, tainted EIPs, and process exits before the start of the trace. A tag was generated from the trace by obtaining the last instruction with tainted operands, and matching it with the list of loaded modules generated by TEMU. Our guest (analysis) system configuration used in the image consists of clean installations of Windows XP SP2 with TEMU drivers and Microsoft Office 2003.

B.2 Results

Anti-virus software typically uses static signature-matching or whitelisting techniques to analyze malware. To validate the analysis results available from commercial AV, we ran a separate semi-automated dynamic analysis of the targeted application under our malicious documents.

Out of 817 unique input documents (725 malicious and 92 legitimate), 295 timed out with our BitBlaze analysis without reporting a tainted EIP, a memory fault, or a newly spawned process.[2] Another 13 of them were incompatible with our analysis infrastructure (using a more recent DOCX format). We could not compare these cases directly to the results obtained from VirusTotal. Therefore, we focus on the remaining 509 malicious documents in the evaluation.

Efficacy of Taint EIP Detection. Taint-tracking detected tainted EIP execution in 477 out of the 509 documents. In 19 cases of the undetected 32 cases, however, a new process was spawned without it being detected by taint-tracking. We treat these as false negatives in taint-tracking. We speculate that this is likely to be due to missed direct flows, untracked indirect flows (via control dependencies, or table-lookups), or attacks using non-control-flow hijacking attacks (such as argument corruption). 13 documents did not lead to a tainted EIP execution, but instead caused a memory fault. This could be due to a difference in our test infrastructure and the victim's, or an attempt to evade analysis. In 33 of the 477 cases where tainted EIP was detected, no new spawned process was created, and the tainted EIP instruction did not correspond to any shellcode. All these cases correspond to a particular instruction triggering the tainted EIP detection in MSO.DLL, a dynamic-link library found in Microsoft Office installations. To understand this case better, we manually created blank benign documents and fed them to Microsoft Office — they too triggered tainted EIP detections. We treat these cases as false positives in taint detection, possibly because of benign dynamic generation of code. All the remaining cases (i.e., 444 out of 477) are legitimate exploits that we could confirm to execute shellcode.

[2] We believe 150 of these are due to user-interaction which we could not presently automate, and the remaining could potentially be analyzed with a faster test platform; we plan to investigate this in the future.

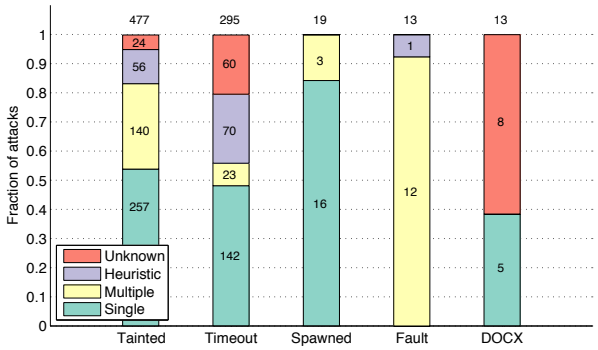

Figure 12: Breakdown of dynamic taint-assisted analysis, and comparison to VirusTotal AV results. *Single*, *Multiple*, *Heuristics*, and *Unknown* correspond to the different AV tags assigned to documents. The main bars show the detection result from BitBlaze: (a) Detected by *Tainted* EIP execution, (b) *Timeout*, (c) *Spawned* process without tainted EIP execution, (d) Memory *Fault* without tainted EIP execution, and (e) *DOCX* unable to run in our analysis environment. Within each main bar, each stacked bar represents the corresponding tag given by VirusTotal.

Dynamic Taint versus VirusTotal. Figure 12 shows the detailed comparison of taint-assisted classification of vulnerabilities versus the results from VirusTotal. Out of a total of 477 documents on which tainted EIP was detected, VirusTotal tagged 397 documents with one or more CVEs. Of the remaining 80 cases that are detected by tainted EIP execution, 24 are undetected by VirusTotal, and 56 are detected, but marked *Unknown* (i.e., no CVE assigned) by VirusTotal. Dynamic taint analysis to determine the tainted EIP was helpful to further refine the results of AV detection for a majority of these 56 tagged-*Unknown* cases. Specifically, for 55 out of the 56 documents, taint-assisted manual analysis was able to resolve it to the exploited CVE.

Out of a total of 477 documents on which tainted EIP was detected, VirusTotal tagged 397 documents with one or more CVEs. Our taint-assisted manual analysis agrees with the VirusTotal CVE tag results on 372 of these 397. That is, 372 documents were detected to execute a tainted EIP for which we could manually correlate to a single CVE that was the same as the one reported by a majority of the AVs in VirusTotal.[3] Thus, for a large majority of the cases, taint-assisted analysis agrees with the AV results. Of the remaining 25 cases, 17 could be identified as misclassifications because the CVE reported by most of the AVs in VirusTotal was not the one that affected the program. The 8 remaining documents were tagged by taint analysis as being false positives even though a CVE was obtained from VirusTotal.

[3] Note that different AVs often tag the same vulnerability with different tags in VirusTotal. We took the tag given by a majority of the reported tags, as the representative of the sample.

A Large-Scale Empirical Analysis of Chinese Web Passwords

Zhigong Li, Weili Han
Software School, Fudan University
Shanghai Key Laboratory of Data Science, Fudan University

Wenyuan Xu
Department of Electronic Engineering, Zhejiang University

Abstract

Users speaking different languages may prefer different patterns in creating their passwords, and thus knowledge on English passwords cannot help to guess passwords from other languages well. Research has already shown Chinese passwords are one of the most difficult ones to guess. We believe that the conclusion is biased because, to the best of our knowledge, little empirical study has examined regional differences of passwords on a large scale, especially on Chinese passwords. In this paper, we study the differences between passwords from Chinese and English speaking users, leveraging over 100 million leaked and publicly available passwords from Chinese and international websites in recent years. We found that Chinese prefer digits when composing their passwords while English users prefer letters, especially lowercase letters. However, their strength against password guessing is similar. Second, we observe that both users prefer to use the patterns that they are familiar with, *e.g.*, Chinese Pinyins for Chinese and English words for English users. Third, we observe that both Chinese and English users prefer their conventional format when they use dates to construct passwords. Based on these observations, we improve a PCFG (Probabilistic Context-Free Grammar) based password guessing method by inserting Pinyins (about 2.3% more entries) into the attack dictionary and insert our observed composition rules into the guessing rule set. As a result, our experiments show that the efficiency of password guessing increases by 34%.

1 Introduction

Passwords are the most widely used credentials for authenticating Web users around the world, including the users that do not speak English. Text-based passwords are likely to remain the dominant mechanism for authenticating users for the foreseeable future [7][19]. Meanwhile, researchers are still in the process of understanding the security strength of passwords and exploiting methods to improve password guessing. Although insightful, most existing work focuses on passwords of English users. Little work has studied the impact of regional convention and languages on password selection utilizing a large dataset of passwords. One exception is Bonneau [6], who studied password strength based on languages by performing an empirical study on Yahoo! users and concluded that Chinese passwords are among the hardest ones to guess. We believe his finding is biased because of his dataset (*i.e.*, `Yahoo` users are familiar with English). In this paper, we analyze passwords of non-English speakers, specifically, Chinese users, which represent *618* million Internet users as of the end of 2013 [12], and compare them with passwords of English users.

To understand the differences between Chinese and English passwords, this paper leverages over 100 million leaked and publicly available passwords from several popular Chinese websites (`CSDN` [13], `Tianya` [33], `Duduniu` [17], `7k7k` [5], and `178.com` [4]) and English websites (`RockYou` [30] and `yahoo` [37]). These Chinese websites only provide Chinese webpages, and we consider their users as *Chinese users*. In addition, English websites mainly intend to serve users who are familiar with English, and we consider the users of `RockYou` and `Yahoo` as *English users*. Note that, these websites (except `Duduniu`, which is an e-commerce website) provide similar services, i.e., non-monetary ones such as web portal, online communities, social networking, online forums, etc. Thus, we consider them comparable and having similar influence on their users when choosing passwords. This makes their password data corpus promising for studying the impact of languages on password composition.

The unfortunate leakages of the large volume of passwords provides us an opportunity to understand password differences between the two groups of users in depth. Such analysis is important, because it enables

	Language	Site Address	Amount	Distinct Accounts
CSDN	Chinese	http://www.csdn.net/	6,428,629	6,423,483
Tianya	Chinese	http://www.tianya.cn/	30,179,474	26,223,020
Duduniu	Chinese	http://www.duduniu.cn/	16,282,969	15,131,833
7k7k	Chinese	http://www.7k7k.com/	19,138,270	15,940,099
178.com	Chinese	http://www.178.com/	9,072,824	9,072,804
RockYou	English	http://www.rockyou.com/	32,603,048	32,602,882
Yahoo	English	http://www.yahoo.com/	442,837	442,837
Total			**114,148,051**	**105,836,958**

Table 1: Basic information of leaked passwords of the websites that are analyzed in this paper. We removed the duplicated accounts between `Tianya` and `7k7k` from the `Tianya` dataset. See details in Appendix A.

better password guessing evaluation and can guide web masters to protect the accounts.

We designed analysis tools and leveraged the guessing resistance indicators (such as α-*work-factors* [28] and β-*success-rates* [10]) to find the differences among accounts of multiple websites, and found the preference of the two groups of users. Then, we improved the efficiency of the Probabilistic Context-Free Grammar (PCFG) based password guessing method [35] by adding regionally preferred patterns (*i.e.* Pinyins) into the dictionary and modifying the generated guessing rules. We summarize our findings and main contributions as follows:

- **Different Characters Sets**: Chinese users prefer digits in their passwords, while English users prefer letters, especially lowercase letters. However, the password strength against guessing is similar for both groups and thus both groups share similar security concerns in protecting passwords.
- **Patterns of Languages and Dates**: Both Chinese and English users prefer to use language-related patterns as passwords. That is, Chinese users prefer Chinese Pinyins and English users prefer English words. As for dates, both groups prefer their conventional formats. That is, Chinese prefer dates with the year at the beginning and English users prefer dates with the year at the end.
- **Improvement of the Efficiency of Password Guessing**: Based on our observations, we add 20,000 Pinyins into the dictionary and add the guessing rules, resulting in an improvement of efficiency by 34% in guessing Chinese passwords using a PCFG based guessing method. This confirms that the Pinyins and date's rules are important in guessing Chinese passwords.

The rest of the paper is organized as follows: Section 2 summarizes our observations on the differences between passwords from Chinese and English users. Section 3 presents the results of guessing using modified Bonneau's methods [6] and PCFG based methods [35]. In Section 4, we discuss the related work and conclude in Section 5.

2 Regional Differences on Passwords

2.1 Dataset Setup

To discover the differences between the passwords of Chinese and English users, we analyzed a corpus of over 100 million passwords from multiple websites that are in Chinese and English, respectively. All the leaked passwords are publicly available for downloading. During our research, we followed the ethical practice and never utilized the leaked passwords for reasons other than understanding the overall statistical observation of passwords.

At the end of 2010, an incident that is known as *CSDN Password Leakage Incident* happened, and passwords from five websites, including `CSDN`, `Tianya`, `Duduniu`, `7k7k` and `178.com`, were leaked in several consecutive days. The total number of leaked accounts is over 80 million, and all the leaked passwords are in plaintext. We summarize the website information in Table 1.

`CSDN` [13] is one of the most popular Chinese IT professional communities, similar to `MSDN`. `Tianya` [33] is the largest online forums and blogs in China. `7k7k` [5] and `178.com` [4] are two websites providing game infor-

	Chinese	English
1	123456 (2.17%)	123456 (0.88%)
2	123456789 (0.65%)	12345 (0.24%)
3	111111 (0.59%)	123456789 (0.23%)
4	12345678 (0.39%)	password (0.18%)
5	000000 (0.34%)	iloveyou (0.15%)

Table 2: The most popular passwords and their occurrence percentages.

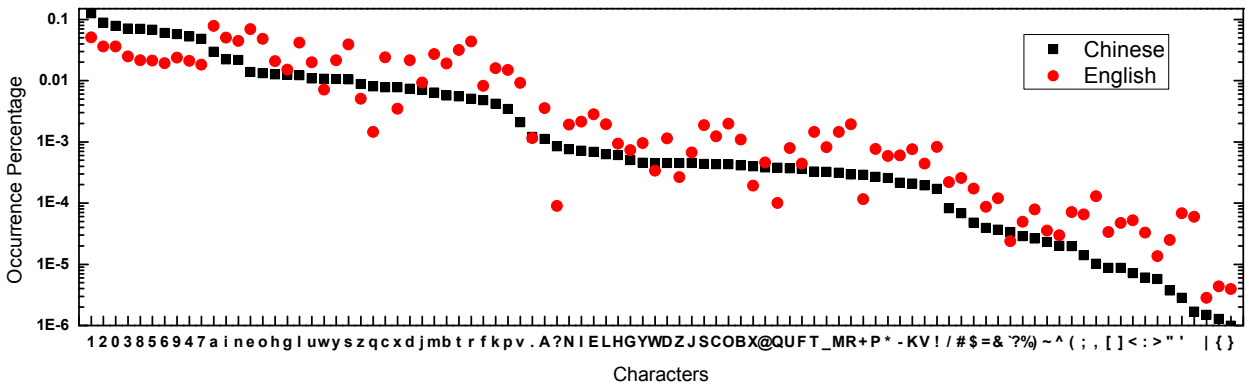

Figure 1: Character distribution, i.e., the occurrence percentage of each character for Chinese and English passwords. The characters are arranged in a descending order according to the percentages in Chinese passwords.

mation and online flash games. Duduniu [17] is a commercial site that mainly sells management software platforms for Internet bars. It is worth noting that all these websites are extremely popular in China, among which CSDN and Tianya have been ranked top 1,000 in Alexa Top Global Sites recently. Thus, their users cover a large percentage of Internet users in China.

Besides their popularity, the leaked password data corpus is promising for understanding the language impact on passwords because few password policies are enforced in the above five Chinese websites before the leakage according to our investigation. For example, CSDN allows a password with as few as five digits, and such a rule remains unchanged even after the password leakage event. Furthermore, Tianya allows passwords as short as six characters since it was founded. Thus, the leaked password data corpus represents the password set that was composed with little influence from password policies.

Password leakage events also happened to English websites as well. In 2009, attackers broke into the database of RockYou and released the 32 million passwords (in plaintext) to the public. In 2012, Yahoo's accounts were leaked. A hacking group 'DD3Ds Company' utilized a union-based SQL injection to obtain login details of about 450 thousand user accounts.

The raw files contain duplication and blank passwords that can affect the analysis. For instance, we detected that attackers copied a portion of 7k7k passwords to Tianya, because the password duplication rate between Tianya and 7k7k is much more than the rate between any other two websites (i.e., about 90% between Tianya and 7k7k and about 30% between any other two websites). We thus removed these duplicate passwords in Tianya using the method described in Appendix A. After removing the accounts with blank passwords and filtering out duplicated accounts, we obtained 105,836,958 accounts, as detailed in Table 1. Finally, we imported them into MySQL for further analysis.

2.2 Password Comparison

2.2.1 The Most Popular Passwords

We list the five most popular passwords of Chinese and English users in Table 2, from which we have the following observations:

- In total, the five most popular passwords constitute 4.14% of all Chinese passwords and 1.69% of all English passwords, which shows that Chinese passwords are more congregated.
- Interestingly, although in English datasets, there are a larger number of letter-only passwords (see details in Section 2.2.3), the top 3 most popular passwords are digit-only. In addition, both groups share similar popular passwords, *e.g.*, 123456 and 123456789.

2.2.2 Character Distribution

To understand the frequency of each character, which includes letters (a-z, A-Z), digits (0-9), and symbols (all printable characters except digits and letters), we analyzed the percentage of each character for Chinese and English passwords and depict them in Figure 1, where the characters are arranged in descending order according to the percentages in Chinese passwords.

- **Digits**. In Chinese passwords, the top used characters are digits. Although English users do not use digits as frequently as Chinese users do, digits are among the most frequently used characters.
- **Letters**. In general, Chinese passwords use letters less frequently than English passwords do. In addition, some letters exhibit similar usage percentages

	Digit -only	Letter-only (Lowercase-only)	Letter+Digit (Lowercase+Digit)	Letter+Symbol (Lowercase+Symbol)	Symbol +Digit	Letter+Digit+Symbol (Lowercase+Digit+Symbol)
CSDN	45.06%	12.39% (11.68%)	39.02% (35.60%)	0.50% (0.42%)	0.61%	2.39% (2.04%)
Tianya	64.56%	10.20% (9.89%)	23.12% (21.27%)	0.25% (0.22%)	0.71%	1.14% (1.01%)
Duduniu	32.86%	11.76% (11.08%)	53.69% (50.93%)	0.52% (0.48%)	0.17%	0.92% (0.80%)
7k7k	60.77%	11.13% (10.75%)	26.41% (23.03%)	0.14% (0.12%)	0.32%	1.14% (0.49%)
178.com	48.07%	9.17% (9.00%)	42.11% (41.25%)	0.06% (0.06%)	0.31%	0.27% (0.26%)
RockYou	15.93%	44.04% (41.68%)	36.22% (33.17%)	1.91% (1.64%)	0.16%	1.71% (1.44%)
Yahoo	5.89%	34.64% (33.08%)	56.62% (50.60%)	0.62% (0.49%)	0.04%	2.18% (1.38%)

Table 3: Compositions of passwords. The percentages outside parentheses are the ones counting both uppercase and lowercase letters, and the percentage inside parentheses are the ones counting only lowercase letters. The sum of the percentages in one row is slightly smaller than one, because symbol-only passwords are not listed, and they only account for a small percentage.

	# of Structures/10K	Most Popular Structure	Most Popular Structure%
CSDN	884	DDDDDDDD	21.50%
Tianya	756	DDDDDD	30.10%
Duduniu	610	DDDDDD	7.25%
7k7k	635	DDDDDD	19.51%
178.com	459	DDDDDD	15.48%
RockYou	803	LLLLLL	5.40%
Yahoo	1165	LLLLLL	9.19%

Table 4: Structures of passwords. # of structures/10K refers to the number of different structures in every 10,000 passwords, and the other two columns contain the structures and occurrence percentages of the most popular passwords in both Chinese websites and English ones. D represents a digit, and L represents a lowercase letter.

for both groups of passwords, *e.g.*, the letter *a* is the mostly used letter in both groups. Some letters show distinct usages, *e.g.*, the letter *q* is frequently used in Chinese passwords but is much less used in English passwords; the letter *r* is much more popular in English passwords than in Chinese ones. This is because of the word patterns in either languages. For instance, the letters *q* and *a* are popular building blocks of Pinyins, but the letter *r* is not. We will discuss Chinese Pinyins and English words in detail in Section 2.2.5.

- **Symbols**. Symbols are used less in both Chinese and English passwords, in general. Interestingly, for both groups of passwords, several symbols share the similar usage percentages: the symbol dot (.) is the most frequently used, and symbols like left brace ({) and right brace (}) are less likely to be used. However, regional differences on symbol usages do exist: the question mark (*?*) is more frequently used in Chinese passwords than in English passwords.

2.2.3 Compositions and Structures of Passwords

To understand the structures of passwords in both groups, we analyzed passwords in two aspects. (1) we divided passwords according to their compositions and calculated the percentages in seven category (shown in Table 3). The categories are pure digits, pure letters, digits and letters, letters and symbols, etc. (2) We calculated the percentages of different types of password structures utilizing representations in the Probabilistic Context-Free Grammar [35]. For example, the structure of *Johns0n!* is modeled as *ULLLLDLS* (U = uppercase, L= lowercase, D = digit, and S = symbol). The structure comparison of both password groups is shown in Table 4 where *# of Structures/10K* refers to the number of different structures in every 10,000 passwords. *The most popular structure* is the one that appears the most in the data-set. From Table 3 and Table 4, we can obtain the following observations:

- A majority (around 50% on average) of Chinese users prefer digit-only passwords. This could be due to their language. Chinese characters cannot be entered directly as a password, and digits appear to be the best candidate when users are creating new passwords. Although Chinese users can use Pinyins as discussed in Section 2.2.5, digits seem to be more convenient. As shown in Table 4, *DDDDDD* is the dominant structure in most Chinese websites. For

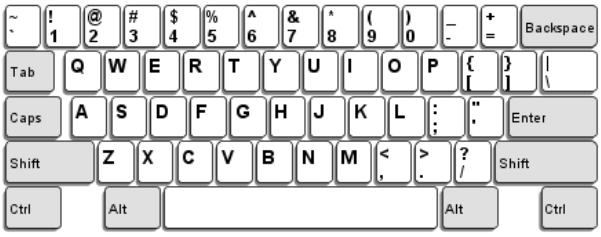

Figure 2: A typical layout of a keyboard (103P) used in China, which is the same as an English keyboard layout.

CSDN, the structure *DDDDDDDD* is the top selection, and *DDDDDD* is ranked at 14. A six-digit number may be an ATM PIN, a birthday, or the last six digits of citizen ID cards. We will discuss details in Section 2.2.6.

- For both password groups, a good portion of passwords contain both letters and digits, and no obvious differences seem to exist between these websites. The owners of the passwords in this category could be users who are concerned with password security but are unwilling to bother with symbols.

2.2.4 Keyboard Patterns

Sometimes, users prefer to create their passwords according to keyboard patterns [32]. Thus, we analyzed the percentages of three primary keyboard patterns. Note that Chinese users utilize standard English keyboards (shown in Figure 2), i.e., they use the same ones as English users.

- **Same Row**: The same row passwords are formed by a consecutive sequence of characters in the same row on keyboard, *e.g.*, asdfhj.
- **Zig Zag**: The zig-zag passwords are formed by a sequence of characters, where each key is adjacent to the next one but not in the same row, *e.g.*, qawsxd.
- **Snake**: The snake passwords consist of a sequence of characters whose keys are adjacent on keyboards yet they are neither in the *Same Row* or *Zig Zag*, *e.g.*, zxcfgh.

	Chinese	English
Same Row	8.31% (0.55%)	2.42% (0.25%)
Zig Zag	0.26%	0.06%
Snake	0.27%	0.08%

Table 5: Percentage of passwords with different keyboard patterns. Most passwords of the *Same Row* pattern are digit-only. The numbers in the parentheses represent passwords that have the *Same Row* pattern and are not digit-only.

Algorithm to Identify Keyboard Patterns. In order to automatically classify passwords into the aforementioned three categories, we assign a coordinate to each character on the keyboard. We define that the x-axis increases from left to right and the y-axis increases from top to bottom. For example, the coordinates of 1 (and !) are (1,0), and the coordinates of q, a, and z are (1,1), (1,2), and (1,3), respectively. Provided the coordinates of the characters, we can determine if a password is in a specific keyboard pattern using the algorithm illustrated in Algorithm 1, where $isAdjacent(pos1, pos2)$ determines whether two letters located in the coordinates $pos1$ and $pos2$ are adjacent in the same row or column.

Result. The statistics analyzed by Algorithm 1 is shown in Table 5, from which we observe that more than 8% of Chinese passwords are composed according to keyboard patterns but fewer English passwords are. After removing all digit-only passwords, the keyboard pattern passwords reduce to about 1%. This is because most passwords of the *same row* pattern are digit only. Nevertheless, Chinese users tend to use keyboard pattern passwords more often than English users do, e.g., there are 0.2% more *Zig Zag* passwords for Chinese than English users. This could be because keyboard patterns are easy to create and remember for Chinese users who are unfamiliar with English.

2.2.5 Chinese Pinyins and English Words

Chinese Pinyin was developed in 1950s and is designed to represent the pronunciation of Chinese characters. Although there are lots of dialects in China, the Pinyins for characters are the same. Trained with Pinyin since primary school, Chinese computer users are familiar with it. Pinyin is the most popular method to input Chinese characters to a computer because it requires almost no extra training for Chinese. Typically, a Chinese character is entered by multiple keystrokes. Although other input methods, such as Wubi, exist, these methods are not as popular due to their steep learning curves.

Since websites do not support passwords composed of Chinese characters directly, unsurprisingly, just like the words in English passwords, Pinyins are widely used in passwords of Chinese users. Ignoring the tones, typically, a word in Pinyins uses a set of 21 sounds representing the beginning of the word called initials, and a set of 37 sounds representing the end of the word called finals. These two combine to form about 420 different basic Pinyin elements [3]. However, users may use various compositions of multiple Pinyins in their passwords. For example, the password *nihao*, is composed of Pinyins *ni* and *hao*.

	Letter-only Passwords		Mixed Passwords	
	Chinese Pinyins%	English Words%	Chinese Pinyins%	English Words%
CSDN	41.61% (5.15%)	15.59% (1.93%)	25.49% (10.68%)	7.97% (3.34%)
Tianya	40.63% (4.15%)	10.39% (1.06%)	23.59% (5.78%)	6.05% (1.48%)
Duduniu	33.28% (3.91%)	15.35% (1.80%)	25.17% (13.87%)	6.48% (3.57%)
7k7k	44.70% (4.97%)	10.04% (1.12%)	21.09% (5.84%)	7.02% (1.94%)
178.com	57.31% (5.25%)	2.20% (0.20%)	23.49% (9.97%)	4.58% (1.94%)
RockYou	6.94% (2.99%)	25.47% (10.98%)	6.88% (2.61%)	28.11% (10.65%)
Yahoo	4.31% (1.46%)	34.92% (11.86%)	4.53% (2.59%)	27.99% (16.01%)

Table 6: Percentage of the passwords that contain Chinese Pinyins or English words. Mixed passwords refer to the ones that contain at least two types of characters with one of them being letters. The percentages inside the parentheses are the proportions out of the entire password dataset, and the percentage ahead of the parentheses are the ones out of the letter-only passwords or mixed passwords. For example, in the row of CSDN, 41.61% (5.15%) means that in the letter-only passwords, 41.61% are composed of Chinese Pinyins, and these passwords occupy 5.15% in the whole dataset of CSDN.

	Top Chinese Pinyins	Top English Words
1	woaini (1.47%)	password (1.28%)
2	li (1.06%)	iloveyou (0.98%)
3	wang (0.97%)	love (0.76%)
4	tianya (0.89%)	angel (0.59%)
5	zhang (0.84%)	monkey (0.45%)

Table 7: The most popular Chinese Pinyins and English words. The percentage base for top Chinese Pinyins is all the Pinyins we extracted from letter-only and mixed passwords in five Chinese websites. Similarly, the percentage base for top English words is all the words we extracted from letter-only and mixed passwords in both English websites.

Algorithm to Identify Pinyins or English Words. We can determine whether a password is composed of Chinese Pinyins or English words by string matching. For example, a password *helloworld* is composed of English words *hello* and *world*. For English words, we chose the Oxford English Dictionary [1] and extracted more than 20,000 commonly used English words.

To improve the matching efficiency, we use Trie (or prefix tree) to identify if the passwords are composed of Chinese Pinyins or English words. We first construct Trie by inserting Chinese Pinyins or English words one by one. With the Tries, we can identify if a password is composed of Chinese Pinyins or English words. The algorithm to insert entries into the Trie is shown in Algorithm 2. In our experiments, we constructed two Tries: one is constructed out of Chinese Pinyins, and the other is built based on the more than 20,000 commonly used English words. The procedure to identify if a password is composed of Chinese Pinyins or English words is shown in Algorithm 3. The structure *node* has two properties. The first is named as *child*, which is an array of *node* and represents the child nodes. The second is a boolean, *isValue*, which represents if the string from the root to the current node is a valid value. The algorithm will try to match the password with the known strings from Trie recursively.

Note that because it is hard to determine the semantic meaning, a password may be semantically meaningless even if it is a composition of Chinese Pinyins or English words. Furthermore, some passwords can be interpreted as compositions of Pinyins and English words at the same time. We removed the passwords with both Pinyins and English words in our analysis.

Result. We performed statistical analysis of the usage of Chinese Pinyins and English words in two aspects. Firstly, we calculated the percentages of passwords that are composed of Chinese Pinyins or English words out of all the letter-only passwords. Secondly, we calculated the percentages of Pinyins or English words out of all the mixed passwords (*i.e.*, the ones contain at least two types of characters with one of them being letters). The results are shown in Table 6. Table 7 lists the top five most popular Chinese Pinyins and English words. From Table 6 and 7, we draw the following conclusions:

- Out of the letter-only passwords, Pinyins are the dominant patterns for Chinese users in composing their passwords, and English words dominate the English passwords. Even when we consider all categories of passwords, these patterns are still the basic building blocks for a large portion of passwords, *i.e.*, more than 10% English passwords contain English words, and about 5% of Chinese passwords consist of Pinyins.

- Interestingly, it seems that love is always the main theme of human beings. As shown in Table 7, *love*

	# Consecutive Exactly Eight Digits	YYYYMMDD	MMDDYYYY	DDMMYYYY
CSDN	1,621,954	29.24%	0.25%	0.43%
Tianya	3,639,517	36.26%	0.35%	0.60%
Duduniu	1,700,329	28.87%	0.28%	0.84%
7k7k	2,470,204	32.41%	0.18%	0.37%
178.com	995,832	30.46%	0.13%	0.19%
RockYou	929,987	2.64%	7.70%	17.66%
Yahoo	6,981	2.78%	12.00%	11.17%

Table 8: Statistics of **eight-digit** date patterns: the number of occurrences of eight consecutive digits and percentages of three date formats. The percentage bases are listed in the second column. Y=year, M=month and D=day. For example, 20130115 is in the format of *YYYYMMDD*.

	# Consecutive Exactly Six Digits	YYMMDD	MMDDYY	DDMMYY
CSDN	809,050	27.21%	4.04%	1.24%
Tianya	9,477,069	23.93%	3.05%	1.19%
Duduniu	2,688,347	17.84%	2.97%	1.78%
7k7k	3,999,958	24.34%	2.63%	0.88%
178.com	2,525,254	13.96%	1.72%	1.30%
RockYou	2,758,871	5.63%	21.90%	18.42%
Yahoo	21,020	4.66%	25.99%	7.77%

Table 9: Statistics of **six-digit** date patterns: the number of occurrences of six consecutive digits and percentages of three date formats. The percentage bases are listed in the second column.

and *iloveyou* are ranked at the second and the third in English passwords. Meanwhile, *woaini* is the top ranked Pinyin, which means *I love you* in Chinese.

- The Pinyins of names are widely used in Chinese passwords. The Pinyins *li*, *wang* and *zhang*, listed as the top used Pinyins for passwords in Table 7, are among the most popular surnames in China. Note that it is difficult to identify first names in Chinese, because they could be almost any combinations of Pinyins.

- The website names appear to be an important part of Chinese passwords. For example, *tianya*, which is the website name, is ranked at the fourth in Chinese Pinyins.

- We found that some passwords from `RockYou` and `Yahoo` are composed of Pinyins, and we suspect that the owners are Chinese. Most of these Pinyins do not map to meaningful expression, and thus we suspect they are names. For example, *yaowei*, which is composed of Pinyins *yao* and *wei*, is most likely to be a name because either *yao* or *wei* can be a surname.

The influence of Chinese Pinyins in password guessing is discussed in Section 3.2.

2.2.6 Dates

Given that digits are commonly used in passwords, we try to understand the meaning of these digits. Since dates are typically represented as a string of digits, in this subsection we analyze the usage of dates in passwords.

Date Format. We focused our attention on six-digit and eight-digit dates. We first extracted all consecutive sequences of exactly six or eight digits from these passwords, and then calculated the dates which are in the range from 1900 to 2099. We classified six-digit dates into three formats: *YYMMDD*, *MMDDYY*, and *DDMMYY*. Similarly, we classify eight-digit dates into *YYYYMMDD*, *MMDDYYYY* and *DDMMYYYY*. The results are shown in Table 8 and 9. Note that there might be ambiguity when interpreting dates. For example, *11121987* may be interpreted as either *November 12, 1987* or *December 11, 1987*. In this case, we assigned the passwords to one of the formats according to the probability distribution of all the passwords that can be uniquely determined. For instance, if 20% of passwords that contain date can be uniquely identified as *MMDDYY* and 80% of them as *DDMMYY*. Then, we assigned 20% of the ambiguous passwords to *MMDDYY* and 80% to *DDMMYY*.

Furthermore, there may be false positive where a general six-digit number is considered as a date. For example, *123123* could be considered as *December 31, 1923*,

	Digit-only	Letter+Digit (Lowercase+Digit)	Symbol+Digit	Letter+Digit+Symbol (Lowercase+Digit+Symbol)
CSDN	51.98%	45.59% (41.36%)	0.50%	1.93% (1.67%)
Tianya	78.84%	19.91% (18.69%)	0.31%	0.72% (0.65%)
Duduniu	41.28%	58.17% (54.86%)	0.24%	0.31% (0.30%)
7k7k	73.90%	25.51% (24.61%)	0.18%	0.41% (0.37%)
178.com	50.91%	48.73% (48.07%)	0.32%	0.04% (0.04%)
RockYou	82.62%	16.52% (14.99%)	0.23%	0.63% (0.54%)
Yahoo	60.94%	38.03% (34.61%)	0.16%	0.86% (0.62%)

Table 10: Compositions of passwords that contain dates. The percentages outside parentheses are the ones counting both uppercase and lowercase letters, and the percentage inside parentheses are the ones counting only lowercase letters.

but most likely it is just two consecutive *123*. Thus, we selected 30 six-digit numbers that might cause such type of false positive [1]. Granted that we could have introduced false negatives or cannot manage to remove all the false positives for sure, these 30 numbers represent the patterns that have special meanings or are easy to remember, and most likely they do not map to any dates. For instance, '520520' has a similar sound as ' i love you i love you' in Chinese. Thus, we believe that eliminating them will increase the accuracy of our statistics.

Table 8 and Table 9 show the results. For example, the 29.24% in the first row in Table 8 means that among the 1,621,954 eight-digit numbers, 29.24% of them are in the format of *YYYYMMDD*. We can conclude that Chinese users prefer to use the format *YYYYMMDD* and *YYMMDD*. This conforms with Chinese conventions where people prefer to begin dates with years. On the contrary, a majority of English users prefer to end the date with years.

Password Composition. What are the compositions of passwords that contain dates? Are they composed of pure digits or mixed with letters? We calculated the percentages of digit-only, letter and digit, symbol and digit, letter and digit and symbol passwords out of all passwords that contain dates (both six-digit and eight-digit dates). As shown in Table 10, for all Chinese and English websites except Duduniu, most dates observed in our analysis are digit-only passwords, *i.e.*, when dates are used as passwords, they are used alone. What ranks the second is the passwords containing letters and digits. Note for Duduniu, the passwords that contain dates are more likely to contain both digits and letters than digits only. This could be because Duduniu is an e-commerce website and its users tend to choose a password with stronger strength, i.e., they tend to select passwords with both digits and letters, but not digits only.

[1]The 30 six-digit numbers are: *111111, 123123, 111000, 112233, 100200, 111222, 121212, 520520, 110110, 123000, 101010, 111333, 110120, 102030, 110119, 121314, 521125, 120120, 010203, 122333, 121121, 101101, 131211, 100100, 321123, 110112, 112211, 111112, 520521, 110111.*

	Beginning	Middle	End
CSDN	21.68%	4.32%	74.00%
Tianya	27.33%	4.75%	67.07%
Duduniu	24.76%	1.36%	73.88%
7k7k	32.17%	2.70%	65.13%
178.com	22.30%	1.03%	76.67%
RockYou	27.40%	3.91%	68.69%
Yahoo	22.66%	5.00%	72.34%

Table 11: Positions of dates. The percentages of passwords that contains dates at the beginning, the middle, or the end.

Date Position. To understand the position of dates in passwords, we analyzed those passwords that contain dates (digit-only passwords are not included).

We categorize the position of the dates as *beginning*, *middle*, and *end*, and summarize the results in Table 11. For both Chinese and English users, they prefer to have dates appear at the end of passwords and rarely place them in the middle.

2.3 Resistance to Guessing

Given the huge differences between Chinese and English passwords, a fundamental question is whether those differences lead to different levels of password strength. In this section, we examine password strength against password cracking.

2.3.1 Metrics to Measure Password Sets

We evaluated how resistant those passwords are against guessing by using the measurement metrics adopted by Bonneau [6][8], which are designed to evaluate the password strength in different regions.

As shown in Table 12, we briefly introduce these metrics: H_∞ is defined as *min-entropy*, a worst-case secu-

Metric	Formula	Term	Description
$H_\infty(\mathscr{X})$	$-\log_2(p_1)$		Worst-case security metric
$G(\mathscr{X})$	$\sum_{i=1}^{N} p_i \cdot i$	*guesswork*	The expected number of sequential guesses to find the password of an account if an attacker proceeds in optimal order
$\tilde{G}(\mathscr{X})$	$\log_2(2 \cdot G(\mathscr{X}) - 1)$		Bit representation of $G(\mathscr{X})$
$\mu_\alpha(\mathscr{X})$	$min\{j \in [1,N] \mid \sum_{i=1}^{j} p_i \geq \alpha\}$	α-*work-factor*	The expected number of guesses needed to succeed with probability α
$\tilde{\mu}_\alpha(\mathscr{X})$	$\log_2\left(\frac{\mu_\alpha(\mathscr{X})}{\lambda_{\mu_\alpha}}\right)$		Bit representation of $\mu_\alpha(\mathscr{X})$
$\lambda_\beta(\mathscr{X})$	$\sum_{i=1}^{\beta} p_i$	β-*success rate*	The probability that an attacker can correctly guess the password of an account given β guesses
$G_\alpha(\mathscr{X})$	$(1-\lambda_{\mu_\alpha}) \cdot \mu_\alpha + \sum_{i=1}^{\mu_\alpha} p_i \cdot i$	α-*guesswork*	The expected number of guesses per account to achieve a success rate α
$\tilde{G}_\alpha(\mathscr{X})$	$\log_2\left(\frac{2 \cdot G_\alpha(\mathscr{X})}{\lambda_{\mu_\alpha}} - 1\right) + \log_2\left(\frac{1}{2-\lambda_{\mu_\alpha}}\right)$		Bit representation of $\tilde{G}_\alpha(\mathscr{X})$

Table 12: Metrics [6][8] list used in our analysis. $\mathscr{X}$ refers to the probability distribution of passwords; N refers to the number of distinct passwords in a password set; p_i refers to the probability of the i-th password in $\mathscr{X}$ where $p_1 \geq p_2 \geq p_3 \geq \cdots \geq p_N$.

rity metric for human-chosen passwords, i.e., when a user chooses the mostly likely password. G is defined as *guesswork*, representing the expected number of sequential guesses to find a password of an account if an attacker proceeds in an optimal order, i.e., trying passwords in a descending order of the password probability. μ_α is called *marginal guesswork* or α-*work-factor*, which measures the expected number of guesses needed to succeed with probability α. *Marginal success rate* or β-*success rate*, λ_β, represents the probability that an attacker can correctly guess the password of an account given β guesses. G_α, the α-*guesswork*, reflects the expected number of guesses per account to achieve a success rate α.

To be more intuitive to programmers and cryptographers, we can convert these metrics into units of bits by taking the logarithmic value. We use a tilde over each letter to denote the values that are converted into bits: $\tilde{G}$, $\tilde{\mu}_\alpha$ and $\tilde{G}_\alpha$.

In this section, we follow the same assumption as proposed by Bonneau [6][8], *i.e.*, attackers know the exact distributions of the target password set and calculate the password strength, i.e., the attackers utilize the distribution of passwords to crack passwords in the same website. We call it *intra-site guessing*. In the next section, we relax the assumption, and we examine the guessing efficiency if the attackers are only aware of password distribution of other websites.

2.3.2 Resistance to Intra-Site Guessing

We summarize the calculated metrics for each website in Table 13 and Figure 3, and we draw the following observations:

- In Table 13, we observe that the β-*success-rates* (λ_5, λ_{10}) of `RockYou` and `Yahoo` are much lower than those of Chinese websites, i.e., given $\beta(e.g., 5, 10)$ guesses, the probability of guessing Chinese passwords correctly is higher. This phenomenon shows that Chinese websites have a lot of repeated passwords, but the $G_{0.25}$ and $G_{0.5}$ are similar (less than 3) between Chinese and English websites (except `178.com`). Thus, it may be easier to guess a small proportion of Chinese passwords, but for a majority of Chinese passwords, guessing them becomes as hard as guessing English ones.

- In Figure 3, the value of α-*work-factors* of `CSDN`, `Tianya` and `7k7k` are small if the expected success rate α is small, but it grows quickly with the increase of α. This phenomenon indicates that although part of Chinese users use the weak passwords that are easy to guess, a considerable number of users still carefully select passwords to protect their accounts. In addition, the users of `Duduniu` tend to choose better passwords. One possible explanation is that `Duduniu` involves monetary transaction and users tend to choose secure passwords.

	$\tilde{G}$	H_∞	λ_5	λ_{10}	$\tilde{G}_{0.25}$	$\tilde{G}_{0.5}$
CSDN	21.29	4.77	9.41%	10.44%	15.60	20.30
Tianya	21.49	4.55	7.15%	8.11%	14.67	19.11
Duduniu	22.55	6.02	2.74%	3.51%	18.94	21.59
7k7k	21.25	4.75	6.53%	7.61%	15.22	19.63
178.com	20.40	5.11	6.40%	8.74%	9.50	15.67
RockYou	22.65	6.81	1.71%	2.05%	15.88	19.80
Yahoo	18.03	8.05	0.78%	1.01%	16.31	17.68

Table 13: Resistance to guessing. H_∞ is the *min-entropy* for the most likely passwords. For $\tilde{G}$, H_∞, and $\tilde{G}_\alpha$, a larger value maps to stronger security. For λ_β, a smaller value indicates a lower possiblity of successful password cracking. Overall, the table shows that a small portion of Chinese passwords are repreaded and weak, but guessing a majority of Chinese passwords is as hard as guessing English ones.

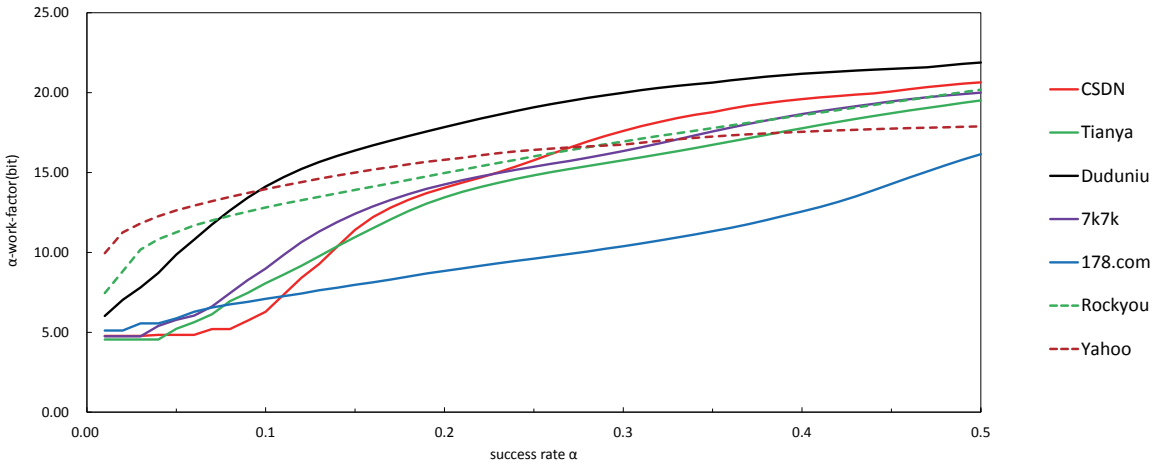

Figure 3: The expected number of guesses needed to succeed with a success rate α (α-work-factors, $\tilde{\mu}_\alpha$) of all seven websites. The dash lines represent English websites and solid lines map to Chinese websites.

3 Cross-Region Guessing

In this section, we would like to answer the following questions.

- Given that an attacker only has the password distribution of English websites, how well can she guess the passwords of Chinese websites?
- Given the knowledge of the differences between Chinese and English passwords, can an attacker improve the efficiency of guessing the passwords of Chinese websites?

The following two subsections answer these two questions.

3.1 Cross-Site Password Guessing

In this section, we examine how well an attacker can guess passwords from a website when she only possesses a password set of another website, and we call such scenarios as cross-site password guessing. This represents the situation when an attacker want to crack passwords of a website whose passwords have never been leaked. We modify the metrics that are modeled for the intra-website password guessing (listed in Table 12) to evaluate cross-site password guessing. We use two metrics, α-*work-factors* and β-*success-rates*, to evaluate the resistance to cross-site guessing. We denote these two metrics by adding a check symbol:

$$\check{\mu}_\alpha(\mathscr{X}) = min\{j \in [1, N_{other}] | \sum_{i=1}^{j} p_{(other)i} \geq \alpha\} \quad (1)$$

$$\check{\tilde{\mu}}_\alpha(\mathscr{X}) = \log_2\left(\frac{\check{\mu}_\alpha(\mathscr{X})}{\check{\lambda}_{\check{\mu}_\alpha}}\right) \quad (2)$$

$$\check{\lambda}_\beta(\mathscr{X}) = \sum_{i=1}^{\beta} p_{(other)i} \quad (3)$$

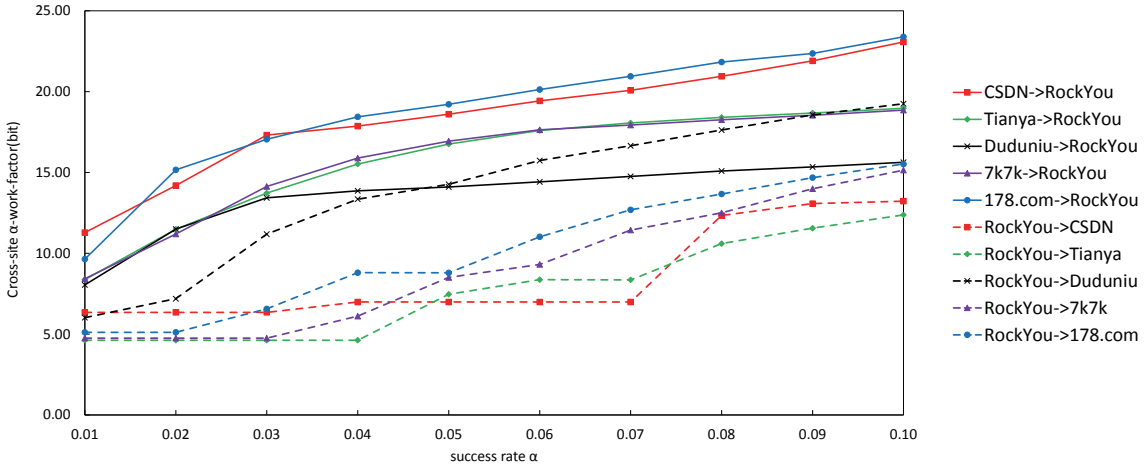

Figure 4: α-work-factors ($\tilde{\mu}_\alpha$) of cross-site guessing, i.e., the expected number of guesses needed to succeed with a success rate α. "X->Y" means using the X's optimal order to guess Y's passwords. For example, "CSDN->RockYou" means using the CSDN's optimal order to guess RockYou's passwords.

	Chinese Websites → RockYou		**RockYou → Chinese Websites**	
	$\check{\lambda}_5$	$\check{\lambda}_{10}$	$\check{\lambda}_5$	$\check{\lambda}_{10}$
CSDN	0.31%	0.35%	3.79%	7.11%
Tianya	1.24%	1.34%	4.78%	5.16%
Duduniu	1.18%	1.50%	2.11%	2.27%
7k7k	1.20%	1.28%	4.39%	4.66%
178.com	0.93%	1.00%	3.19%	3.33%

Table 14: β-success-rates of cross-site guessing. The data in columns 2 and 3 maps to the scenarios that we used each Chinese datesets to guess Rockyou passwords, and the data in columns 4 and 5 maps to the ones that we used Rockyou passwords to guess the ones of each Chinese website. These data shows that the cross-site guessing between Chinese and English users is hard.

In the above metrics, $p_{(other)i}$ refers to the probability of the other websites' i-th password in $\mathscr{X}$. For example, we utilize the CSDN's optimal password order to estimate the strength of Tianya's passwords, and $\mathscr{X}$ is the probability distribution of Tianya. In the CSDN's optimal order, "123456" is the first password. Given that in Tianya's passwords "123456" accounts for 0.52%, $p_{(CSDN)1}$ is 0.52%.

Using the methods mentioned above, we examine two scenarios: (1) given the passwords from the five Chinese websites as a prior knowledge, how well can we guess the passwords of RockYou; (2) given the passwords of RockYou, how well can we guess the passwords of the five Chinese websites. Note that we did not take Yahoo into consideration because of its small data size. The results of α-*work-factors* and β-*success-rates* of cross-site guessing are shown in Figure 4 and Table 14, where we can conclude that cross-site guessing is much harder than intra-site guessing (shown in Figure 3 and Table 13).

A lower β-*success-rates* means that the probability of correct guesses given β guesses are lower. In cases of using the information of Chinese passwords to guess the RockYou passwords, the β-success rates ($\check{\lambda}_5$ to $\check{\lambda}_{10}$) (listed in the 2nd and 3rd columns of Table 14) are lower than the intra-site guessing ones, i.e., $\lambda_5 = 1.71\%$ and $\lambda_{10} = 2.05\%$ for RockYou. In cases of using the information of the RockYou passwords to guess Chinese passwords, the β-success rates ($\check{\lambda}_5$ to $\check{\lambda}_{10}$) (listed in the 4th and 5th columns of Table 14) are also lower than the corresponding intra-site guessing listed in Table 13. A higher α-*work-factors* means that it takes a larger number of guesses to hit the right passwords. Compared with intra-site guessing (shown in Figure 3), for the same α value, the α-*work-factors* of the cross-site guessing (shown in Figure 4) is larger. Thus, cross-site guessing is harder.

Algorithm 1 Identify Keyboard Patterns

Input: S: a string
Output: the keyboard pattern of S

```
if S.length < 4 then
    return NO_PATTERN
end if
letters[] ← S.toCharArray()
samerow ← TRUE
zigzag ← TRUE
for i = 1; i < letters.length(); i++ do
    pos1 ← letters[i − 1]
    pos2 ← letters[i]
    if isAdjacent(pos1, pos2) then
        samerow ← samerow&isSamerow(pos1, pos2)
        zigzag ← zigzag&!isSamerow(pos1, pos2)
    else
        return NO_PATTERN
    end if
end for
if samerow then
    return SAME_ROW
end if
if zigzag then
    return ZIG_ZAG
end if
return SNAKE
```

Algorithm 2 Insert into the Trie

Input:
S: a string (a Chinese Pinyin or English word) that needs to be inserted into the Trie
Root: the root of the Trie

```
S ← S.toLowercase()
letters[] ← S.toCharArray()
node ← Root
for i = 0; i < letters.length(); i++ do
    pos ← letters[i] − 'a'
    node.child[pos].val ← letters[i]
    node ← node.child[pos]
end for
node.isValue ← TRUE
```

3.2 Guessing with Probabilistic Context-Free Grammar

The PCFG-based guessing method [35] increases the efficiency of password cracking process by trying passwords according to a decreasing order of password probability. The key of PCFG is to generate password rules (or structures). The rules can be constructed either from passwords themselves or word-mangling templates that can be filled in with dictionary words, for example. In our experiments, we built rules from three sources: (1) password sets, (2) dictionaries, and optionally (3) dates. We chose to use PCFG to examine whether the aforementioned rules are useful for guessing Chinese passwords, because it has been shown to be efficient in password guessing [21][24].

3.2.1 Methodology

We are interested in two questions: (1) How important are Pinyins and date formats for guessing Chinese passwords? (2) Given that an attacker is only aware of the English password distribution, can she synthesize a password distribution utilizing the differences that we have observed to improve the efficiency of cracking Chinese passwords?

To answer those questions, we created rules out of three types of sources for the PCFG-based guessing method: password training sets, dictionaries, and dates. For password training sets, we generated the following ones. Note that all training sets contain 2,000,000 passwords, respectively.

- **RockyouTS**: This training set contains passwords that are randomly chosen from `RockYou`. This represents a training set that only contains English password information.
- **MRockyouTS**: This training set also contains passwords from `RockYou`. However, the passwords are carefully selected so that its distribution follows the Chinese password distribution: 50% of the passwords are digit-only, and 10% are letter-only. This data set helps to examine whether the structure of passwords is enough to assist password guessing.
- **RockyouDuduTS**: Half of the passwords of this training set are randomly chosen from `Duduniu`, and the other half are randomly chosen from `RockYou`. This dataset helps to examine whether combined samples of Chinese and English passwords can assist password guessing.
- **DuduTS**: This training set contains passwords randomly chosen from `Duduniu` only. This represents the scenario that an attacker manages to obtain Chinese password sets.

In order to examine the effect of Pinyins in password guessing, we construct two dictionaries:

- **EDict**: This dictionary is a combination of the *Dic-0294* and *English-Lower*. *Dic-0294* is obtained

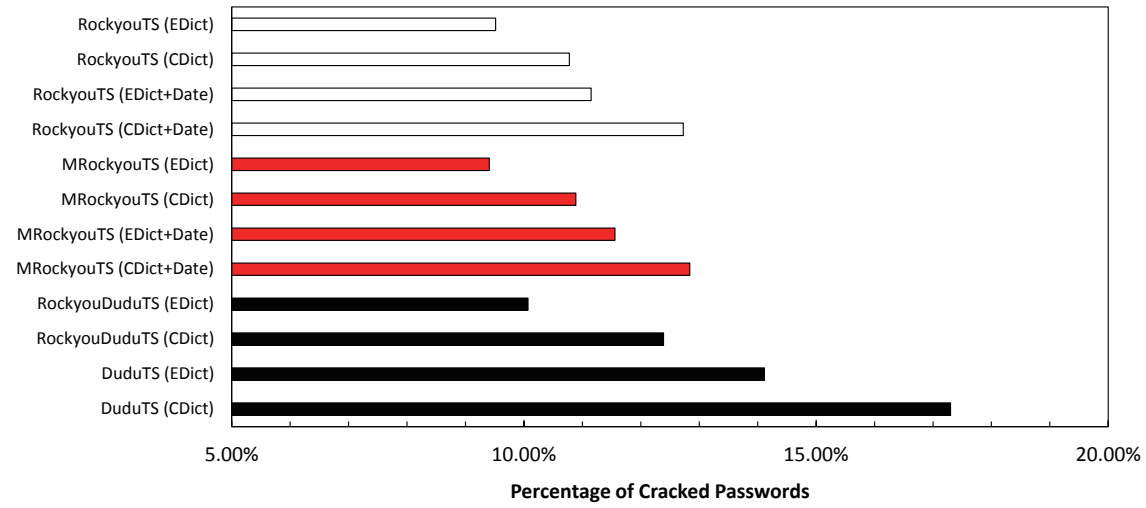

Figure 5: Passwords guessed within 10B guesses. Terminologies are explained in Section 3.2.1 in detail.

from a password guessing website [3] and *English-lower* is obtained from John the Ripper's public website [2]. *EDict* has 869,310 unique entries in total.

- **CDict**: To form this dictionary, in addition to *EDict*, we add 20,000 most frequently used Pinyins from the five Chinese websites. As a result, the size of *CDict* is larger than *EDict* by about 2.3%.

Besides Pinyins, dates also play an important role in password guessing. Since dates are digits, we modify the rules generated by the PCFG directly. We add 20,000 six-digit dates and 20,000 eight-digit dates that are most frequently used in the Chinese websites to the rules. These dates are assigned with the highest probabilities in the observed rules of six-digit numbers and eight-digit numbers, respectively. In total, these rules increase the number of six-digit and eight-digit rules by about 15% for *MRockyouTS* and about 31% for *RockyouTS*. We do not apply these rules to training sets *RockyouDuduTS* and *DuduTS*, because they already contain enough Chinese dates.

We used the above dictionaries and the modified rule set to guess the passwords of CSDN, and try 10 billion guesses per experiment.

3.2.2 Results of the PCFG based Guessing

As shown in Figure 5, the name of the training set is labeled on the left. In the parentheses, *EDict* and *CDict* represents which dictionary the guessing is based on and *Date* means that we added the dates to the rules generated by PCFG. According to Figure 5, we have the following conclusion.

- Chinese Pinyins and dates play an important role in guessing Chinese passwords. By adding 20,000 Pinyins into the dictionary, we managed to increase the percentage of password guessing. For *RockyouTS*, from *EDict* to *CDict*, the guessing efficiency increases by 13% and from *EDict+Date* to *CDict+Date*, the guessing efficiency increases by 14%.

  Furthermore, according to Section 2.2.3, more than half Chinese passwords are digit-only. For *RockyouTS*, the guessing efficiency increases by 17% after adding dates into *EDict* and it increases by 18% after adding dates into *CDict*. Last but not least, under the same dictionary, adding dates changes the percentage of guessed passwords of *RockyouTS* more than that of *RockyouDuduTS*.

- If we use the training set *RockyouTS* and *MRockyouTS*, the differences between the percentages of guessed passwords are small (less than 0.45% in all scenarios). This means that the distribution of password categories (e.g., letter-only, digit-only, etc.) does not play an important role in password guessing. It is the string patterns that make difference, since Chinese and English users prefer to use different patterns of digits and letters. Thus, using *RockyouDuduTS*, which consists both English password and Chinese password patterns can help the password guessing.

In total, from *EDict* to *CDict+Date*, we increase the guessing efficiency by 34% for *RockyouTS*. This guessing experiment imply that Pinyin and date's rules should be considered in password protection in websites. *E.g.*,

Algorithm 3 IdentifyComposition

Input:
S: a string that needs to match elements of Trie
Root: the root of the Trie

Output:
Whether the string S is composed of the element (s) in the Trie.

```
1: if S is NULL or S.length() is 0 then
2:    return FALSE
3: end if
4: letters[] ← S.toCharArray()
5: node ← Root
6: for i = 0; i < letters.length; i++ do
7:    pos ← letters[i]−'a'
8:    if node.child[pos] is NULL then
9:       if i is 0 then
10:         return FALSE
11:      end if
12:      if node.isValue is FALSE then
13:         return FALSE
14:      end if
15:      return IdentifyComposition(S.substring(i))
16:   else
17:      node ← node.child[pos]
18:      if IdentifyComposition(S.substring(i + 1)) is
         TRUE and node.isValue is TRUE then
19:         return TRUE
20:      end if
21:   end if
22: end for
23: return node.isValue
```

Web masters should tell Chinese users to reduce the usage of Pinyin or dates in composing their passwords.

4 Related Work

Although graphical passwords, biometrics and other alternatives to text-based passwords have been proposed, text-based passwords still predominate today's Internet due to its ease of implementation. A large body of research has shown the characteristics of user-created passwords [14][16][22][23][31][29][15].

Morris *et al.* [25] described the history of the design of the password security scheme and studied the password habits of 3,289 Unix users. Yan *et al.* [38] studied the password memorability and security. They found that users rarely choose passwords that are both hard to guess and easy to remember. Howe *et al.* [20] studied the behavior of home computer users because home computer users are more likely to suffer from various attacks, *e.g.*, phishing [36], dictionary attacks [27], heuristic password guessing [35], or brute force attacks. Florencio *et al.* [18] reported a large-scale study of Web passwords habits. The study involved half a million users over a three-month period. They found that on average, each user has 6.5 passwords and about 25 websites accounts. Kelly *et al.* [21] studied 12,000 actual passwords from several perspectives. They found that certain passwords policies which can improve the strength of user-created passwords are underestimated. In addition, a blacklist of weak passwords improves the security of passwords greatly. However, the aforementioned literature rarely mentioned the password difference between different regions, especially between Chinese and English users.

Bonneau [6] analyzed the language dependency of password guessing. The results show that among all `Yahoo` passwords, passwords created by Chinese are almost the hardest to guess. However, our experiments show that (1) the passwords of both English and Chinese users are similar in strength as shown in Figure 3 and Table 13; (2) if an attacker is aware of the fundamental differences between two languages (as pointed out in this paper), she or he can guess Chinese passwords efficiently. Moreover, our empirical study is based on two groups of websites: five Chinese websites, and two English websites, which represents a larger and more diverse corpus of passwords than `Yahoo` data set in Bonneau's work, and our corpus include passwords from users that only speak Chinese, unlike the Chinese users in Bonneau's work who should be familiar with English. Bonneau *et al*. [9] also investigated the lingering effects of character encoding on the password ecosystem based on password datasets from Chinese, English, Hebrew and Spanish speakers. Comparing with the results in [9], our large-scale empirical analysis in this paper also shows that the strength of the passwords of Chinese and English users is similar. Moreover, we firstly quantitatively measure how an attacker can leverage the lingering effects to crack more Chinese passwords.

In terms of measuring the strength of passwords, NIST standards [11] propose to use Shannon's entropy to estimate the strength of a single password. Unfortunately, this method does not work well. Bonneau [6][8] proposed a set of metrics to measure the strength of passwords. These metrics are independent of what the passwords are, but depend on the distribution of the passwords. We modify these metrics to estimate the strength of passwords across websites. In addition, Kelly *et al.* [21] used guess numbers to measure the strength of passwords.

Guessing passwords has attracted much attention. Narayanan *et al.* [26] discussed a password-guessing algorithm based on Markov model. In this model, guessing passwords is based on the frequency of each character. Weir *et al.* [35] proposed a PCFG based password guess-

ing method. The PCFG generates password structures in the highest probability order based on a training set of passwords. Then, it generates word-mangling rules and guesses passwords from these rules. This approach provides us with an opportunity to examine the differences between Chinese and English passwords. In addition, Veras *et al*. [34] employed Natural Language Processing techniques to understand the semantic patterns in passwords, then cracked more passwords than a state-of-the-art approach did.

5 Conclusion and Future Work

To the best of our knowledge, this paper is the first large-scale empirical study on Chinese Web passwords, leveraging a corpus of 100 million publicly available passwords. By comparing Chinese and English passwords, we find that Chinese users prefer digits in their passwords. Moreover, Pinyins and dates also appear often in their passwords. Leveraging these observations, we show that by adding rules and Pinyins into the dictionary for guessing passwords, we can improve the guessing efficiency of cracking Chinese passwords by 34%.

With an increasing number of password creation policies being enforced by websites, a direction for future study is to investigate the *status quo* of the password creation policies in Chinese websites and to study the impact of these policies on password statistics. Also, it is worthy exploring the semantic meanings of the Chinese passwords.

A Method to Remove the Copied Passwords in Tianya

`Tianya` and `7k7k` have an unusually large number of the same accounts (identified by email) with the same passwords. Since the statistic features of these duplicated accounts are different from the ones between any other websites, thus we suspected that the attackers have copied accounts from `Tianya` to `7k7k` or vice versa.

To investigate whether the accounts are copied from `Tianya` to `7k7k` or vice versa, we performed the following analysis. We first divided all accounts from `Tianya` and `7k7k` into two groups: One group contains the users who have the same accounts and passwords both at `Tianya` and `7k7k`, and the other contains the users who do not. We call the passwords of the two groups *reused passwords* and *not-reused passwords*.

After analyzing the compositions (e.g., digit-only passwords) of the *reused passwords* and *not-reused passwords*, we found that the proportions of various compositions are similar between the *reused passwords* and the `7k7k`'s *not-reused passwords*, but different with *Tianya*'s *not-reused passwords*. As a result, we believe that it is likely that accounts have been copied from `7k7k` to `Tianya` and we deleted the *reused passwords* from `Tianya`.

Password Portfolios and the Finite-Effort User: Sustainably Managing Large Numbers of Accounts*

Dinei Florêncio and Cormac Herley
Microsoft Research, Redmond, USA

Paul C. van Oorschot
Carleton University, Ottawa, Canada

Abstract. We explore how to manage a portfolio of passwords. We review why mandating exclusively strong passwords with no re-use gives users an impossible task as portfolio size grows. We find that approaches justified by loss-minimization alone, and those that ignore important attack vectors (e.g., vectors exploiting re-use), are amenable to analysis but unrealistic. In contrast, we propose, model and analyze portfolio management under a realistic attack suite, with an objective function costing both loss and user effort. Our findings directly challenge accepted wisdom and conventional advice. We find, for example, that a portfolio strategy ruling out weak passwords or password re-use is sub-optimal. We give an optimal solution for how to group accounts for re-use, and model-based principles for portfolio management.

1 Introduction

Due to the growth in online services, many users now manage dozens of password-protected accounts. Many service providers, awareness campaigns (US DHS [1]), and government entities (US-CERT [2]) stress two foundations for password security:

A1: Passwords should be random and strong; and

A2: Passwords should not be re-used across accounts.

Despite this, users have long been observed to choose weak passwords. Leaked datasets, such as the 32 million plaintext passwords from Rockyou, reveal that most users fall far short of following "traditional" advice on password strength. Evidence also indicates widespread password re-use [21]. While admonitions against this are almost universal, ignoring that advice seems equally universal. Clearly, users find managing a large password portfolio burdensome. Both password re-use, and choosing weak passwords, remain popular coping strategies.

Numerous efforts have been made to address the neglect of password strength by users. Many sites stress the importance of, and offer tips on how strong passwords can be made easier to construct and remember; e.g., US-CERT [2] and others commonly suggest passphrase-based and other mnemonic approaches. But while significant attention has been devoted to motivating and helping users choose strong individual passwords, there is little guidance on how to choose and manage large numbers of them. We aim to give, and justify, such guidance.

We explore how a large portfolio of passwords can be maintained without ignoring that users have limited abilities. Can password re-use be part of sensible portfolio management, or is it never justifiable? Is a unique strong password for every account, including blog sites and throw-away accounts, truly the best use of limited human memory resources? In practice, many users gather accounts into groups that re-use a password, but little guidance exists on choosing appropriate groups. Given that re-use does and will happen, we explore how to do so in a principled way, and answer these questions.

Our findings directly challenge some conventional wisdom. For example, we find: *strategies that rule out password re-use or the use of weak passwords are sub-optimal*. Both are valuable tools in balancing the allocation of effort between higher and lower value accounts.

We first review password-related demands on users, and consider users' options under the reasonable but too-rare assumption of *finite user effort*. This realism yields an inherent trade-off between two desired outcomes: greater password strength and avoiding re-use. Acknowledging fixed user effort budgets, more of one means less of the other.

We explore the implications of password re-use, and outline an optimal password-sharing strategy: for a fixed number of passwords and a given set of accounts, how to partition accounts to minimize total expected loss. Loss analysis is greatly complicated by cross-contamination issues due to password re-use. We address this by a novel

*USENIX Security 2014, August 20-22.

partitioning of attacks into three broad classes covering the major threat vectors, itself of independent interest.

2 Related Work

In 2000, Dhamija and Perrig [18] interviewed 30 participants reporting 1–7 unique passwords for 10–50 web sites. Circa 2001, Sasse and Brostoff [45] surveyed 144 employees reporting on average 16 passwords including non-online activity. A 2004 survey of 218 college students by Brown et al. [11] indicated on average 8.18 password accounts serviced by 4.45 unique passwords. In 2006 Gaw and Felten [24] surveyed 58 (mainly student) participants by online questionnaire with in-lab follow-up of 49, exploring how users manage online passwords, the extent of reuse and how users justify it, and the use of related passwords; they reported on average 13 passwords and found reuse increased over time—new accounts accumulated faster than new passwords. Riley's 2006 survey [44] of 315 college students (8.5 accounts on average) reported: 74.9% have a set of predetermined passwords they frequently re-use; 54.6% very frequently or always use a same password for multiple accounts; 33% use some variation of a same password for multiple accounts; and 60% do not vary the complexity of their passwords with the nature of a site. In a 2007 study of password use/re-use across three months by over a half million users, Florêncio and Herley [21] reported on average 25 accounts serviced by 6.5 unique passwords, re-used passwords used on average at 5.7 sites, and strong passwords re-used less.

Notoatmodo's 2007 thesis [42] explored password re-use and users' perspectives of their real-world passwords—and especially relevant to our work, how users mentally group both accounts and passwords into categories, relationships between account and password groups, and details of users' reasons both for, and for not, reusing passwords. The 26 participants surveyed had on average 12.9 accounts and 8.1 passwords; most reused passwords (132 of 336 accounts had unique passwords). Reuse was found again (see above) to increase with number of accounts. A hypothesis progressed was that users manage their accounts and passwords by mentally separating both into categories based on perceived account similarities and password similarities,[1] Regarding grouping accounts, and which accounts they felt were "high importance", most participants had only one high importance account group (1.54 such groups on average), and high importance groups were found to be smaller (fewer accounts per group: mean 1.84 vs. 2.78 for low importance groups). 45% reported reusing at least one password from a high importance group vs. 96% reusing at least one password from a low importance group; 70% had passwords exclusively used for an account in high importance groups (2.9 such passwords on average). In line with our views, Notoatmodo suggests *"reusing passwords on unimportant accounts which contain no sensitive information should not be discouraged ... Expecting users to create unique, strong passwords for all their accounts is ... unreasonable ... Instead, users should be educated to identify which accounts [not to] reuse passwords on."* While granting that password re-use is dangerous, Karp [36] also argues for re-use (*"human nature being what it is, not reusing passwords is equally dangerous"*) but in a different direction: by a password manager tool re-using a user password as a master password combined with details of a target site (e.g., site name) for site-specific passwords.

The "domino effect" of password re-use is well-documented (e.g., Ives et al. [32]; Gouda et al. [25]). The need for re-use is exacerbated by large numbers of passwords consuming user's memory capacity [3]. In scarce empirical work on implications of password re-use, Bonneau and Preibusch [9] analyze password implementations across 150 free websites, explaining technical means by which password re-use allows low-security sites—often unmotivated to spend effort or user experience securing passwords—to compromise high-security sites. The same authors [43] explore this question as a negative externality of password policies, finding a tragedy of the commons whereby sites with the lowest security needs can endanger those with the highest. Florêncio and Herley [22] find that the imposition of stringent password policies is better correlated with insulation from the consequences of poor usability than the need for greater security.

While the degree of password re-use naturally varies with the users studied, their circumstances and environment at a give time, evidence clearly shows it is widespread. The accuracy of self-reported re-use statistics is debatable, but a lower bound on re-use in real life is possible from leaked password databases from two different sites: from each database, recover a (userid, password) list, find userids common to both (e.g., re-used email addresses), then count password re-use instances. Das *et al.* [17] estimate that 43-51% of users re-use passwords across sites, and give algorithms that improve an attacker's ability to exploit this fact; this exceeds the 12-20% rate of some earlier studies noted above [24, 21]. Lemos [38] reports that intersection of the breached database pair (Yahoo Voices, Sony online) and (Sony online, Gawker) found usernames had re-used passwords across two sites 59% and two-thirds of the

[1] Examples of similarities for grouping passwords: "school stuff", email accounts, online banking, and semantic properties related to security (e.g., overall length, number of letters). Examples for account grouping: type of service related to the account (e.g., financial, education, communication), similar levels of risk or importance.

time in the two pairs. RockYou's leaked dataset [30] was explored by Bonneau [7, p.83] and Weir et al. [48]. Zhang et al. [49] easily predict new passwords from old when password aging policies force updates.

Over a 2011 two-week diary study of password use by Hayashi et al. [28], 20 participants reported 8.6 accounts on average, and to not use any memory aids for 60% of accounts; 19 of 20 said they reused passwords for multiple accounts. This may indicate under-estimating password re-use risk vs. writing passwords down. From a 2010 one-week diary-based study wherein 32 staff from two organizations produced just over 6 passwords each, Inglesant et al. [31] suggest that password polices be designed not to maximize password strength but rather to aid users in setting strengths appropriate to specific use contexts. Grawemeyer et al. [26] explore re-use among coping strategies in managing collections of passwords, in a detailed 2011 diary study of 22 participants over 7 days. In 2014, Stobert et al. [47] also explore user coping strategies for managing passwords, with guided interviews and questionnaires on 27 participants—noting as a user concern "rationing effort to best protect important accounts", and that "many participants [reported] having a specific password that they reused widely on accounts of low interest, low importance, or infrequent use".

The idea of grouping passwords, e.g., by level of importance, has seen little academic study, but Cheswick et al. [15, pp.140-141] suggested four categories: worthless, slightly important, quite secure, and top security. Cheswick more recently [13] suggests three classes: those that (a) have no importance; (b) are inconvenient if stolen; or (c) result in a major problem if abused. Five categories each are given by Grosse et al. [27] (based on account value) and Florêncio et al. [23] (based on consequence of compromise). Cheswick [14] also reviews common password guidance, and the ongoing suitability of circa-1985 U.S. government password guidelines. Florêncio and Herley suggest defender goals are well modelled by minimizing loss plus effort [20].

Nithyanand et al. [41] explore issues related to password re-use, under an attack model focused on server-side breakin (excluding phishing, client-side malware); seek solutions to maximize "remaining value" (i.e., minimize loss, vs. loss plus effort herein); show their password allocation problem is NP-complete; and find heuristic solutions to special cases (for accounts of equal value, with identical compromise probabilities, etc.).

3 The Difficulty of Managing a Portfolio

Issues related to complexities of human memory, encoding and recalling information (see [10]) currently preclude a satisfactory cognitive model or measure of the load passwords place on users. Nonetheless we begin with a naive model to highlight impossible-to-meet assumptions, and to position and motivate later discussion. We stress that *our later modeling* (Sections 4 onward) *abandons these assumptions and this naive model*, tackling a more realistic setting. We acknowledge that our equations in this Section, e.g., for the difficulty of associating passwords with accounts, give at best crude estimates. We emphasize also that this paper considers ordinary text passwords, not text or graphical variations using cues; we make no claims regarding such schemes.

An active web-user may have a hundred or more password-protected accounts. Ideally a user with N accounts chooses N strong passwords. If passwords were random collections of equi-probable characters, the difficulty of remembering them would be related to their length. Assume each such password is $\lg S$ bits. The effort required to manage the portfolio might naively appear to be $N \lg S$. But beyond remembering N passwords, users must remember which matches which account. We now explicitly consider this often overlooked sub-task.

3.1 Matching Passwords to Accounts

There are $N \cdot (N-1) \cdots 1 = N!$ possible mappings of N unique passwords to accounts; no encoding of this information uses less than $\lg(N!)$ bits, unless passwords contain clues as to which site they serve, violating A1 above. Thus the number of bits to be remembered to manage a portfolio of N passwords, each of $\lg S$ bits, is at least:

$$E(N) = N \cdot \lg S + \lg(N!). \tag{1}$$

(As noted above, this approximation fails to address the complexities of human cognition, but suffices for the argument below.) Clearly this grows rapidly with N, the second term super-linearly by Stirling's approximation ($\ln N! \approx N \ln N - N$). Consider a conscientious user, with $N = 100$ accounts. Choosing unique random passwords of 40 bits for each account rewards him with the obligation to remember $100 \times 40 + \lg(100!) = 4525$ bits (equivalent to 1362 random digits or 170 random 8-digit PINs). This burden far exceeds what users can manage by memorization (*i.e.*, without other aids); for most it is insupportable. How can users reduce it? An obvious shortcut, with significant side effect, is to choose weaker (less random) passwords; the linear dependence on $\lg S$ suggests reducing strength as much as possible.

While using weaker passwords clearly reduces the first term of (1), no matter how weak N distinct passwords are, the second term is unaffected. Considering that term alone, $N = 100$ yields $\lg(N!) = 525$. This is double the $\lg(52!) = 226$ bits required to memorize the order of a shuffled card deck, and equivalent to remembering 158 random digits—random since as noted, no encoding of an $N \times N$ assignment takes fewer than $\lg(N!)$ bits. Thus,

the assignment burden alone, including the problem of *password interference* [16], is evidently beyond a reasonable expectation of users.

So the two staples A1, A2 of password advice appear impossible to meet individually, let alone simultaneously. How do users proceed? They "cheat" on A1 by choosing passwords far weaker than advised. But this isn't enough—no matter how weak the passwords, a user must still remember $\lg(N!)$ random bits for password assignment. A further coping strategy is needed.

3.2 Password Re-use as a Coping Strategy

Consider next a user with N accounts using $G \leq N$ passwords to cover them. Assume for now each password is used at $n = N/G$ accounts, that the password-to-group assignment is random and (for simplicity) that G divides N. The burden of remembering passwords drops to $G \cdot \lg S$ bits. What of the further burden of remembering which password goes where? The G groups of accounts each have $n = N/G$ elements. There are C_n^N possible combinations for the first group, C_n^{N-n} for the second, etc., so the number of possible assignments of N accounts to G equal-sized groups is:

$$\left(\begin{array}{c} N \\ n \end{array}\right) \cdot \left(\begin{array}{c} N-n \\ n \end{array}\right) \cdots \left(\begin{array}{c} n \\ n \end{array}\right) = \frac{N!}{(n!)^G}.$$

Thus the user effort (memory burden in bits) drops to:

$$\begin{aligned} E_G(N) &= G\lg S + \lg(N!) - G \cdot \lg(n!) \qquad (2) \\ &\approx G\lg S + N\lg G \end{aligned}$$

the last line following by Stirling's approximation again.

Now compare the burden of managing a portfolio with and without password re-use. For example, even if $\lg S$ is as low as 20, from (2), the burden of managing 100 accounts with 10 passwords is $E_{10}(100) = 506$ bits, while from (1) the burden of doing so with 100 is $E(100) = 2525$ bits. Thus, in this instance, password re-use reduces the memorization burden by a factor of five.

3.3 Tradeoff: Re-use & Password Strength

What other solutions use the same effort? A portfolio of N passwords can be managed in many ways. If $E_G(N)$ is fixed then $\lg S \approx (E_G(N) - N\lg G)/G$. So, $\lg S$ falls faster than $1/G$: doubling the number of passwords more than halves the number of bits per password. So, if $G = N$ (no password re-use), then $\lg S$ must be small.

Fig.1 shows the locus of solutions in the G-$\lg S$ plane when $N = 100$ and the budget is $E_G(100) = 400, 550$ and 700 bits. This reveals the essential tradeoff: less re-use (*i.e.*, increasing G) implies weaker passwords. For example, at fixed effort $E_G(N) = 400$, two possible operating points are $(G = 4, \lg S = 52.5)$ and $(G = 5, \lg S = 36.2)$. At fixed effort, the question is not whether achieving password strength and avoiding re-use are good, but how these relative goods are best traded off. Deciding, e.g., between these two operating points depends on whether reducing password re-use (by increasing G from 4 to 5) reduces the risk of harm by more or less than reducing password strength (from 52.5 to 36.2 bits). The rapid decline of $\lg S$ in Fig.1 as G increases suggests that, far from being unallowable, password re-use is a necessary and sensible tool in managing a portfolio. Re-use appears unavoidable if $\lg S$ must remain above some minimum (and effort below some maximum). Fig.1 further suggests that G should be small: high values of G seem to imply very low values of $\lg S$. This enormous saving in user effort that password re-use provides may explain its ongoing prevalence in practice [24, 19, 21, 45].

Note on entropy: caution is needed to avoid historical pitfalls such as assuming particular ranges for $\lg S$ based on metrics appropriate only for *random* passwords, or misleading rules-of-thumb on what is necessary to withstand attack. We intend $\lg S$ to represent user effort to remember a password, not attacker guessing difficulty; the two may be correlated but should not be used in place of each other. For example, if a user has 7 unique passwords, and each names a major Hawaiian island, then $\lg S = \lg 7 \approx 2.8$ bits. But this offers little guide on how hard these passwords are to guess. It is also well understood [48, 8, 37, 39] that $t \cdot \lg C$ and NIST's crude password entropy estimate [12], significantly overestimate the difficulty of guessing *user-chosen* length-t passwords from C-character alphabets. Equally, such metrics must not be mis-used to estimate users' capabilities or effort, lest we drastically over-estimate what a reasonable cognitive burden is.

4 Objective Function: Loss + Effort

Suppose a user has N password-protected accounts. Advice such as A1, A2 implicitly assume the goal is to minimize loss. Let P_i be the probability of compromise in a given period (e.g., per year, under the current password management strategy), and L_i the loss endured upon such compromise. We intend that P_i capture the probability that an attacker gains the means to access account i, whether or not that means is used or results in loss. We intend L_i to capture the *expected value* of the consequences of account compromise (regardless of attack vector), including direct losses and any indirect costs involved in remediation. The total expected loss is

$$L = \sum_{i=1}^{N} P_i \cdot L_i. \qquad (3)$$

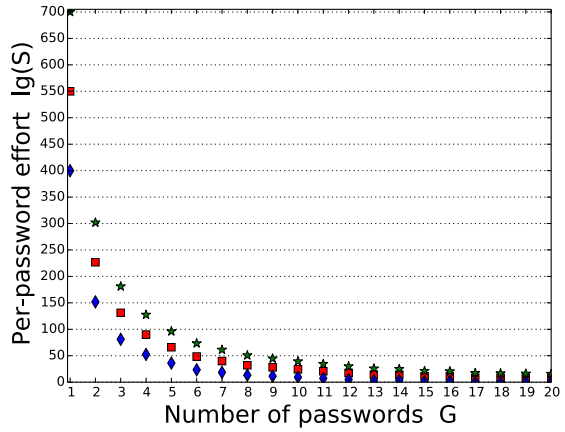

Figure 1: Locus of achievable solutions trading off re-use and password strength for fixed effort $E_G(N) = 400,550,700$ in (2) at $N = 100$. Note that when effort is kept constant, lower levels of re-use are only achieved by having weaker passwords.

A major complication we will find—and defer to Section 5—is that some attacks affect more than one account; e.g., malware and system attacks affect all accounts, and if passwords are re-used then an attack against one account can affect many others. But for now, suppose that attacks are only against individual accounts. Then the P_i depend on effort E_i devoted to account i but not to E_j. The probability of compromise $P_i = P_i(E_i)$ is presumably monotonically non-increasing with effort. Investing more effort generally reduces P_i; a stronger password reduces the risk that it falls to password-guessing attacks.

If aiming to minimize expected loss L, the solution occurs when L has derivative zero with respect to $E = \sum_i E_i$, which from (3) gives the system of equations

$$\frac{dP_i}{dE_i} = 0 \quad \text{for} \quad i = 1,2,3,\cdots,N. \tag{4}$$

The solution is trivial: the optimum is achieved when further effort can't reduce the probability of loss for any of the N accounts. Thus to minimize L, we should increase each E_i until no further reduction is possible (further effort does not affect P_i). If $P_i(E_i)$ is monotonically decreasing—so further effort always reduces P_i—then expected loss is minimized at infinite effort. Thus *the lack of a constraint on effort leads to an unrealistic solution.* Note also that users gravitate toward a solution very different from this effort-maximizing one. From this we infer: *the objective function users minimize is not merely expected loss*—if it were they'd always invest effort that could reduce loss and always follow A1, A2.

This optimization has an obvious flaw: minimizing L implicitly values user effort at zero. Users presumably care about loss due to account compromise, *but they also factor in the effort they must spend to reduce that loss.* They may be willing to spend effort to reduce loss, but at some point there are diminishing returns; and it is wasteful to continue after the cost of further effort exceeds expected reduction in loss. Thus, rather than an unconstrained optimization [29] ignoring reluctance to increase effort, we should solve a constrained problem explicitly including cost of user effort.

One way to incorporate a constraint is to minimize loss subject to a bound—e.g., say $\sum E_i < E_{max}$ to model users with an upper limit on the effort they are willing to exert. This is reminiscent of the compliance budget [5, 4]; it can be achieved with Lagrangian multipliers. A more general approach, which we follow, is to minimize not the expected loss, but the sum of effort plus loss, $L+E$. As a precedent for this approach, economics Nobel laureate Becker notes [6] that attempts to minimize crime lead to perverse results, and it is preferable to minimize the costs of crime plus the costs of detecting, prosecuting and punishing it. For example, it makes little sense to spend $1 more on policing effort if that reduces the effects of crime by less than $1.

To illustrate the importance of the objective function we revisit the question of finding optimum allocation of effort[2] when $dP_i/dE_j = 0, i \neq j$ (*i.e.*, no cross-account attacks). The optimum occurs when the derivative (with respect to E) of objective function $L+E$ is 0: $dL/dE + 1 = 0$. Using (3) to substitute for L gives the system

$$L_i \cdot \frac{dP_i}{dE_i} = -1 \quad \text{for } i = 1,2,3,\cdots,N. \tag{5}$$

Thus, at optimum effort allocation,[3] the marginal return on effort to reduce P_j is a factor L_i/L_j higher than that to reduce P_i :

$$\frac{dP_j}{dE_j} = \frac{L_i}{L_j} \cdot \frac{dP_i}{dE_i}. \tag{6}$$

If the loss for the most important account is, say, 10^4 times that for the least important ($L_1 = 10^4 L_N$) then the marginal return on effort should differ by that factor. Thus, *effort should not be spent equally on all accounts*.

While we are unlikely to find an exact form for how the probability of harm varies with effort, using a parametric form can help illustrate the relations. Basing an example on Shamir's quote "to halve your vulnerability you have to double your expenditure" [46], we examine what happens when there is a reciprocal relation between them, *i.e.*, $P_i(E_i) \propto 1/E_i$. This gives $dP(E_i)/dE_i \propto -1/E_i^2$. Substituting into (6) indicates how the relative effort for two accounts should depend on the relative losses:

$$E_j = \sqrt{\frac{L_j}{L_i}} \cdot E_i.$$

[2] This includes max cumulative effort and where/how to allocate it.
[3] This is also true at other points, though not proven here.

So if two accounts differ in value by factor 10^4, ideally the effort expended would differ by a factor 100. We reiterate: this analysis, as it depends on the parametric form for $P_i(E_i)$, is for illustrative purposes only.

Now contrast this solution minimizing $L+E$, with that found by minimizing L alone (system (4) above). First, if minimizing L, all passwords should be as strong as possible, meaning that (at the optimum) no additional effort can reduce the risk for any account. When minimizing $L+E$ this isn't the case: (5) says that (at the optimum) additional effort may still reduce risk for every account, but it is sub-optimal to spend it. Second, when minimizing L, the optimum protection given to an account is independent of L_i. When minimizing $L+E$ some accounts should be (possibly far) less protected than others: (5) shows that the rate of return on effort should be *inversely related to the account value*.

Thus, using objective function $L+E$ (not L) makes an enormous difference in solutions. We posit that much of the advice directed at users aims to minimize L only, and is ignored as users implicitly care about E also and have found operating points attempting to minimize *their* objective function; these points may or may not be optimal, but have been arrived at by *ad hoc* methods. We note that in minimizing $L+E$ we neglect the non-linear response to probabilities predicted by Prospect Theory [35]. We believe that the rational model which offers (Kahneman [34]) "great precision in some situations and good approximation in many others" is the most realistic one that we can currently make progress on, and significantly advances a model that neglects E. Finally, use of the term *portfolio* is not accidental. Since 1952 [40] it has been recognized that managing a portfolio of equities raises issues drastically different from managing individual securities. In an analogous situation for passwords, due to cross-account attacks, the security of accounts cannot be considered in isolation, yet the literature has given little attention to the portfolio problem.

5 Modeling Loss, Effort, Attack Classes

While (5) offers to guide effort allocation when minimizing $L+E$, it assumed $dP_i/dE_j = 0$ for $i \neq j$; we postponed issues of cross-account attacks. This might be reasonable if guessing were the only attack and account passwords were unique; the probability P_i of compromise of account i would then depend only on how passwords withstood attack. But that over-simplifies. With password re-use, compromise of one account can leak to others, and client-side malware affects all accounts. Such attack vectors are too important to ignore. P_i depends on effort not just devoted to account i but also, e.g., to address client malware or avoid phishing, and the security of other sites the password is re-used on.

If we can't assume partial derivatives of zero, then on minimizing $L+E$, instead of (5) we get the system

$$\sum_{i=1}^{N} \frac{\partial P_i}{\partial E_j} \cdot L_i = -1 \quad \text{for } j = 1,2,3,\cdots,N. \qquad (7)$$

This is not simply a linear system. The N unknowns E_j, specified implicitly by the constraint on N^2 partial derivatives, relate non-linearly to the L_i. The intuition of (5) is now lost. A simple interpretation (e.g., marginal return on effort should be inversely related to loss) is no longer discernible, as instead of appearing singly, the partial derivatives are now constrained by a sum.

Note that if we minimize L instead of $L+E$ we get a system similar to (7), but with zero on the right side. Since losses must be non-negative and the partial derivatives are non-positive, the solution is achieved by setting $\partial P_i/\partial E_j = 0$ for all i, j. This would again indicate optimality occurs when no further effort can reduce any of the loss probabilities. Thus, the fully general system is tractable if we use the wrong objective function. Alternatively, a simplified system (*i.e.*, assuming $\partial P_i/\partial E_j = 0$ for $i \neq j$) is tractable using a realistic objective function. However, the general system using the realistic objective function is challenging. Our way forward is to re-structure the problem to isolate types of attack affected by different types of effort. By including the major attack vectors, the model is necessarily more complicated than that yielding (5), but will allow insight on how to manage a portfolio when minimizing $L+E$.

5.1 Attack Classes and Attack Vectors

We partition attacks into three classes:

- **Class I attacks (*FULL*)**: these compromise all password-protected accounts of a user. They involve general attack vectors targeting the client machine. Upon success, the attacker acquires actual passwords. Example: client-side malware (e.g., persistent keyloggers), which we assume provides attacker access to all of a user's passwords.

- **Class II attacks (*GROUP*):** these compromise all of a user's accounts protected by the same shared ("group") password, with the attacker obtaining that password; this includes singleton groups. Examples: phishing, brute-force and other guessing, shoulder-surfing, server break-ins to obtain password files, network channel compromise. We assume the attacker will try appropriate credentials with this password on all relevant sites (a finite number), determining associated account userids from public information or otherwise, and gain access to all accounts that use this password. Com-

	Class I (Full, direct)	Class II (Group, direct)	Class III (Single, indirect)
Attack Vectors	Client-side malware (keyloggers, *etc.*)	Phishing, password guessing, shoulder-surfing, system-side database compromise, network channel compromise	Session hijacking, cross-site scripting, password reset mechanisms
Effort elements addressing attack	Run AV, disable unused apps/interfaces, run up-to-date software (apply patches), avoid suspicious links, don't click on email attachments	Choose strong passwords, don't re-use passwords, change passwords often, don't write down, avoid phishing sites	*little advice*

Table 1: Attack classes for password-protected accounts, attack vectors, and relevant user effort elements (defensive actions).

promising one account thus may imply losses in all same-password accounts of the user.

- **Class III attacks (*SINGLE*):** these compromise only a target account, without obtaining the actual password.[4] Example attack vectors: cookie stealing, single-session hijacking (e.g., by cross-site request forgery), exploiting password reset vectors (but not those that mail-back original passwords). The attacker may gain account access, but cannot leverage this to access other accounts, even same-password accounts.

While this classification is still a simplification—e.g., some passwords are easily derived from related passwords [49]—it allows us to model cross-contamination. To handle the case where passwords are modified-and-shared rather than simply shared between groups, as observed by Das etal [17], would require an adjustment to this model (e.g. by modifying Class II). Table 1 synopsizes the attack classes, their principal vectors and user effort that addresses them. Note that the user effort related to passwords (*e.g.*, strength, avoiding re-use, avoiding phishing sites) is concentrated in Class II. Class I deals with system-wide attacks. Class III deals with attacks affecting only a single account, not others sharing the same password.

The probability of individual account compromise can now be split as:

$$P_i \approx P^I + P_i^{II} + P_i^{III} \tag{8}$$

where superscripts denote attack class. Here, and throughout the paper, the compromise probabilities are assumed small enough that the well-known approximation $(1-\prod_i(1-P_i)) \approx \sum_i P_i$ can be used. For Class I we omit the subscript from attack probability P^I, since it has the same value for all accounts. Now, if a user has $G \leq N$ unique passwords, sharing password w_j across a set $\mathscr{A}_J$ of accounts, the expected loss becomes:

$$\begin{aligned} L &= P^I \sum_{i=1}^{N} L_i + \sum_{J=1}^{G} \Big(\sum_{i\in\mathscr{A}_J} P_i^{II} \Big) \Big(\sum_{i\in\mathscr{A}_J} L_i \Big) + \sum_{i=1}^{N} P_i^{III} L_i \\ &= P^I \sum_{i=1}^{N} L_i + \sum_{J=1}^{G} P_J \cdot L_J + \sum_{i=1}^{N} P_i^{III} L_i. \end{aligned} \tag{9}$$

To distinguish, e.g., account i from password-sharing group J, we abuse notation with upper-case indices; and similarly subscripts to denote sums over groups, so

$$L_J = \sum_{i\in\mathscr{A}_J} L_i \quad \text{and} \quad P_J = P_J^{II} = \sum_{i\in\mathscr{A}_J} P_i^{II}, \tag{10}$$

dropping P_J^{II}'s superscript as this is for Class II only.

The three terms on the right side of (9) match the three attack classes. The first term is the probability of a Class I attack, weighted by the entire portfolio value. The second term is the sum across the G password-sharing groups, each weighted by the value of the accounts in that group. This highlights the drawback of password re-use: a compromise is not isolated to one account, but spreads to others. The third term is the sum of probability of individual account compromise weighted by the account value.

5.2 Modeling Effort Allocation and Effectiveness

To minimize an objective function that includes both loss and effort, both must be mapped to the same dimension. For simplicity, we assign a monetary value E for the time and effort—a mapping that is naturally user-dependent. The cost of this management has different components; preventing different attacks often requires different mechanisms. Thus again, this is split based on the class of attack the effort addresses:

$$\begin{aligned} E &= E^I + E^{II} + E^{III} \\ &= E^I + \sum_{J=1}^{G} E_J^{II} + \sum_{i=1}^{N} E_i^{III}. \end{aligned} \tag{11}$$

Under the assumption that effort is applied independently across classes, from (11) we also have: $\partial E/\partial E^I =$

[4] In the case of password resets mentioned next, the attack may recover a new temporary reset password, but not the original password possibly shared across other accounts.

$\partial E/\partial E^{II} = \partial E/\partial E^{III} = 1$. E^I is the cost of defensive effort related to Class I attacks—including, e.g., the total cost and time/effort associated with purchasing/running anti-virus software, and all effort related to keeping a computer malware-free. E^{II}_J is the cost of effort involved in combating Class II attacks on a group that share the same password (brute force, social engineering, etc.). Clearly, $E_G(N)$ given in (2), the cost of managing the password portfolio, is a portion of E^{II}. However, E^{II} also includes effort devoted to other Class II attacks, such as phishing [33]. E^{III} relates to account-specific efforts, which may include, e.g., managing one-time passwords or second-factor authentication devices.

Assuming the three types of efforts can be controlled independently, objective $L+E$ is minimized when

$$\frac{\partial(L+E)}{\partial E^I} = \frac{\partial(L+E)}{\partial E^{II}} = \frac{\partial(L+E)}{\partial E^{III}} = 0 \qquad (12)$$

which simplifies to:

$$\frac{\partial L}{\partial E^I} = \frac{\partial L}{\partial E^{II}} = \frac{\partial L}{\partial E^{III}} = -1. \qquad (13)$$

Substituting our expression for loss (9) into each of these three equalities, the parade of equations concludes with:

$$\left(\sum_{i=1}^{N} L_i\right) \frac{\partial P^I}{\partial E^I} = -1 \qquad (14)$$

$$L_J \cdot \frac{\partial P_J}{\partial E_J} = -1, J = 1 \cdots G \qquad (15)$$

$$L_i \cdot \frac{\partial P^{III}_i}{\partial E^{III}_i} = -1, i = 1 \cdots N. \qquad (16)$$

Note that we have used the fact that the effort devoted to group J does not affect either the probability of loss for group K (*i.e.*, $\partial P^{II}_K/\partial E^{II}_J = 0$ when $K \neq J$) or the effort devoted there (*i.e.*, $\partial E^{II}_K/\partial E^{II}_J = 0$ for $K \neq J$).

5.3 Implications of the Model

Equations (14)-(16) help formalize the concept of optimization of defensive investment (i.e., effort) related to expected loss. We briefly discuss each further.

Class I equation. Eqn (14) relates to Class I attacks, e.g., client-end malware like keyloggers. It isolates the cost of avoiding such attacks from efforts directly related to password management. The sum over all L_i reflects the definition: Class I attacks compromise *all* of a user's passwords—thus the loss may be quite large, especially if the sum strongly dominates individual L_i values. The absence of individual P_i in (14) reflects that defensive effort (cost) related to reducing likelihood of Class I losses is unrelated to costs associated with managing individual passwords. This is notable as current password advice to end-users *is* predominantly related to managing individual passwords (e.g., choosing stronger, more complex passwords, not re-using across accounts), none of which is related to (14).

Common advice related to (14) includes (see Table 1): keeping software up-to-date with patches; using AV (anti-virus) protection; disabling unused applications and interfaces; "hardening" the platform OS.

Regarding overall investment in client-end protection, (14) informs us that effort expended defending Class I attacks should be driven by: (i) the total value of all accounts the user accesses from the client device—the larger this value, the more worthwhile even small defensive efforts which reduce the probability of losses; and (ii) the degree to which incremental defensive effort reduces the probability of Class I attacks. Note that, counter-intuitively, the effort optimally expended is *not* driven by the absolute probability of Class I attacks—since effort spent doesn't necessarily reduce the probability of successful attack, even if P_i is large.

Class II equation. Note that (15) is a set of equations, one for each password-sharing group J. L_J accumulates losses over the accounts sharing a password, based on the assumption that once a password is compromised, all accounts sharing it may suffer. P_J sum probabilities over all accounts in the group, for a similar reason.

Regarding overall investment in defenses against Class II attacks, (15) informs us that the allocation of such effort should be driven by the following, considered now *for each group:* (i) the total value of all accounts in the shared-password group—the larger this value, the more worthwhile defensive efforts which reduce the P_J; and (ii) the cumulative sum, across all groups accounts, of the degree to which incremental defensive effort reduces the probability of Class II attacks. As above for Class I, the optimal effort expended is *not* driven by the absolute probability of Class II attacks; the same is true for (16) and Class III.

The similarity between (15) and (5) should be obvious: we again have a constraint involving a single partial derivative. A few conclusions can be drawn that mirror those drawn about the simpler model in Section 4. First, all passwords should *not* be equally strong (that would be wasteful, allocating excessive effort to low-value account groups at the expense of high-value ones). Second, the rate of change of P_J with respect to effort should be inversely proportional to L_J. This means that (unless a user has excess capacity of effort they wish to spend, and no higher-value groups to spend it on) groups with $L_J \approx 0$ *should* be very exposed and *should* have weak passwords, since as $1/L_J \to \infty$, they should be at the point where $\partial P_J/\partial E_J$ is extremely high; thus even tiny invested effort would reduce P_J significantly, but spending effort there would be wasteful as we care not about

P_J but $P_J \cdot L_J$. Effort is better spent on an account group with high L_J (even if $\partial P_J/\partial E_J$ is very low). It makes no sense to invest at all on accounts where $L_J = 0$, so long as any other account has $L_J > 0$.

Toy example. To illustrate (15), suppose two bank accounts sharing a common password have loss values 10 and 12. Assume that the first account is phished, and thereafter an attacker tries the same password with appropriate obtained userid on all banks. Assume further that additional effort $\delta E = 3$ units (e.g., a stronger group password) reduces individual account compromise probabilities from 0.1 to 0.09 (first account) and from 0.05 to 0.03 (second). Then the initial expected loss (see (9)) of $(10+12)(0.1+0.05) = 3.3$ is reduced, by extra effort, to $(10+12)(0.09+0.03) = 2.64$. Thus extra effort of 3 units reduced loss by only 0.66. This can also be observed by looking at the differences (or derivatives, as in (15)); the change is $(10+12)(-0.01/3 - 0.02/3) = -0.22$. And, in this example, as -0.22 is less negative than -1, we have higher investment than optimal—the cost of effort invested exceeds the reduction in loss it provides. The equations thus confirm our expectations, despite the "units of measure" carrying little meaning.

Class III equation. Finally, (16) reminds us that, regardless of password policies, we must keep in mind and beware reset mechanisms and alternative access paths. Class III attacks involve only a single account and are unrelated to group sharing of passwords, being unrelated to the actual choice of passwords. As noted in Table 1, users get little advice related to Class III attacks (and hence $\partial P_i^{III}/\partial E_i^{III} \approx 0$). In the sequel, (16) is discussed little, as risks associated with these attacks are largely impervious to user effort, our present focus. Regarding overall effort defending Class III attacks, (16) tells us that, considering now *each account individually,* the allocation of such effort should depend on: (i) the account value; and (ii) the degree to which new effort reduces the probability of Class III attacks on it.

6 Account Grouping for Password Re-use

We saw in Section 3 that, without additional coping mechanisms, re-use is unavoidable for large N. We now show that it can help, even for smaller portfolios. Since we seek to minimize L+E there are two components to consider: changes in effort, and in expected loss. For loss, we need consider only Class II attacks, as Class I and III attacks are unaffected by re-use.

Consider the case of three accounts, two relatively low-value (L_1, L_2), one high-value (L_3) so $L_3/(L_1 + L_2) = m >> 1$. For simplicity assume further $P_1^{II} \approx P_2^{II}$ (we will drop superscripts II, as only Class II attacks are relevant). Now compare Case A (using three unique passwords) vs. Case B (re-use one password across low-value accounts, with unique password for high-value). For Case A, expected Class II losses are: $P_1L_1 + P_2L_2 + P_3L_3$. For Case B, re-use increases the expected loss over the first two accounts by $\Delta L = (P_1+P_2)(L_1+L_2) - (P_1L_1 + P_2L_2)$; as $P_1 = P_2$ now, this is $P_1L_2 + P_2L_1 = P_1(L_1+L_2) > 0$, but the user manages one fewer password. Assume the saved effort ΔE is used to strengthen the high-value password[5] reducing the expected loss related to the third account from P_3L_3 to $(P_3(1-e))L_3$ where $0 < e < 1$. So Case B is preferable (has lower expected loss) provided the increase ΔL in expected loss over the first two accounts is less than the expected decrease on the third, i.e., provided: $P_1(L_1+L_2) < eP_3L_3$, or equivalently,

$$m > P_1/(eP_3) \tag{17}$$

We expect (17) often holds—e.g., if $m = 50$ (a financial account with value 100 times that of a free or low-value subscription site) and $P_1 \approx P_3$, then (17) is true for $e > 1/50 = .02$, i.e., a 2% or greater reduction in probability of loss due to a strengthened password. The right side of (17) becomes even smaller if $P_3 > P_1$, and if $P_3 < P_1$ then (17) still holds for a correspondingly larger e. Thus certainly, re-use can be beneficial.

Of course, guessing is but one possible Class II attack; some others also increase the consequences of re-use. The risks of some, like phishing, can be reduced by the user, while that of others, like server-side attacks, are largely impervious to user effort (see 7.3).

6.1 Share among Accounts of Similar P/L

We now explore how to re-use passwords "properly". Based on the loss model, we give an optimal password re-use strategy in the following sense: for a fixed number of passwords, and a given set of accounts (thus effort is fixed), find how to group accounts to minimize total expected loss.

As before, assume a user splits N accounts into G groups each sharing a unique password. Per the second term on the right of (9), the total Class II loss is:

$$L^{II} = \sum_{J=1}^{G} (\sum_{i \in \mathscr{A}_J} P_i^{II})(\sum_{i \in \mathscr{A}_J} L_i) \tag{18}$$

Is there an optimal way to partition this set of accounts into shared-password groups $\mathscr{A}_J$?

We first address the case of adding a new account to an existing portfolio; i.e., we have G groups and must decide to which group a new account is best added. From (18), adding a new account with (P_i, L_i) to group J, the incremental loss is (with L_J, P_J as in 5.1):

$$\Delta L = P_iL_J + L_iP_J + P_iL_i \tag{19}$$

[5] If users do not do this, the case for re-use is lost; this is critical.

From (2), the incremental effort is $\Delta E \approx \lg G$. Since neither ΔE, nor the third term of ΔL depend on the group J, the objective function, $L+E$, depends on the group assignment only through the first two terms of (19). Thus the new account should be added to the group $\mathscr{A}_J$ minimizing $P_i L_J + L_i P_J$. This brings an interesting insight: if any group J exists such that $P_J < P_K$ and $L_J < L_K$ for all G (i.e., the group has both a smaller total probability and a smaller total loss than all other groups), then all new accounts should be added to that group J, until one of the two inequalities fails.

Thus without loss of generality, the remaining case is in deciding between two groups $\mathscr{A}_J$, $\mathscr{A}_K$ when $P_J < P_K$ and $L_J > L_K$. Here, new account i should be assigned to $\mathscr{A}_J$ (vs. $\mathscr{A}_K$) if and only if:

$$P_i L_J + P_J L_i \leq P_i L_K + P_K L_i \tag{20}$$

This can be rewritten as

$$\frac{L_i}{P_i} \geq \frac{L_J - L_K}{P_K - P_J} \tag{21}$$

Fig.2 illustrates this constraint graphically. Recall that a line of slope m in the PL plane is given by $L = m \cdot P + c$. Thus, (21) says that account i should be placed in group $\mathscr{A}_J$ (vs. $\mathscr{A}_K$) if and only if point (P_i, L_i) lies above a line with slope $(L_J - L_K)/(P_K - P_J)$ going through the origin. Fig.2 shows the construction of a (solid red) line with slope $(L_J - L_K)/(P_K - P_J)$; it passes through points (P_K, L_J), (P_J, L_K). The dashed red line is one of the same slope, but through the origin.

In summary, the decision boundary between adjacent groups $\mathscr{A}_J$ and $\mathscr{A}_K$ is given by the line:

$$L = \left(\frac{L_J - L_K}{P_K - P_J} \right) \cdot P. \tag{22}$$

A necessary condition for optimality is the absence of *profitable single moves* in the following sense: if a partitioning of accounts is optimal, the total loss cannot be decreased by moving any account i from group $\mathscr{A}_J$ to any other group $\mathscr{A}_K$. This can be expressed as

$$P_i L_{J^*} + P_{J^*} L_i \quad \leq \quad P_i L_K + P_K L_i \quad \text{for all } K. \tag{23}$$

Here (P_K, P_{J^*}) are the total loss probabilities, and (L_K, L_{J^*}) the total losses, resp., for groups K and J^* where J^* denotes group J after removing account i. Similar to (21), we can rewrite (23) as

$$\frac{L_i}{P_i} \geq \frac{L_{J^*} - L_K}{P_K - P_{J^*}} \quad \text{for all } K. \tag{24}$$

Consider the case when the number of accounts N becomes large, in which case P_i and L_i are typically small relative to P and L. We can then assume the total loss and probability of each group does not change much by adding or removing a single account. Thus $P_{J^*} \approx P_J$ (i.e., $P_J \approx (P_J + P_i)$).

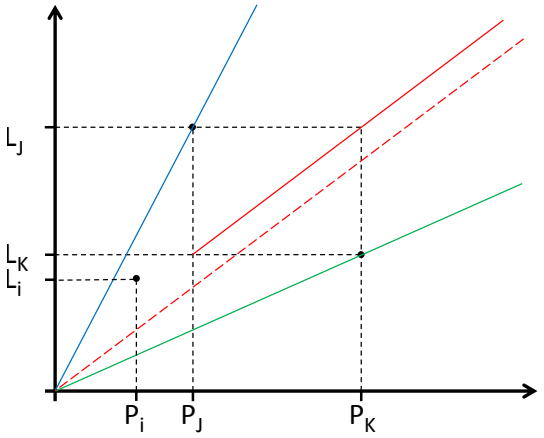

Figure 2: Optimal assignment of a new account (P_i, L_i) between two groups J and K. If the new account falls above the dashed red line, total loss will be smaller when the account is assigned to group J.

We first show that given an optimal grouping, for any groups J and K the decision boundary is bounded by:

$$\frac{L_K}{P_K} \leq \frac{L_J - L_K}{P_K - P_J} \leq \frac{L_J}{P_J}. \tag{25}$$

The decision boundary slope (Fig.2, dashed red line) thus must be between that of the green and blue lines.

To show this, note that group K must contain at least one account i with $L_i/P_i \geq L_K/P_K$ (since all of the L_i and P_i are ≥ 0). Thus (21) holds, implying account i belongs in group $\mathscr{A}_J$ rather than $\mathscr{A}_K$ unless the righthand inequality of (25) holds. The reverse argument applies to show the lefthand inequality in (25).

Now (22) tells us that the decision boundaries are lines through the origin; so each group has at most two neighbors. Further, (25) when applied to every pair of "adjacent" groups in the PL plane, implies the same ordering applies to not only the ratio of L and P differences as in (22), but also the ratio of their values:

$$\frac{L_1}{P_1} \geq \frac{L_2}{P_2} \geq \cdots \geq \frac{L_G}{P_G} \tag{26}$$

where, without loss of generality, the groups have been ordered clockwise, according to their order in the PL plane. In general for groups $\mathscr{A}_J$, $\mathscr{A}_K$, recall that $P_J < P_K$ implies $L_J > L_K$. From this it follows that, given an ordering for the ratio, the same ordering must apply to the expected loss and the reverse ordering for probability, i.e.,

$$P_1 \leq \cdots \leq P_G \quad \text{and} \quad L_1 \geq \cdots \geq L_G. \tag{27}$$

Thus ordering the account groups by decreasing total loss, they have increasing total probability; due to the possibility of equality, none of the orderings is strict.

6.2 Groups Similarly Weighted by PL

Consider next how large and how disparate different groups will be. We show that under certain conditions, the groups formed have similar individual products PL. With focus again on the outcome as G increases, from Section 6.1 the groups obey an ordering in terms of P, L, and L/P, and the decision line slope (dashed red line in Fig.2) must be between the slopes of the two adjacent groups. Thus, assuming accounts exist around every point in the PL plane, as G increases the adjacent groups have increasingly similar slopes, with bounds on the decision boundary slope per (25). Since, from (27), the L_i are non-increasing, and from (27), the P_i are non-decreasing, we have $L_J \geq (L_J + L_K)/2 \geq L_K$ and $P_J \leq (P_J + P_K)/2 \leq P_K$. It follows from (25) that, as G increases:

$$\frac{L_J - L_K}{P_K - P_J} \approx \frac{(L_J + L_K)/2}{(P_J + P_K)/2}. \tag{28}$$

Re-arranging yields:

$$(L_J - L_K)(P_J + P_K) \approx -(P_J - P_K)(L_J + L_K) \tag{29}$$

Expanding products and eliminating common terms,

$$P_J L_J \approx P_K L_K \tag{30}$$

Thus the product of probability and loss for adjacent groups is about equal, increasingly so as the numbers of groups G and accounts per group increase.

6.3 Pedagogical Illustration through Two Generated Datasets

To illustrate, we generated two datasets, assigning accounts to groups with an optimization program obeying the "no profitable moves" rule. The simulation models 100 accounts, with randomly assigned P_i and L_i, to be divided in five groups (shown by different colors in the figures). The program assigns accounts to a group one at a time. After each assignment, it tests all possible single moves and swaps, performing any profitable moves before moving on to assign the next account. In the first dataset, corresponding to Fig.3 and Table 2, P_i and L_i are independently drawn from uniform distributions.

In practice, the combination of (23), (25), and (30) means that whenever passwords are to be re-used across accounts, the optimum strategy is to do so across accounts with similar P/L ratio, and add enough accounts per group to achieve similar total PL products for each group. The resulting account assignments split the PL plane into slices (see Fig.3). This implies that most high-value accounts end up in the same group (particularly if they have low compromise probability), and most low-value accounts end up in another group (particularly if they have high compromise probability)—apparently in line with what many users currently do. Table 2 reports selected characteristics of the 5 password groups; note the similar values of PL across groups, strictly decreasing L, and strictly increasing P and P/L.

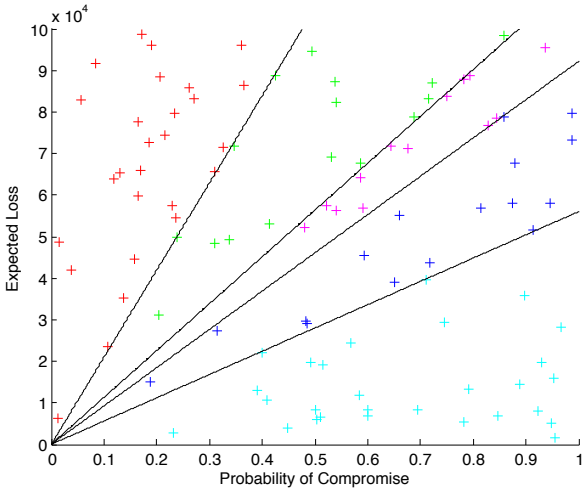

Figure 3: Password grouping, under the "no profitable moves" strategy. For this example, 100 accounts are uniformly placed at random in the PL plane, and optimally assigned to one of 5 groups. Note the linear decision boundaries, corresponding to P/L ranges (slices).

While the dataset used to produce Fig.3 allows visualization of the linear decision boundaries, such a dataset with independent distribution over P and L is not what we would expect in practice. We thus generated a second dataset (see Fig.4 and Table 3) where L_i follows a power law distribution and the expected value of P_i is inversely proportional to (the square of) L_i. While all observations on the previous dataset still hold, further insights are evident. As on this dataset high-value accounts are less likely to have high P_i, the high-value accounts end up grouped together. Indeed, group 1 includes 53 accounts, more than half of the set, while group 5 has only 4 accounts (see Table 3).

The total resulting loss across all five groups is 7.94×10^4. To see how this optimal assignment compares to a random assignment, we computed total loss on the same dataset on randomly assigning accounts to the 5 groups (in 100,000 Monte Carlo trials), finding an average PL of 1.16×10^8 (std deviation 0.24×10^8). Thus the optimal loss was 1500 times smaller than by random assignment, and 5 standard deviations below the mean.

We emphasize that both datasets are modelled examples to illustrate principles. For other datasets, the general findings will hold, but actual construction of groups may significantly differ depending on the data.

Group #	P	L	PL	P/L	max P/L	min P/L	Group Size
1	1.88e+01	3.96e+05	7.44e+06	4.75e-05	6.09e-04	1.80e-05	28
2	1.14e+01	8.08e+05	9.17e+06	1.40e-05	1.77e-05	1.09e-05	16
3	9.35e+00	9.71e+05	9.08e+06	9.63e-06	1.08e-05	8.93e-06	13
4	7.94e+00	1.14e+06	9.06e+06	6.96e-06	8.72e-06	4.79e-06	16
5	4.91e+00	1.82e+06	8.93e+06	2.70e-06	4.73e-06	3.22e-07	27

Table 2: Characteristics of each group in the grouping corresponding to Figure 3.

Group #	P	L	PL	P/L	max P/L	min P/L	Group Size
1	2.29e+01	3.24e+02	7.41e+03	7.06e-02	9.46e+02	1.44e-03	53
2	6.70e-01	1.76e+04	1.18e+04	3.80e-05	1.24e-03	4.45e-06	24
3	6.42e-02	2.40e+05	1.54e+04	2.68e-07	1.66e-06	3.01e-08	11
4	7.04e-03	2.45e+06	1.72e+04	2.88e-09	1.66e-08	4.09e-10	8
5	1.26e-03	2.19e+07	2.77e+04	5.76e-11	2.80e-10	9.29e-12	4

Table 3: Characteristics of each group in the grouping corresponding to Figure 4.

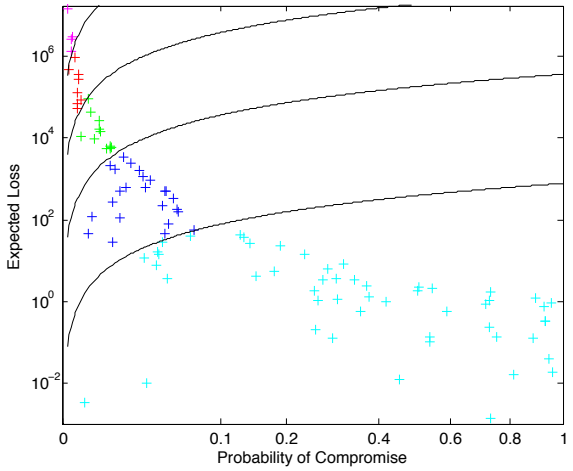

Figure 4: Password grouping, second dataset (P_i's drawn from a distribution with mean inversely proportional to L_i^2). Due to the non-linear axis, the decision boundaries are no longer linear. The number of accounts in each group differs from Fig.3.

7 Special Cases

Next, special cases illustrate how the model addresses additional assumptions and circumstances.

7.1 Case 1: Unknown P_i (Modeled as Equal)

The model highlights two variables with large effect on the problem: loss and compromise probability. Most users could give some estimate of loss that would result from compromise of a specified account—perhaps not entirely accurate, but representative of expected loss, even if only in relative terms. In contrast, user estimates of probabilities would likely be far worse, perhaps without sense of even relative P_i's. We thus consider here what results from the optimization model on assuming equal probabilities $p = P_i$ for all i. Slice-based partitioning still applies, as does the ordering—the latter now easier with all accounts on a vertical line in the P_iL_i plane. The main question is how many accounts will each group have, and how does that relate to the L_i of accounts in each group.

If group J has N_J accounts, write $P_J = pN_J$. Then (30) yields $(pN_J)(L_J) \approx (pN_K)(L_K)$, or, equivalently:

$$\frac{N_J}{N_K} \approx \sqrt{\frac{L_K/N_K}{L_J/N_J}}. \tag{31}$$

Thus groups with high-value accounts will have fewer accounts; optimally, the number of accounts N_J in a group J varies inversely with the square root of the average loss L_J/N_J in that group.

To illustrate, we re-run the optimization process on the second dataset (see Section 6.3), but now assuming ignorance of individual probabilities, modeling equal P_i. The principles discussed earlier now result in the accounts being split by strict ordering of losses. The number of accounts in the 5 groups is now (82, 11 4, 2, 1), vs. (53, 24, 11, 8, 4) in Table 3. As might be expected, total losses increase to 1.24×10^6, vs. 7.94×10^4 for optimization using known probabilities. This is 16× higher than the optimum, but still 93× smaller than the average loss from random assignment (see Section 6.3).

7.2 Case 2: Group Passwords of Unequal Strength

We showed in Section 5.3 that passwords should *not* have the same strength. We now show how the assumption made in Section 6 (that P_i did not change much when we moved account i from password group J to group K) can be relaxed, so that there is no incompatibility. Here we

briefly analyze the impact, on optimization results, when P_i is password-dependent and groups have passwords of different strength. Denote the (now group-dependent) compromise probabilities $P_{i\in J}$, $P_{i\in K}$. Then by the argument used in (20), account i should be assigned to $\mathscr{A}_J$ if and only if

$$P_{i\in J}L_J + P_J L_i \leq P_{i\in K}L_K + P_K L_i. \tag{32}$$

We again seek a bounding condition on L_i/P_i, but now using what group-neutral P_i value? We use the geometric average $P_i = \sqrt{P_{i\in J}P_{i\in K}}$ and define the squareroot ratio $r = \sqrt{P_{i\in J}/P_{i\in K}}$. Then (32) yields

$$\frac{L_i}{P_i} \geq \frac{rL_J - (1/r)L_K}{P_K - P_J}. \tag{33}$$

Note $r>1$ if group J has password weaker than K. Thus with respect to group assignment, a weaker group J password has an effect equivalent to scaling up group losses L_J, making it harder to satisfy the condition for assignment to group J. Other results regarding the slicing, P and L ordering, and so on remain as before.

7.3 Case 3: Unequal Server Break-in Probabilities

Finally, consider the effects of different levels of security at the server. The probability of server break-in is largely outside users' control, but the consequences are not: a user may decide to share a password across accounts, only to have one of the servers leak her password, compromising all accounts sharing it. While the previous analysis already takes into consideration server break-in (as a Class II attack), we now analyze how two sites with different server break-in probabilities will affect the optimum allocation.

Consider two accounts i and j, with same values $L_i = L_j$ but different probabilities, $P_i = P_j + \delta_i$, where δ_i is the added break-in probability due to a site i server poorly managed compared to j. Upon assigning account i (poorly managed) to a group, the added probability δ_i will imply a higher ratio P_i/L_i, so the account will (likely) be grouped with accounts with higher P/L, typically lower-value accounts. Furthermore, as discussed in Section 5.3, these groups may have a weaker password. Thus, for a server with higher break-in probability, optimum password grouping seems to push towards grouping the related account with lower-value accounts.

Related to this, our criteria for optimality depend on how loss probabilities change with respect to effort, but not on the magnitudes of the probabilities themselves. Consider the possible case of a threat unaddressable by user effort, swamping all others. Let $P_i = P_{i,u} + P_{i,\bar{u}}$, where $dP_{i,\bar{u}}/dE = 0$. If $P_{i,\bar{u}} > 10^3 P_{i,u}$, it may be fruitless to spend substantial user effort if such expenditure affects only the third decimal place in P_i. Nonetheless, this is what our criterion for optimality suggests. System-side or back-end (server) risks may swamp risks under user control; we simply do not know.

7.4 Case 4: Coping Alternatives including Password Managers

Despite violating long-standing password guidance, writing passwords down is, if properly done, increasingly accepted as a coping mechanism. Other strategies to cope with the human impossibility of using strong passwords everywhere without re-use include single-sign-on, use of email-based password reset mechanisms, and password managers. Such "password concentrators", a form of password re-use, allow access to many accounts from one master access point, with account passwords stored either locally or in the cloud. While not explored in detail here, each can be analyzed in our framework; we illustrate for password managers.

The main threats (recall Table 1) when re-use is employed are client-side malware (all accounts fall), and various Class II attacks such as guessing, phishing, sniffing wireless links and server breaches (all accounts in the same sharing group fall). We must modify this picture slightly if a password manager is used. For Case A (password store on a user's local machine), the main risk is still Class I attacks like client-side malware. There is a decreased risk of phishing presumably, as users remember fewer individual passwords; similarly for guessing attacks, as arbitrarily strong passwords now require no user effort, and the master password that unlocks the store resides on the client. A server-side breach compromises only a single account. Thus, a password manager with client-side store approximates our model with $G = N$. The cost, of course, is that portability across different client devices is lost as the passwords (if they are unique and random) are effectively anchored to the client on which they are stored.

Consider next (Case B) a cloud-based store, protected by a single password. Phishing and guessing attacks against any system-assigned secrets at the end-servers remain unchanged. Now however, additional guessing, phishing and server breach attacks exist against the single master password which can result in the compromise of all accounts. Class I attacks (e.g. due to malware on the client) are unchanged. A password manager with a password-protected cloud-based store approximates our system with $G = 1$. It trades one set of risks for another: the use of random and unique passwords in such a system reduces both the risks related to any single manager-chosen password being stolen and those related to re-use in the face of server compromise. However, it introduces

severe new risks: if the master password is guessed or used on any malware-infected client, or the cloud store is compromised, then all credentials are lost.

8 Discussion and Implications

Recapping, recall first the task of end-users: to choose passwords random and strong (entropy $\lg S$ bits) without re-use. The effort to manage N such passwords without re-use is modelled as $N \lg S + \lg(N!)$; as portfolio size increases, this overwhelms user capability.

M1: *Remembering random and unique passwords is infeasible for other than very small portfolios.*

Users coping strategies include weak passwords and re-use. There is a large disconnect: what standard advice mandates as essential turns out to be impossible. We suggest this is due to a failure to explicitly include user effort in the objective function. Seeking to minimize loss alone leads to unrealistic effort-maximizing solutions. While some recent work [5, 4, 29] criticizes the practice of ignoring the burden password advice places on users, it has not to our knowledge been included directly in the objective function. We make a related observation:

M2: *While advice typically minimizes L over a single or small set of sites, user best interest is to minimize $L+E$ over an entire portfolio.*

The diversity of attacks complicates our search for an optimum effort allocation. Short-cuts are tempting; we can minimize $L+E$ while ignoring cross-account attacks (as in Section 4), or consider all attack types and minimize L alone. The first scopes the problem too narrowly, the second leads to the unrealistic demand to invest unbounded effort. While both yield "solutions" that are simpler than the model in Section 5, our work suggests that realistic analysis must address a realistic attack model *and* a realistic objective function.

M3: *Realistic analysis of password effort allocation requires incorporating attack vectors affecting 1) all accounts; 2) accounts sharing a password; and 3) single accounts.*

Our segmentation of the space into Class I, II and III attacks yields interesting insights. Minimizing $L+E$ over a portfolio implies user effort be spent unequally across accounts. As can be seen from (15), all passwords should not be equally strong; equal spending overspends on low-value, and underspends on high-value accounts (or account groups). Recall that, from (27), there is an ordering of the group values L_J; the largest may be many times greater than the smallest ($L_1 \gg L_G$). Any group for which $L_J \approx 0$ should have $\partial P_J/\partial E_J$ high (meaning a weak password). If we again invoke the reciprocal relation between P_J and E_J suggested in Section 4, we'd again find $E_1 = \sqrt{L_1/L_G} \cdot E_G$. Thus a $10^4\times$ value difference between the most and least valuable groups would imply a $100\times$ difference in invested effort. In this sense, not only are weak passwords understandable and allowable, but *their absence* would be sub-optimal:

M4: *A password portfolio strategy that rules out weak passwords is sub-optimal.*

Next, while sharing a password across a group of accounts can amplify consequences if it is compromised, we find it is sub-optimal *not* to re-use. First, (1) indicates re-use becomes unavoidable when N is large. Second, (2) and Fig.1 demonstrate the tradeoff involved even if N is small enough that re-use is theoretically avoidable; i.e., re-use increases the probability of loss from certain attacks, but also reduces effort. The question then is not whether re-use is good or bad, but whether the effort required to avoid re-use can be better spent on other attack types. Section 6 gives an example.

M5: *A password portfolio strategy that rules out password re-use is sub-optimal.*

The optimal strategy places accounts with similar P/L ratio in groups sharing a password. Enough accounts are added to each group to achieve similar PL products per group. Most high-value accounts (particularly if they have low P_i) end up in the same group(s), and most low-value accounts (particularly if they have high P_i) in another group(s).

M6: *Optimal password grouping tends to (i) group together accounts with high value and low probability of compromise; and (ii) group together accounts of low value and high compromise probability.*

The above observation lines up well with anecdotal accounts of what many users actually do. Our findings also agree with the informal claim [29], that users' actual effort allocation represents an efficient operating point. Thus, actual user password-related behavior is closer to optimal than current expert advice.

Password managers (cf. Section 7.4) may improve usability and reduce some risks, but remain vulnerable to Class I attacks (e.g., client-side malware). Managers that store passwords only on the client improve resistance to Class II attacks, since they can choose better passwords and eliminate re-use. However, in storing only on the client this gives up one of the major advantages of passwords, i.e. portability. Managers that store passwords in the cloud remove this restriction, but introduce a new system-wide attack: as before if the client is infected with malware all accounts are compromised, but now this

happens also if the cloud store is breached or the master password is stolen or guessed. Thus, cloud-storage managers trade one type of vulnerability for another.

M7: *Password managers using client-only storage allow a portfolio with random passwords and no re-use, but lose cross-client portability. However, if cloud storage is used it resembles a portfolio with only one group, since a new attack on either the master password or the store itself threatens all accounts.*

Another disconnect stems from many password-related threats being unrelated to the standard advice on maintaining a portfolio: Class I attacks, server breaches and Class III attacks are not reduced by password advice staples such as A1 and A2. Since successful Class I attacks sum the losses across all accounts, the advice to protect against them is disappointingly vague, while advice to protect against the less consequential Class II attacks is far more detailed and effort-consuming. It appears that users are given the advice that is most easily given, rather than the advice that would have greatest impact. Comparing (14) and (15) shows that at optimality the marginal return on effort spent on Class I attacks should be lower than that for any Class II group (*e.g.*, effort should not be wasted strenghtening passwords for a group with low L_J if any effective Class I measure remains undone). Greater focus is needed to explore which advice, for example from Table 1, provides protection against which attack vectors:

M8: *We lack metrics for the cost to end-users, of following standard advice, and the effectiveness of following it on reducing overall expected loss.*

An important outcome of our review is that, when minimizing $L+E$, optimality depends on the losses L_i, and on how the probability of loss varies with respect to effort $\partial P_i/\partial E_i$. In contrast if one minimizes L, the solution depends on neither. Without better knowledge of real-world values for L, and especially $\partial P_i/\partial E_i$, we are unlikely to achieve optimal resource allocation in practice. Conventional user behavior appears to be based almost exclusively on L, which users may be able to estimate; $\partial P_i/\partial E_i$ values are almost entirely overlooked. This points to an important research direction: while recent work has greatly improved understanding of password guessing resistance [8], we are almost entirely ignorant on how this evolves with effort.

M9: *Without better estimates of how loss probability changes with effort, we should not expect to be able to allocate effort (even close to) optimally.*

Finally, can concrete advice for users be distilled from our findings? For example, absent knowing how P_i change as a function of various types of effort, we lack a prescriptive way to determine the optimal number of groups G. Nonetheless, the knee of the curves in Fig.1, and what we know of user behavior [24, 21, 14] points to the number of groups being below 10 if no other aids are used. The values of loss probabilities P_i are entirely unknown; expected loss values L_i, or at least relative importance, are more easily estimated or ordered. Thus the variables needed to find an optimal grouping are (and are likely to remain) unavailable to most users. We might however simplify, e.g., assuming all P_i equal, or that P_i values differ by an order of magnitude between heuristically-defined categories (*e.g.*, banks, merchants, throwaway accounts, *etc.*).

While the optimal strategy involves selective re-use and weaker passwords, benefits accrue only if the effort saved is re-deployed elsewhere for better returns. Users must not arbitrarily weaken and re-use passwords. Thus empirical studies are needed to determine if our guidelines can be followed by users.

We hesitate to give definitive advice. First, this requires more insight than our current understanding of L_J and $\partial P_J/\partial E_J$ values allows. Second, we are reminded how far bad assumptions (e.g., minimizing L vs. $L+E$) can lead us astray. Consider, however, a strategy that chooses G in the range 5 to 10, and assigns accounts to groups by value so that the number of accounts in a group is as in Section 7.1. Given the uncertainty about unknown parameters, a strategy like this may be the best we have—and may even be optimal.

9 Concluding Remarks

We have explored the task of managing a portfolio of passwords. A starting point for our analysis was the critical observation that to be realistic, efficient password management should consider a realistic suite of attacks and minimize the sum of expected loss and user effort. Our model yields detailed results; it indicates that any strategy that rules out weak passwords or re-use will be sub-optimal. We have shown that optimality requires forming groups whose accounts in sum have similar PL values ($P=\sum P_i, L=\sum L_i$). This suggests simple guidelines, such as: if P_i is similar across accounts, then optimal grouping will put high-value accounts in smaller (or singleton) groups, and low-value accounts in larger groups. Our findings are consistent with certain user behaviors (e.g., [47]) that contradict accepted advice, offering to justify the behavior and giving evidence for the model's utility. We find that optimally, marginal return on effort is inversely proportional to account values. We note that while password re-use must be part of an optimal portfolio strategy, it is no panacea. Far from optimal outcomes will result if accounts are

grouped arbitrarily.

Telepathwords: preventing weak passwords by reading users' minds

Abstract

To discourage the creation of predictable passwords, vulnerable to guessing attacks, we present *Telepathwords*. As a user creates a password, Telepathwords makes real-time predictions for the next character that user will type. While the concept is simple, making accurate predictions requires efficient algorithms to model users' behavior and to employ already-typed characters to predict subsequent ones. We first made the Telepathwords technology available to the public in late 2013 and have since served hundreds of thousands of user sessions.

We ran a human-subjects experiment to compare password policies that use Telepathwords to those that rely on composition rules, comparing participants' passwords using two different password-evaluation algorithms. We found that participants create far fewer weak passwords using the Telepathwords-based policies than policies based only on character composition. Participants using Telepathwords were also more likely to report that the password feedback was helpful.

1 Introduction

Users are often advised or required to choose passwords that comply with certain policies. Passwords must be at least eight characters long. They must contain characters from at least three out of four character categories (uppercase characters, lowercase characters, digits, and symbols). The password should not be based on a dictionary word.

While rules for composing passwords often feel arbitrary and capricious, they respond to a problem of genuine concern: left to their own devices, a significant fraction of users will choose common passwords that attackers may guess quickly. Composition rules were created decades ago under the assumption that minimum-length and character-set requirements would result in passwords that were harder for attackers to guess. It is only in the past few years that researchers have begun to test this hypothesis (and found the evidence to support it far weaker than assumed).

Indeed, password-composition rules feel arbitrary and capricious because, quite simply, they often are. Users can hardly be blamed if they question the credibility of rules that reward those who choose the common password `P@ssw0rd` over those who enter a long randomly generated string restricted to lowercase letters (e.g., to facilitate typing on a touch-screen keyboard) or of password meters that offer irreconcilably different quality estimates for the same string [4]. If we are to prevent users from selecting weak passwords, we must first improve the technology used to identify weak choices, but also overcome any skepticism caused the failure to clearly explain the need for the restrictions being imposed.

Our proposal, *Telepathwords*, is different from previous weak-password prevention schemes in that, as users enter their proposed password, it shows its best predictions for the next character they will type in real time (see Figure 1). Telepathwords makes these predictions using knowledge of common behaviors users exhibit when choosing passwords, common strings they frequently use to construct passwords, and a general model of the user's language. Telepathwords presents users who enter weak passwords with immediate and compelling evidence that their intended password may be easier to guess than they had previously assumed: a display of the characters they are about to type.

We describe the design, implementation, human-subjects testing, public deployment, and user response to the Telepathwords system. The results of our security testing are particularly compelling. In a 2,560-person Mechanical Turk study, passwords created using Telepathwords significantly outperformed (using both entropy and guessing number metrics) those created under length and character composition policies, while remaining as memorable as passwords chosen with the least stringent requirement (an eight-character

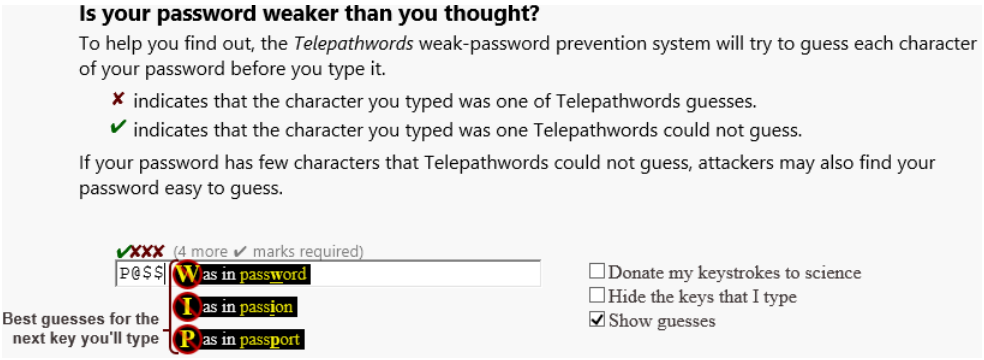

Figure 1: The Telepathwords system, shown here as deployed in a publicly available password-weakness checker, attempts to guess the next character of a users' password *before* he or she types it.

minimum-length requirement). They matched or slightly beat passwords created under a policy that checked against a large cracking-dictionary, while at the same time having more users state that they found the visual feedback useful. The improvements in guessing resistance were most pronounced for the most vulnerable part of the distribution. That is, the weakest passwords created using Telepathwords require orders of magnitude more guesses than the weakest passwords created under policies based on composition and length. This suggests that Telepathwords can offer meaningful improvement in defending against online guessing attacks; an improvement that we hope can rebuild users' confidence that the constraints being imposed on them are indeed necessary.

2 Design and Implementation

We begin our discussion of the Telepathwords system by describing the intended user experience, then discuss the overall architecture and prediction algorithms required to implement that experience. We also describe the feedback mechanisms we included to observe usage of the system, as well as the limitations inherent to our implementation.

2.1 User Experience

Telepathwords enhances the text field into which users type new passwords with two additional elements: a *prediction display* and a *feedback bar*. Figure 1 illustrates both, with the prediction display just to the right of the typed password (`P@$$`) and the feedback bar immediately above it.

2.1.1 Prediction display

The prediction display shows the three characters (or fewer) that Telepathwords predicts the user is most likely to type next. As users are most likely to be familiar with prediction from autocomplete, where the predictions represent a *desirable* mechanism to save labor, we needed to emphasize that the characters telepathwords predict are *undesirable*, as these choices are least likely to make the password harder for attackers to guess. We thus display predicted characters in block uppercase within the prohibition symbol, or 'universal no symbol': a red circle with a slash through it. We anticipated the symbol would be familiar to users because it is standardized (ISO 3864-1, though we did not strive to achieve full compliance in our use), widely used in road signs, and pervasive in popular culture such as t-shirts and movies.

To the right of the character we present a short explanation of why that character was predicted. If we predicted the character because we detected the user typing a repeating sequence of characters, we display 'repeating' followed by the character sequence being repeated. If it is the next character of a common string, we present the words 'as in' followed by that string, with the next character boldfaced and underlined. For example, in Figure 1, the input of "P@$$" yields predictions: "W as in pass**w**ord," "I as in pass**i**on," and "P as in pass**p**ort."

2.1.2 Feedback bar

In the feedback bar above the password-entry field, we show either a checkmark or crossout symbol aligned directly above each of the characters already typed. A checkmark means the character was not predicted by Telepathwords, whereas a crossout indicates it was one of the characters guessed. We also display a crossout if the user types a common substitute for one of the predicted characters, such as an `@` to avoid using an `a`. To the right of these symbols we provide guidance as to how many more hard-to-guess characters are recommended, or would be required if Telepathwords were deployed with a particular minimum hard-to-guess character requirement. For example, Figure 1 shows one check and three crossouts above the user input "P@$$" since each of the last three characters was predicted based on the characters that came before it.

2.1.3 Special cases

In many applications, password-creation fields are configured to hide the keys typed, replacing them with a generic symbol (usually a solid circle or an asterisk). When the password field is configured to hide the characters that have been typed, we also replace those characters with a solid circle in our prediction string. The predicted characters are still shown.

When users type a common substitute for a predicted character, such as a *$* when an *s* is predicted, we display the following message customized for the replacement:

> Replacing a predictable letter with a key that looks similar?
>
> Attackers also know to substitute **$** for **s**, so it does little to improve your password.

We faced a particularly delicate conundrum in how to handle predictions that completed profanities. An examination of the Rockyou leaked dataset reveals that profanities are not uncommon choices. Unlike applications of prediction in search queries, we could not simply remove these predictions, as this would lead users to believe falsely that profane passwords were less weak than they actually are. On the other hand, we could not display profanities to users who might have no intent of typing them, and who might be minors. We decided that providing good security advice mandated that we predict the next character, but we replace the rest of the profane string with a string of solid circles in the explanation of the prediction. We also display a pop-up message if users complete a profanity, alerting them to the fact that profanities are common in passwords and thus quite predictable. In crafting this message, we decided to embrace the inevitability that some users might find humor in our attempts to hide profanity.

> Do you email your mother with that keyboard?
>
> Many people include profanity in their passwords. Attackers know this. If you also use profanity, you'll just make your password easier for attackers to guess.

2.2 Architecture

Telepathwords employs a client-server architecture, using JavaScript to present a front-end user interface using predictions asynchronously queried from a prediction server. The constraints of client-side prediction would not have allowed our prediction engine to use a 1.5GB language corpus (see Section 2.3.1), which we hope to grow in order to increase prediction quality and recognize additional languages.

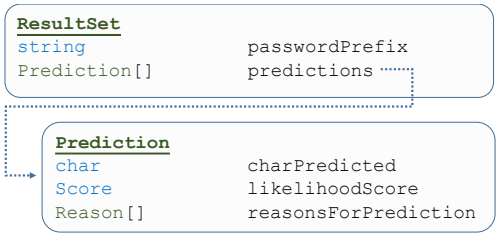

Figure 2: When the client queries the server with a password prefix, the Telepathwords prediction engine generates a result set containing a series of predictions, each of which may have been predicted based on a number of reasons (e.g., a dictionary match or a keyboard pattern).

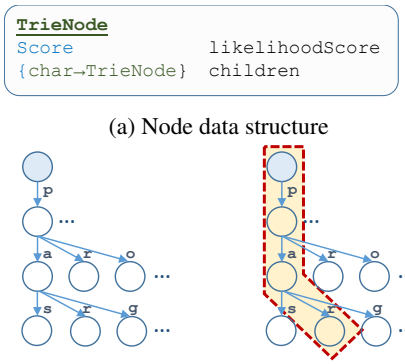
Other weak-password-prevention systems, such as common password meters, eschew server-side predictions. One justification is security. However, the current architecture of the web necessitates that whatever password the user eventually chooses will inevitably be sent to the website's servers in a plaintext-decryptable format. To prevent the size of a prediction from revealing the prefix sent to the server, we use a custom format to compress and then pad responses to a common length. We route all client-server communications over HTTPS.

A second reason to eschew server-side predictions is performance. However, network latencies are relatively small in comparison to users' expectations of response time, and can be made smaller by moving servers closer to users and pre-fetching likely queries, as demonstrated by the speed of auto-complete in web search. For example, though our deployment used servers in a single geographic location to serve users worldwide, the median latency between key-up and the rendering of a prediction at the client was a fifth of a second (see Section 3).

One additional security risk we decided to take was to maintain a cache of previously queried prefixes on the server, whereas we would otherwise be able to delete all evidence of a past request after serving a prediction. This greatly increases the likelihood that when the n^{th} character of a password arrives, the server will already have done the work to process the first $n-1$ characters.

2.3 Prediction algorithms

When performing a prediction, we create a result set data structure and populate it with a set of predictions, as illustrated in Figure 2. Each prediction object represents a possible next character of the password and a score that indicates its estimated likelihood. There may be more than one reason to predict a character, and so each prediction object contains a set of reason objects. We populate the result set by spawning a set of *predictors*, algorithms which identify reasons for predicting a character



(a) Node data structure

(b) A section of the trie (c) Descent to node *par*.

Figure 3: The trie data structure maps strings to likelihood scores. Nodes (circles) with higher scores appear to the left of lower-scoring siblings. Subfigure (c) illustrates a walk to the node storing the likelihood score for string *par*.

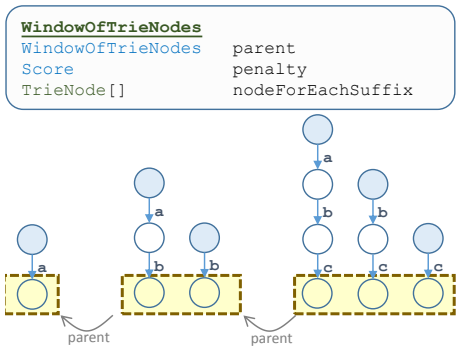


Figure 4: Telepathwords uses a sliding window to walk the trie for each suffix of the queried string. If the query string is a single character (e.g., *a*), the sliding window will contain only one node (left). A two-character string (*ab*) will a sliding window that walks the trie to two different nodes (center). The query string *abc* yields a window that covers the suffixes *c*, *bc*, and the full suffix *abc* (right). Adding one character to the query causes the pointer to each node to descend to the child node for that added character, and creates a new node in the window by stepping from the root node to the added character. Telepathwords may add a penalty to the window when the path down the trie is different from the actual string queried, such as if a window is created to represent a transposition.

will be typed next, add that reason to the prediction object for that character, and increase the predictions score as necessary.

When all the predictors have run, we rank the predictions and reasons. Before sending predictions to the client, we discard predictions and reasons that are not ranked high enough to be displayed to the user. We cache the result set so that we can use it again for future queries for this string, or extensions of this string.

Telepathwords currently contains predictors for common character sequences, keyboard movements, repeated strings, and interleaved strings.

2.3.1 Common character sequences

This predictor detects known prefixes of common character sequences from language models and databases of common passwords, and predicts the remaining suffix. The expected likelihood of the prediction increases with the length and frequency with which the prefix was observed when the model was built.

To search quickly through a large prefix of known strings and their frequencies, we use the space-efficient completion trie of Hsu and Ottaviano [10], as illustrated in Figure 3. The trie used by Telepathwords contains a 1.5GB English-language model derived from browser search queries and a set of passwords that occurred five times or more in the RockYou dataset. We removed all capitalization and spaces from the language model before building the trie.

Completion tries are already used for auto-completion and word-breaking applications, and these applications require algorithms that adapt to common misspellings and typos. For example, existing systems will walk a completion trie reversing the two characters at the suffix, applying a penalty to account for the fact that transpositions occur with much lower frequency than correctly sequenced characters. If the transposed prefix occurs with sufficient frequency to overcome the penalty, the system may continue to track that transposition and make predictions based on it.

Since Telepathwords uses tries to look for common strings that may begin anywhere in the query (e.g., `passw` in the query `notapassword`), we maintain a window of completion-trie nodes for each possible starting position, as illustrated in Figure 4. We track the trie node for each possible suffix of the query. In addition, we maintain two special windows: one that walks the trie only when letters are typed and one that does so only when digits are typed. These special windows help to detect words broken up by non-alphabetic characters (e.g., `pa1234ssword`) or numbers broken up by non-digits (e.g., `12x34y678z9`).

In contrast to other applications of tries, users choose passwords with the deliberate goal of creating a string that is hard to predict, leaving many more anomalies to detect and work around than if divergences from known strings occurred only by accident. We thus maintained a large list of windows for each queried password prefix so as to preserve nodes that might not immediately appear

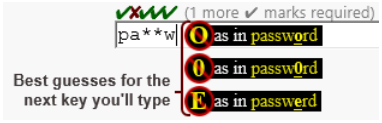

Figure 5: The **common character sequence** predictor walks the ancestry chain to see if a completion that was broken by an unpredicted character might still provide the best guess for what happens next. For `pa**w`, the third ancestor (`pa`) predicted the `w` in the fifth position, and since there are no other likely predictions, predictions using this ancestor reach the top.

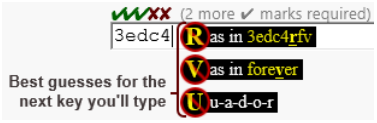

Figure 6: The password `3edc4`, composed of vertical columns on a QWERTY keyboard (`3edc`, `4rfv`, etc.), triggers the **keyboard-movement predictor** yielding `r` as the top guess for the next character. The second prediction guesses that the `4` is used in place of `for` in `forever`, and the third prediction guesses that `ecuador` is interleaved into every other character of the password.

valuable but might prove predictive as more characters arrive.

We also built a table mapping common character substitutions, such as `3` for `e`, `$` for `s`, and `0` for `o`, that are often provided in password-creation guidance (in our view, misguidedly). If we detect a character that is often substitute for another, we create a window using the character we believe was substituted for and assign that window an appropriate penalty.

To detect when users type distractor characters in place of predicted characters, then carry on with the predicted string, we walk up the ancestry path of the current prefix to look for predictions that may have been abandoned due to such behavior. For example, if the user has typed the prefix `pa**w`, the algorithm will walk up from `pa**w` to the ancestor prefix `pa`, determine that the prediction of `password` for this prefix would have correctly predicted the `w` in the fifth position, and may thus revive that prediction to predict a `o` in the next position. See Figure 5. Similarly, we use the standard error-correction technique of detecting when a user has skipped a key and typed the second character predicted in place of the next character predicted.

The analysis of each password prefix of length n begins with the analysis of its immediate prefix of length $n-1$. Thus, the cost of analysis grows at least linearly with the length of the password. We maintain a main-memory cache of recently analyzed query strings so that results can be re-used when the suffixes of a previously-queried string are queried.

Even under heavy load, the cache is small in comparison to the 1.5GB language corpus. In our deployment, the language corpus is stored in main memory. During development, we found performance to be sufficiently fast using a solid state drive (SSD) to store the corpus and only mapping pages into main memory on demand. In our deployment, we prefetched the full corpus into DRAM as our servers did not have SSDs.

Figure 7: The start of a repeating string triggers the **repetition predictor**.

2.3.2 Keyboard movements

We developed this predictor to detect passwords composed of a sequence of characters typed by moving one's finger over a sequence of adjacent keys.

We built a keyboard model that maps characters to x and y coordinates that represent the column and row of the key used to type each character on a keyboard. We represent an n-character password prefix as a sequence of n key positions, then generate a series of $n-1$ movements from the first to the last character. We then work backward from the end of the prefix to count the number of consecutive moves that are to adjacent keys and, of those, the number of consecutive moves in the same direction. We count movements that wrap from one end of the keyboard (e.g., from top to bottom) as adjacent.

We have currently mapped only QWERTY keyboards, but the implementation is generalized to support any mapping of characters to coordinates.

2.3.3 Repeated strings

This predictor looks for instances of repeated strings in password prefixes. For each possible suffix of length n, it looks for repeated sequences of the suffix. The longer the repeated sequence, the stronger the prediction. If the repetitions are adjacent to each other (`xyabcabcabc`), then the predictor guesses the next character in the repeated sequence (or the first if the end has been reached). If the suffix and its copy are not adjacent, then the early copy and the intervening string are assumed to be in the process of repeating. For example, in `abcdefabc` the suffix `abc` is repeated twice and the predictor guesses that `def` will come next.

2.3.4 Interleaved strings

This predictor looks for passwords composed of two predictable strings interleaved with each other, such as `p*a*s*s*w*o*r*d` or `ppaasswwoorrdd`. It splits passwords to separate the odd- and even-indexed characters and runs the other predictors (with interleaving-detection turned off) on the substrings. If, for example, the next character is at an even-index, it uses the even-index substring to make the prediction, and also examines the predictability of the odd-index substring in evaluating the likelihood that the query actually represents two interleaved strings.

2.4 Telemetry

Our public deployment of Telepathwords maintains a limited log of user behaviors, including page loading, resizing, key-up events, and prediction rendering events. Unless users explicitly opt-in to 'donate' their keystrokes to science, we record the timing of keyup events, the number of keys added or deleted, and the position of the change, but not the actual keys typed. We also record whether characters currently in the password field were among those predicted, recording data similar to that which is displayed in the feedback bar.

While we store logs online, the server is unable to read their contents. At the start of a user session the client-side JavaScript requests a one-time session-encryption key from the server. The server generates the key, encrypts it with a public key, and then writes the encrypted session key to the first entry of the log for the session. It then sends the key to the client and maintains no further record of it. The private key is not stored on any publicly facing server. The client XORs the log data stream with a bit stream generated by using AES in counter mode with the Stanford Javascript Crypto Library (SJCL) [27]. We opted for this approach, inspired by Kelsey and Schneier [23], because of its simplicity and as concerns over confidentiality far outweighed that of integrity. As logs are never read online, and no action is taken with them but to store them, we do not know of a scenario in which an adversary could learn the contents of the logs by modifying them.

2.5 System Limitations

The current deployment of Telepathwords has some limitations that are inherent to research prototypes. The language corpus is US-centric and somewhat dated, and so unlikely to pick up on words or phrases uncommon in the United States or that have entered the common lexicon since 2012. An ideal set of corpora would be international and receive constant updates from the latest search queries, news, and other topical sources.

Telepathwords cannot currently detect reversed character sequences (`gfedcba` in place of `abcdefg`) unless that reversal is itself already common enough to be in the language corpus (as it is for `drowssap`, for example). One way to implement reversal detection would be to reverse the more common strings in our language corpus, assess a penalty for the reversal, and insert them into our completion trie.

The privacy promises made by the current deployment of Telepathwords prohibit analysis of passwords for any purpose other than the issuing of predictions, and so the language corpus, scoring rules, and known set of common password-creation behaviors do not grow over time. Thus, if users flock to common behaviors in response to Telepathwords (as they do in response to password-composition rules) we may not be able to detect these behaviors in the current deployment.

3 Deployment

Our first deployment of the Telepathwords technology is a password-testing website, similar in purpose to existing websites that offer to test the 'strength' of passwords [9, 16, 20], which is hosted at https://telepathwords.research.microsoft.com. We took great pains to avoid positioning the service as measuring any form of 'strength' or 'security', as no system can be certain that any user-chosen password is truly strong or secure. There is no guarantee that a password that *appears* strong would not be predictable by an attacker with better knowledge of how certain users construct passwords.

As with any publicly facing Internet service, we deployed Telepathwords with some trepidation not knowing what usage levels to expect and not knowing what factors we may have failed to anticipate when performing load-testing experiments. In our pre-deployment throughput tests, Telepathwords processed 454,486 passwords in a database of breached Yahoo! Voices passwords in under 7 hours using 3 cores of a 3Ghz Xeon E5 1607 (roughly five passwords per core-second.)

We opened up our system to the public on December 5, 2013 and saw our highest usage rates shortly afterward, as the technical press published articles about the release.

3.1 Data collected

We downloaded our encrypted logs to a researcher's workstation for decryption and analysis. We graph the arrival rate of users to our service in Figure 8, which illustrates the burst of traffic during initial release dissipating over time. We are also able to observe the delay experienced by users between the time they typed a key and received a prediction for what the following key

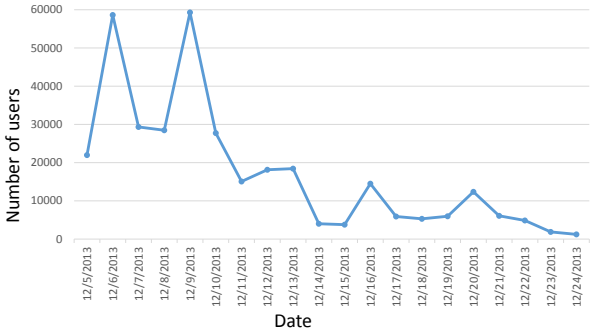

Figure 8: Sessions served per day by the Telepathwords service shortly after release. (A Session is counted when the Telepathwords page loads and the server receives a request for a session ID and encryption key used for logging.)

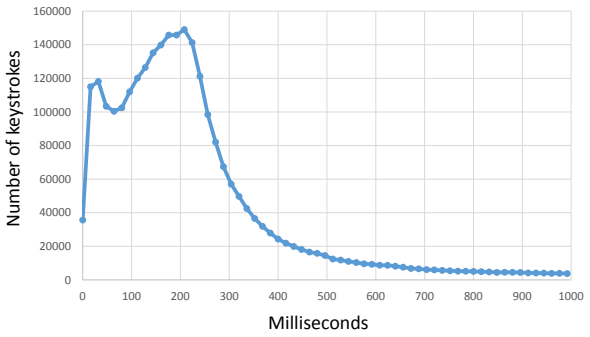

Figure 9: The distribution of the delay between the "keyup" and "render" events for all keystrokes during the recording period. The median occurs at 208ms.

would be, graphed in Figure 9. The median delay was 200ms. A peak in the graph around 20ms is likely due to fast rendering of predictions cached within the browser.

We are also able to use the logs to track how much activity users perform during each user session. In Figure 10, we examine the distribution of number of keys pressed per user session, seeing that some users appeared to use the site to test multiple passwords.

4 Experimental Methodology

In addition to the deployment, we conducted a comparative evaluation of Telepathwords and a number of existing password-composition policies via a two-part online study using Amazon's Mechanical Turk crowdsourcing service. To facilitate comparisons with prior work, much of our methdology mirrors that of a recent line of research from Carnegie Mellon University, including that of Kelley [12], Komanduri [13], Mazurek [15], Shay [24, 25], Ur [28], and others.

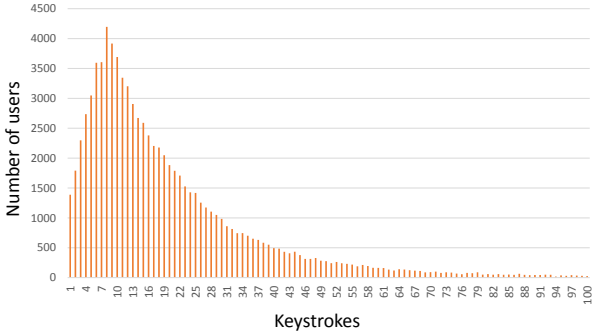

Figure 10: The number of keystrokes received per user session provides insight into user engagement with the site. The median is 15 and the mean is 21 keys pressed per session.

Our experiment was approved by Carnegie Mellon University's institutional review board prior to the start of our study.

4.1 Recruiting and Data Collection

We recruited participants from Amazon's Mechanical Turk by listing a Human Intelligence Task (HIT) in which we offered 55 cents to "Take a 5-minute survey with 70-cent bonus opportunity!" We required participants be 18 years of age and located in the United States.

We asked participants to imagine that their email account had been compromised and that they needed to create a new password to replace it. We used a round-robin algorithm to assign participants one of six password-composition policies. As users typed their proposed password, we provided real-time feedback indicating the conditions that needed to be met for participants to satisfy their assigned policy. Whereas prior CMU studies checked compliance with password policies after participants had submitted them, in this study we enabled the submit button only after a participant had satisfied the policy (and correctly retyped the password).

After participants submitted the password, we presented a survey with up to 24 questions to ask about their experience creating the password, more general questions about their password habits, and their demographics. Following the survey we asked participants to recall their passwords, giving them five attempts to do so. We displayed their password to them if they could not recall it within those five attempts. This concluded *part one* of our study.

Two days later, we invited participants to return for *part two* of our study, sending them an email via an interface provided by Mechancial Turk. We offered 70 cents to return for this HIT, in which we asked participants to recall their passwords. Again, we allowed par-

ticipants five attempts to provide the correct password. We displayed participants' passwords if they were unable to succeed within five attempts, though we did not tell them this a priori. We wanted participants to complete the study whether or not they recalled their password, so we provided them with a last-resort mechanism for recovering their passwords: a link, which would send an email, which contained a link, which led to a webpage, which displayed the correct password. We took this intentionally circuitous approach, rather than simply showing participants their passwords on request, to discourage them from using the recovery mechanism without first trying to recall their passwords. Outside the extra effort for password recovery, we did not further penalize participants for failing to recall their passwords; if we had, and future participants learned about it, they might have been more likely to store their passwords.

Finally, we asked participants to take an 18-question survey asking about their password-recall process and whether they had stored their passwords.

Except as noted, we focus our analysis on those participants who finished the first part of our study. Our analysis of dropout rates examines all participants who begin the study, and our analysis of part two examines only those participants who finished part two. We exclude participants from part two if they did not complete it within three days of the invitation.

4.2 Treatments

The only features of our study that varied between participants were the assigned password-composition policy, whether the password field hid the characters typed into it, and a few survey questions about policies specific to certain treatments. Of the six password policies we assigned to participants, two use a Telepathwords-based policy and four use policies based on composition-rules and (in one case) dictionary checks.

- **telepath, telepath-v** These two conditions employed a Telepathwords-based policy that required users to provide a password with at least six characters that were not predicted by the system. The system does not predict the first character, and so the first character of each password always counted toward the requirement. The two conditions differed only in that passwords would be shown by default as they were being typed in telepath-v and were hidden by default in telepath.
- **basic8** This condition required passwords of at least eight characters in length.
- **3class8** This condition also required passwords of at least eight characters in length, adding the requirement that the password include three of four character classes: uppercase letters, lowercase letters, digits, and symbols. This policy mirrors the default password policy for Microsoft Windows Active Directory.
- **3class12** This condition required passwords of at least 12 characters in length from three of four character classes.
- **3class8-d** This condition required passwords to include at least eight characters, from three of four character classes, and required that the string of all letters within the password not match any of the roughly 3M words in the free Openwall cracking dictionary [5].

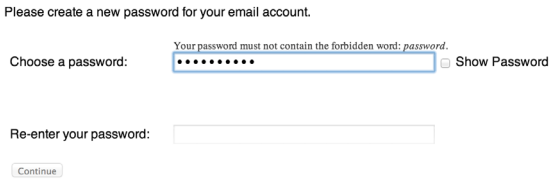

Figure 11: The 3class8-d treatment on the experimental website.

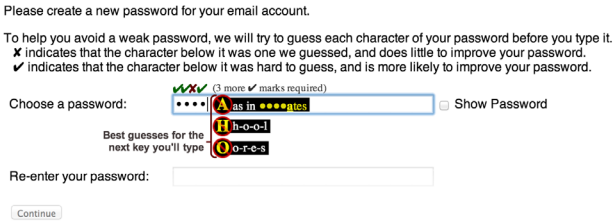

Figure 12: The telepath treatment on the experimental website.

We displayed the requirements that had not yet been met directly above the password-entry field, as shown in Figure 11. If the password had not yet met the length requirement, we displayed that requirement. If a password met the length requirement, we displayed remaining composition requirements, if any. If the password met the length and composition requirements but failed a dictionary check (for 3class8-d), we displayed the match and indicated that the password must not contain the matched word.

We displayed a checkbox that allowed participants to show or hide the characters being typed. With the exception of telepath-v, the password was hidden by default.

	basic8	3class8	3class12	3class8-d	telepath	telepath-v

Table 1: We tally the set of participants who began part one of our study, finished it, and who returned for part two. We measure recall rates for part one (shortly after password selection) and part two. We break down part-two recall rates to factor out participants who reported re-using passwords they already knew or storing their passwords.

5 Experimental Results and Analysis

The application of multiple statistical tests increases the chance of producing a Type I error, finding a significant difference where none exists. To compensate for this, we use a standard two-step process. First, we only perform pairwise tests if an omnibus test is significant. We use the Kruskal-Wallis omnibus test (KW) for quantitative data and the χ^2 test for categorical data. Second, we correct all pairwise tests using the Holm-Bonferroni method (HC). We use the Mann-Whitney U for quantitative pairwise comparisons and Fisher's Exact Test and the χ^2 test for categorical pairwise comparisons.

We performed our experiment in February 2014. We recruited 2,844 workers to accept our HIT for part one of our study. Of these, 2,560 finished, received payment, and received invitations to return two days later. A total of 1,627 participants (64%) returned for the second HIT within three days of when we sent their invitation. Participants' demographics reflected a typical population of workers on Mechanical Turk, with a median reported age of 27, nearly 60% reporting as male, and 44% reporting having at least a bachelor's degree.

We show the progress of participants through our study in Table 1. We removed from our analysis five participants who created more than one password by using the back button or reloading the password-creation page.

The condition with the highest dropout rate was 3class8-d, while the lowest dropout rate was telepath-v. Table 2 shows the dropout rates for each condition. It also gives the test's p-value for the null hypothesis (that the difference between dropout rates was unaffected by condition) for each pair of conditions. For example, at $p = 0.01$ (resp. $p = 0.007$) the difference in dropout rates between 3class8-d and 3class8 (resp. telepath-v) is significant. For all of the other condition pairs the hypothesis that condition had no effect on dropout rate is not ruled out. Note that the table has a triangular structure since we list the result of each pairwise test only once, and this same format is used for our other categorical tests (i.e. Tables 3, 4, 5, 6 and 7).

			Fisher's Exact Test p (Holm-Bonferroni corrected)				
Treatment	Part one dropout		telepath	3class12	basic8	3class8	telepath-v
3class8-d	67/469	14%	1.000	.458	.318	.010	.007
telepath	56/476	12%		1.000	1.000	.318	.255
3class12	47/472	10%			1.000	1.000	1.000
basic8	45/476	9%				1.000	1.000
3class8	35/475	7%					1.000
telepath-v	34/476	7%					

Omnibus χ^2_5=19.373, p=0.002

Table 2: The fraction of participants who dropped out during part one, with corrected pairwise comparisons of all treatment groups.

The median time spent to create a password was 32 seconds for participants in basic8, 43 for 3class8, 53 for both 3class12 and 3class8-d, 85 for telepath-v, and 96 for telepath. We anticipated participants using Telepathwords might spend more time, as these treatments included three lines of instructions not present in other treatments (see Figure 12) and their novelty may have led to more exploration.

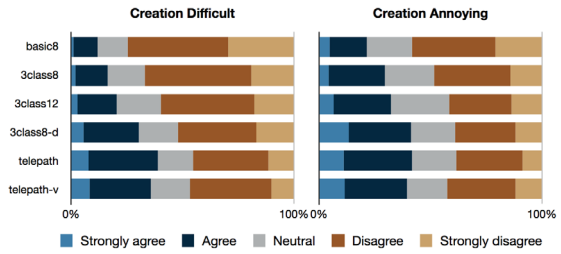

Figure 13: "Creating my password was difficult" and "Creating my password was annoying."

5.1 Recall

We provide recall rates for part one of the study for reference only, as just minutes had passed since participants had chosen their passwords. In the second section of Table 1, we see that 61.5% of participants indicated that they had not stored their password and that we had not detected them pasting or auto-filling a password into the recall field. Differences between treatment groups were not statistically significant (χ^2_5=9.231, p=0.1).

We looked at the number of part two recall attempts by the subset of participants who did not store their passwords, did not use the reminder feature, and did not re-use a previous password. Of these 502 participants, 79.3% entered the password on the first attempt, and 14.5% entered it on the second attempt. While the omnibus test shows a significant difference between conditions for taking more than one attempt (χ^2_5=13.943, p =0.016), the pairwise tests showed no significant differences. Among the 398 of these participants who entered their password correctly on the first attempt, the median password-entry time was 14.8 seconds; this did not vary significantly by condition (KW χ^2_5=4.705, p =0.453). Looking at the 1159 participants who did not use the reminder, 80.9% entered the password correctly on the first try. This differed by condition (χ^2_5=12.604, p =0.027), but no pairwise test was significant.

5.2 Participant Sentiment

In addition to recording participant behavior, we asked participants about their experience. We asked all participants whether they felt that creating their password was difficult or annoying, with results in Figure 13. We show the pairwise comparisons across conditions for difficulty in Table 3 and annoyance in Table 4.

The three policies that tested participants' passwords against lists of common passwords (the Telepathwords conditions and 3class8-d) had a greater proportion of participants who were annoyed than those using the purely composition-based policies. The differences with the simplest policies were significant, as shown in Table 4.

			Fisher's Exact Test p (Holm-Bonferroni corrected)				
Treatment	Creation difficult		telepath-v	3class8-d	3class12	3class8	basic8
telepath	163/420	39%	.374	.078	<.001	<.001	<.001
telepath-v	158/442	36%		.374	<.001	<.001	<.001
3class8-d	123/402	31%			.006	<.001	<.001
3class12	87/425	20%				.374	.005

Omnibus χ^2_5=61.805, p<.001

Table 4: The fraction of participants in each treatment who agreed that it was annoying to create the password during the experiment.

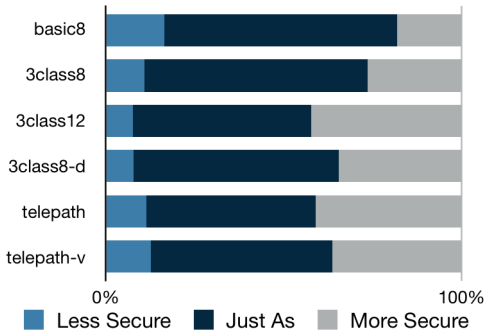

Figure 14: "When compared to the password I use for my primary email account, the password I created for this study was:".

We also asked participants whether they believed their study-created password to be more, less, or just as secure as their primary email password. The results are in Figure 14. Belief that the study passwords were more secure

Treatment	More Secure		Fisher's Exact Test p (Holm-Bonferroni corrected) telepath	telepath-v	3class8-d	3class8	basic8
3class12	180/425	42%	1.000	.329	.134	<.001	<.001
telepath	172/420	41%		.552	.309	<.001	<.001
telepath-v	161/442	36%			1.000	.013	<.001
3class8-d	139/402	35%				.075	<.001
3class8	116/440	26%					.027
basic8	78/431	18%					

Omnibus χ^2_5=83.62, p<.001

Table 5: The fraction of participants who selected "More secure" in response to "When compared to the password I use for my primary email account, the password I created for this study was:".

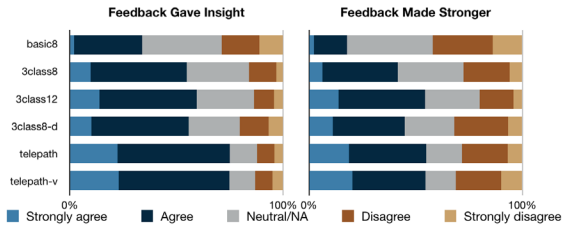

Figure 15: "The visual feedback I received gave me insight into the quality of my password" and "The visual feedback that was displayed helped me to create a stronger password that I would have otherwise."

ranged from 18.1% for basic8 to 42.4% for 3class12, and significant differences are in Table 5.

We displayed visual feedback in *all* conditions to help participants comply with their assigned policy. We asked participants if they believed the feedback gave them insight into their passwords and if it helped them to create better passwords. We show their responses in Figure 15 paired with significance tests in Tables 6 and 7.

The Telepathwords treatments, along with 3class12, had the greatest proportion of participants who believed the feedback helped them create a stronger password. A significantly larger portion of participants in the two Telepathwords conditions agreed that the feedback provided more insight than the other treatments—including the dictionary-based feedback in 3class8-d. This is tempered of course by the higher number who found password creation difficult or annoying with the tool. We see this as a hopeful sign that Telepathwords can help improve the credibility of technology designed to prevent users from choosing weak passwords.

Treatment	Gave Insight		Fisher's Exact Test p (Holm-Bonferroni corrected) telepath-v	3class12	3class8-d	3class8	basic8

5.3 Security Results

In Table 8 we present statistics summarizing the composition of passwords created under each policy, and security scores calculated by three metrics. We focus our analysis on the passwords identified to be weakest as an attacker is most likely to try these first. Dictionary attacks to obtain beachheads into organizations succeed when the first account is breached. Thus, improving the security of the weakest password in an organization by a small amount is far more likely to prevent an attacker from obtaining a beachhead than a large improvement to the average password would. This is particularly true for an online attack where a limited number of guesses per account can be tried.

We did not encounter any repeat passwords in our sample, so we cannot use frequency as a metric. Rather, the first metric we apply is an entropy calculation generated by the open-source `zxcvbn` password meter [30]. Its advantages are that it is publicly available, open-source, and already relied on by large-scale systems, including DropBox. Its primary disadvantage is that it was de-

signed to meet the constraints required for deployment as a client-side password meter; it needed to be small enough to download quickly and efficient enough to run in JavaScript. As such, it cannot perform the same level of computational analysis or apply the same body of knowledge as a tool designed for guessing.

The second metric we apply is a guess-number calculator developed by Saranga Komanduri, which first appeared in Kelley *et al.* [12, 25]. We call this metric Weir+ because it builds on the guessing approach of Weir et al. [29]. Its advantages are that it is designed with the explicit goal of measuring the number of guesses required to crack a password, can be trained to target specific password policies, and represents the state of the art in measuring strength against a guessing attack. The disadvantages of Weir+ include that it is available only by contacting the author, written in multiple programming languages, and has not been made easy to configure. Further, its results may vary based on the size and quality of the training data. In order to create a large training set of passwords that comply with the Telepathwords policies, we used the 133,109 passwords in the Yahoo! Voices breach data set that received a score of 6 hard-to-guess characters or more from Telepathwords, which represents 29% of the 453,488 passwords revealed by that breach.

Our final metric is the score provided by the current version of Telepathwords itself—the number of hard-to-guess characters. We find this informative for comparing treatments *other* than those that employ Telepathwords. The scores for participants in telepath and telepath-v are provided exclusively for completeness, as participants who were able to generate a password that met the Telepathwords policy will score well by default (though we note that two participants received a 5 due to a change to predictions from the version deployed during the experiment and the version used to calculate scores).

Regardless of metric, the telepath and telepath-v passwords do substantially better than all other conditions, with the possible exception of 3class8-d. We present the scores for each metric in Table 8.

For the `zxcvbn` entropy measure, we show in Figure 16 that telepath and telepath-v passwords outperform those from all other conditions for the weakest password in each condition and the weakest 2.5%, 5%, and 10% of passwords. Thus, Telepathwords did the best job of preventing weak passwords. Only when we consider the median entropy do 3class12 and 3class8-d become competitive. The improvement with respect to 3class8 and basic8 is enormous.

Figure 17 illustrates the Weir+ measurements. Again the two Telepathwords conditions show enormous improvement over basic8 and 3class8. They show considerable improvement over 3class12 on minimum entropy, and on entropy of the weakest 2.5%, 5%, and 10%. The 3class8-d condition is roughly comparable to the two Telepathwords conditions, except when we consider minimum entropy, where it does considerably worse.

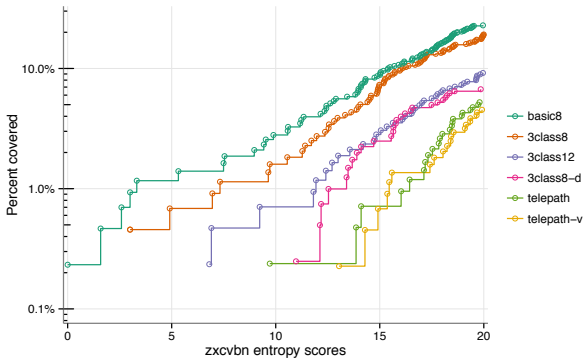

Figure 16: We sort the passwords in each condition by `zxcvbn`-entropy scores, from lowest to highest, and present the fraction of passwords with scores at or below a given value. Only passwords with entropy scores of 20 or less are shown in order to highlight the weakest passwords in each condition.

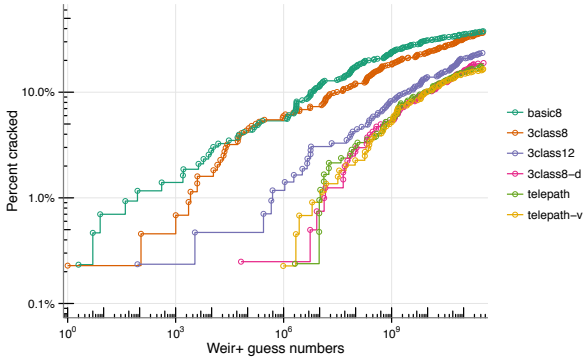

Figure 17: We sort the passwords in each condition by their Weir+ guess number, from lowest to highest, and present the fraction of passwords that with guess counts at or below a given number of guesses.

To substantiate further the impact of using Telepathwords and dictionary-based approaches, we present in Table 9 the weakest 2.5% of passwords according to each metric. For example, the weakest 2.5% under 3class8 contain such obvious and easily-guessed choices as `Password1` and `P@5sword`, which compare unfavorably with those in either of the Telepathwords conditions of 3class8-d.

		Mean characters per class				zxcvbn Entropy					Telepathwords score					Weir+ score			
	N	Upper	Lower	Digit	Symbol	Min	2.5%	5%	10%	Med	Min	2.5%	5%	10%	Med	Min	2.5%	5%	10%

telepath	420	1.0	7.0	2.5	0.6	9.7	17.9	19.7	22.4	32.0	5	6	6	6	7	21.0	26.1	29.3	33.0
telepath-v	441	1.1	7.0	2.7	0.5	13.0	18.4	20.4	22.4	32.8	6	6	6	6	7	19.9	27.4	29.9	33.2

Table 8: Security metrics of passwords created by participants. We show minimum and median zxcvbn and Telepathwords scores, along with percentiles selected to indicate the vulnerability of each condition to early guessing. We report Weir+ scores as the $\log_2$ of their guess numbers for comparison with entropy scores. We do not show median Weir+ scores as only basic8 reached 50% cracked in our analysis.

Table 9: The weakest 2.5% of passwords as scored by each metric (weakest at top). For the Telepathwords metric, the weakest passwords in the telepathwords conditions are not shown because there are too many passwords at the minimum score threshold to present here.

5.4 Limitations

All artificial experiments have limitations and ours was no exception. We make note of two such limitations.

Our study used a role-playing scenario to encourage users to create passwords. Participants playing roles may choose weaker passwords than they would for an account they value. They might also choose stronger passwords than they would for an account they didn't value. Schechter *et al.* [22] have shown that participants in security studies behave differently when the laboratory en-

vironment frees them from risk, and Fahl *et al.* [7] have shown a specific effect for choice of passwords. While limiting the interpretations of absolute scores, so long as these effects impact conditions equally, the methodology still facilitates cross-condition comparisons—the primary focus of the experiment. In fact, if our goal is to study the ability of technology to help unmotivated users choose better passwords, having participants who are less motivated than they would be in real-world conditions may be beneficial.

We measured recall over a short period of two to five days in a context where participants entered their password a few minutes after choosing it. In contexts in which users do not re-enter their passwords immediately after creating them, or in which they do not return for more than five days, they may be more likely to forget them. In contexts where users use their passwords more frequently after creating them, they may be less likely to forget them within two to five days. Had we selected different return periods we might have been more likely to see differences in recall rates.

6 Related Work

While some security practitioners simply hope that passwords, and their associated weaknesses, can be wished away, Bonneau *et al.* [3] have argued that passwords are not going away anytime soon. Password-composition rules date back at least to 1979, when Morris and Thompson reported on the predictability of the passwords used by users on their Unix systems; they proposed that passwords longer than four characters, or purely alphabetic passwords longer than five characters, will be "very safe indeed" [19]. Bonneau analyzed nearly 70 million passwords in 2012, 33 years later, to measure the impact of a six-character minimum requirement compared with no requirement [2]. He found that it made almost no difference in security. In a study of the distribution of password policies, Florêncio and Herley found that usability imperatives appeared to play at least as large a role as security among the 75 websites examined [8].

Early studies of proactive password-quality verification mechanisms includes the work of Spafford [26], who suggests an efficient method for storing a dictionary for checking. Bishop *et al.*, in 1995, suggested checking passwords for dictionary entries, user information, and other common patterns at password creation [1]. They also provided some statistics on these patterns in passwords. Weir *et al.* also examined password-composition rules by looking at samples of passwords [29]. These works did not look at passwords created under varying rules, however.

Microsoft Windows has enforced password-composition rules at least as far back as 2000, with the default requiring at least 8 characters from three of four character classes: uppercase, lowercase, digits, and others [17, 18]. One problem with the Windows implementation is that when Windows rejects a user's proposed password, it does not provide a list of the rules being enforced or identify specifically which rules the password is violating.

Many websites offer password meters that provide feedback on the strength of passwords as users type them. Based on a survey of the top 100 websites in 2012, most password meters use simple password-composition rules such as length and number of non-lowercase characters to determine when a password is good enough to reach the next level on the meter [28]. Egelman *et al.* [6] examined whether the presence of a password meter made any appreciable difference in password strength. They found that the meter made a difference when users were changing their password for an existing important account; but the meter had little effect when users were registering a new password for a low-importance account. Ur *et al.* also studied the effect of password-strength meters on password-creation. They found that when users became frustrated and lost confidence in the meter, more weak passwords appeared [28]. Very recently, de Carné de Carnavalet and Mannan [4] examined several password meters in use at popular websites and found gross inconsistencies, with the same password registering very different strength across different meters. Collectively, these findings are in line with our concern that password policies and meters may harm credibility and lead users to put less effort into choosing a good password.

One exception to the reliance on composition rules in password meters is `zxcvbn`, an open-source meter developed and used by DropBox, which uses a small language corpus to calculate entropy estimates in real time [30]. Designed to run entirely in the users' browser, it is written in JavaScript and compresses down to 320KB. While `zxcvbn` provides a much-needed improvement in the credibility of its strength estimates when compared to approaches relying solely on composition rules, this credibility is unlikely to be observed by users. In fact, its perceived credibility may suffer if users, who have been told that adding characters increases password strength, see scores decrease when certain characters are added. For example, when typing `iatemylunch`, the strength estimate decreases from the second-best score (3) to the worst score (1) when the final character is added. Even if users find `zxcvbn`'s strength estimates credible, they are unlikely to understand the underlying entropy-estimation mechanism and thus be unsure how to improve their scores. The advice `zxcvbn` offers, such as using inside jokes and unusual use of uppercase, could potentially

lead users to cluster around common strategies, yielding a set of new common passwords for attackers to guess.

Schechter *et al.* [21] offered another alternative to password-composition rules, suggesting a system that prevents users from choosing passwords popular among a large set of users. Another approach that seeks to limit dangerously common passwords was proposed by Malone and Maher [14]. These approaches, however, are most appropriate for systems with tens of millions of users, in which uniqueness is a strong indicator that a password is hard to guess. Relatively weak passwords may be unique among hundreds or thousands of user accounts.

The human-subjects experiment we perform in this work seeks to replicate the methodology used in prior password studies. Many of our choices in recruiting, question design, and the timing of the invitation to part two of the study reflect a desire to facilitate comparison with prior work. This includes the work of Komanduri *et al.* [13] and Kelley *et al.* [12], who used similar study designs to perform comparative analyses of password-composition rules. These prior studies found that increasing length requirements in passwords generally led to more usable passwords that were also less likely to be identified as weak by their guessing algorithm [13, 12]. Most recently, Shay *et al.* studied password-composition policies requiring longer passwords, finding the best performance came from mixing a 12-character minimum with a requirement of three character sets [25]. One key difference between our work and most prior studies is that all of our treatments provided feedback to users as they typed their passwords. With the exception of Ur *et al.*'s examination of meters providing optional guidance [28], all of these prior studies from Carnegie Mellon required participants to submit passwords *before* testing for, or providing feedback on, compliance with a policy.

A valuable use case for Telepathwords-based policies, which do not place any character-set requirements on passwords, is the affordance of creating all-lowercase passwords for easy entry on a touch screen. Jakobsson and Akavipat proposed a scheme for mobile devices that uses easily-typed passwords with auto-completion for easier password entry [11].

Fahl *et al.* [7] pointed out limitations in studies that use role-playing to generate passwords, as we do in this study. They find significant differences between passwords generated in these scenarios and real passwords. Komanduri *et al.* found that users created stronger passwords when asked to role-play, compared to when asked simply to create a password for a study [13]. Mazurek *et al.* used a methodology similar to ours and compared their results to genuine user passwords in a university [15]. They found that while the experimental passwords were slightly weaker than the genuine passwords, they were similar in many other respects.

7 Conclusion

Telepathwords provides users with significantly more insight into the quality of their passwords than all other approaches, and results in passwords stronger than approaches that do not use dictionaries. For example, the metrics suggest that to crack 1% of Telepathwords passwords, an attacker needs to make more than a factor of a thousand more guesses per password than for passwords created under the default password policy employed by Microsoft Windows Active Directory. While a higher number of users found password creation difficult or annoying using the tool, the security improvements did not come at any measurable impact to memorability.

Towards reliable storage of 56-bit secrets in human memory

Joseph Bonneau
Princeton University

Stuart Schechter
Microsoft Research

Abstract

Challenging the conventional wisdom that users cannot remember cryptographically-strong secrets, we test the hypothesis that users can learn randomly-assigned 56-bit codes (encoded as either 6 words or 12 characters) through *spaced repetition*. We asked remote research participants to perform a distractor task that required logging into a website 90 times, over up to two weeks, with a password of their choosing. After they entered their chosen password correctly we displayed a short code (4 letters or 2 words, 18.8 bits) that we required them to type. For subsequent logins we added an increasing delay prior to displaying the code, which participants could avoid by typing the code from memory. As participants learned, we added two more codes to comprise a 56.4-bit secret. Overall, 94% of participants eventually typed their entire secret from memory, learning it after a median of 36 logins. The learning component of our system added a median delay of just 6.9 s per login and a total of less than 12 minutes over an average of ten days. 88% were able to recall their codes exactly when asked at least three days later, with only 21% reporting having written their secret down. As one participant wrote with surprise, "the words are branded into my brain."

1 Introduction

Humans are incapable of securely storing high-quality cryptographic keys . . . they are also large, expensive to maintain, difficult to manage, and they pollute the environment. It is astonishing that these devices continue to be manufactured and deployed. But they are sufficiently pervasive that we must design our protocols around their limitations.

—Kaufman, Perlman and Speciner, 2002 [54]

The dismissal of human memory by the security community reached the point of parody long ago. While assigning random passwords to users was considered standard as recently in the mid-1980s [26], the practice died out in the 90s [4] and NIST guidelines now presume all passwords are user-chosen [32]. Most banks have even given up on expecting customers to memorize random four-digits PINs [22].

We hypothesized that perceived limits on humans' ability to remember secrets are an artifact of today's systems, which provide users with a single brief opportunity during enrolment to permanently imprint a secret password into long-term memory. By contrast, modern theories of the brain posit that it is important to *forget* random information seen once, with no connection to past experience, so as to avoid being overwhelmed by the constant flow of new sensory information [10].

We hypothesized that, if we could relax time constraints under which users are expected to learn, most could memorize a randomly-assigned secret of 56 bits. To allow for this memorization period, we propose using an alternate form of authentication while learning, which may be weaker or less convenient than we would like in the long-term. For example, while learning a strong secret used to protect an enterprise account, users might be allowed to login using a user-chosen password, but only from their assigned computer on the corporate network and only for a probationary period. Or, if learning a master key for their password manager, which maintains a database of all personal credentials, users might only be allowed to upload this database to the network after learning a strong secret used to encrypt it.

By relaxing this time constraint we are able to exploit *spaced repetition*, in which information is learned through exposure separated by significant delay intervals. Spaced repetition was identified in the 19$^{\text{th}}$ century [43] and has been robustly shown to be among the most effective means of memorizing unstructured information [35, 11]. Perhaps the highest praise is its popularity amongst medical students, language learners, and others who are highly motivated to learn a large amount of vocabulary as efficiently as possible [34, 91].

To test our hypothesis, we piggybacked spaced repeti-

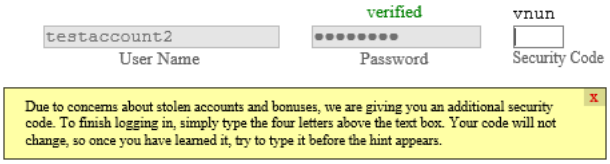

Figure 1: The login form for a user logging in for the first time, learning a code made of *letters*.

tion of a new random secret onto an existing login process utilizing a user-chosen password. Our system can be seen in action in Figure 1. After receiving a user's self-chosen password, we add a new field into which they must type a random security code, which we display directly above this field. With each login we add a $\frac{1}{3}$ second delay (up to a maximum of 10 seconds) before displaying the hint for them to copy, encouraging them to type the code from memory if possible to save time.

We recruited remote research participants to perform a study that required logging into a website 90 times over up to 15 days, which they did at an average rate of nine logins per day. We assigned each participant a random 56-bit 'security code' encoded into three chunks of either four lowercase letters or two words. After participants began to enter the first chunk before it was displayed, we added a second and likewise for the third and final chunk. We did not tell participants that learning the random secret was a goal of the research study; they simply learned it to save time. Participants experienced a median additional delay from using our system of just 6.9 s on each login, or about 11 m 53 s total over the entire study.

Three days after participants completed the initial study and had stopped using their security codes, we asked them to recall their code from memory in a follow-up survey which 88% completed. They returned after a median of 3 days 18 hours (mean 4 days 23 hours). We found that 46 of 56 (82%) assigned *letters* and 52 of 56 (93%) assigned *words* recalled their codes correctly. Only 21% reported writing down or otherwise storing the security codes outside their memory and the recall rate was actually higher amongst those who didn't.

While 56-bit secrets are usually overkill for web authentication, the most common use of passwords today, there are several compelling applications for "high value" passwords such as master passwords for password managers, passwords used to protect private keys, device-unlock passwords, and enterprise login passwords where cryptographically-strong passwords can eliminate an entire class of attack. In debunking the myth that users are inherently incapable of remembering a strong secret, we advocate that using spaced repetition to train users to remember strong secrets should be available in every security engineer's toolbox.

2 Security goals

Evaluating the difficulty of guessing user-chosen passwords is messy [56] and security engineers are left with few hard guarantees beyond empirical estimates of min-entropy, which can be as low as 10 bits or fewer [18]. By contrast, with random passwords we can easily provide strong bounds of the difficulty of *guessing*, if not other attack vectors against passwords [20].

2.1 The cost of brute-force

Random passwords are primarily a defense against an *offline attack* (eq. *brute-force attack*), in which the attacker is capable of trying as many guesses as they can afford to check computationally. We can estimate the cost of brute-force by observing the Bitcoin network [3], which utilizes proof-of-work with SHA-256 to maintain integrity of its transaction ledger and hence provides direct monetary rewards for efficient brute force. While SHA-256 is just one example of a secure hash function, it provides a reasonable benchmark.

In 2013, Bitcoin miners collectively performed $\approx 2^{75}$ SHA-256 hashes in exchange for bitcoin rewards worth $\approx$ US$257M. This provides only a rough estimate as Bitcoin's price has fluctuated and Bitcoin miners may have profited from carrying significant exchange-rate risk or utilizing stolen electricity. Still, this is the only publicly-known operation performing in excess of 2^{64} cryptographic operations and hence provides the best estimate available. Even assuming a centralized effort could be an order of magnitude more efficient, this still leaves us with an estimate of US$1M to perform a 2^{70} SHA-256 evaluations and around US$1B for 2^{80} evaluations.

In most scenarios, we can gain equivalent security with a smaller secret by *key stretching*, deliberately making the verification function computationally expensive for both the attacker and legitimate users [66, 57]. Classically, this takes the form of an iterated hash function, though there are more advanced techniques such as memory-bound hashes like `scrypt` [69] or halting password puzzles which run forever on incorrect guesses and require costly backtracking [25].

With simple iterated password hashing, a modern CPU can compute a hash function like SHA-256 at around 10 MHz [1] (10 million SHA-256 computations per second), meaning that if we slow down legitimate users by ≈ 2 ms we can add 14 bits to the effective strength of a password, and we can add 24 bits at a cost of ≈ 2 s. While brute-forcing speed will increase as hardware improves [38], the same advances enable defenders to continuously increase [72] the amount of stretching in use at constant real-world cost [19], meaning these basic numbers should persist indefinitely.

2.2 Practical attack scenarios

Given the above constraints, we consider a 56-bit random password a reasonable target for most practical scenarios, pushing the attacker cost around US$1M with 14 bits (around 2 ms) of stretching, or US$1B with 24 bits (around 2 s) of stretching. Defending against offline attacks remains useful in several scenarios.

Password managers are a compelling aid to the difficulty of remembering many passwords online, but they reduce security for all of a user's credentials to the strength of a master password used to encrypt them at rest. In at least one instance, a password management service suffered a breach of the systems used to store users' data [63]. Given that password managers only need to decrypt the credentials at startup, several seconds of stretching may be acceptable.

Similarly, when creating a public/private key pair for personal communication, users today typically use a password to encrypt the private key file to guard against theft. Given a sufficiently strong random password, users could use their password and a unique public salt (e.g., an email address) to seed a random number generator and create the keys. The private key could then simply be rederived when needed from the password, preventing the need for storing the private key at all. This application also likely tolerates extensive stretching.

Passwords used to unlock personal devices (e.g. smartphones) are becoming increasingly critical as these devices are often a second factor (or sole factor) in authentication to many other services. Today, most devices use relatively weak secrets and rely on tamper-proof hardware to limit the number of guesses if a device is stolen. Strong passwords could be used to remove trust in device hardware. This is a more challenging application, however. The budget for key-stretching may be 14 bits or fewer, due to the frequency with which users authenticate and the limited CPU and battery resources available. Additionally, entering strong passwords quickly on a small touchscreen may be prohibitive.

Finally, when authenticating users remotely, such as logging into an enterprise network, security requirements may motivate transitioning from user-chosen secrets to strong random ones. Defending against *online guessing*, in which the attacker must verify password guesses using the genuine login server as an oracle, can be done with far smaller random passwords. Even without explicit rate-limiting, attacking a 40-bit secret online would generate significantly more traffic than any practical system routinely handles. 40-bit random passwords would ensure defense-in-depth against failures in rate-limiting.

Alternately, attackers may perform an offline attack if a remote authentication server is breached. In general, we would favor back-end defenses against password database compromises which don't place an additional burden on users—such as hashing passwords with a key kept in special-purpose hardware, dividing information up amongst multiple servers [52] or one limited-bandwidth server [41]. Random passwords would also frustrate brute-force in this scenario, although the opportunity for key-stretching is probably closer to the 2 ms (14 bit) range to limit load on the login server.

3 Design

Given our estimation that a 56-bit secret can provide acceptable security against feasible brute-force attacks given a strong hash function and reasonable key stretching, our goal was to design a simple prototype interface that could train users to learn 56 bits secret with as little burden as possible.

Spaced repetition [43, 70, 62] typically employs delays (spacings) of increasing length between rehearsals of the chunk of information to be memorized. While precisely controlling rehearsal spacing makes sense in applications where education is users' primary goal, we did not want to interrupt users from their work. Instead, we chose to piggyback learning on top of an already-existing interruption in users' work-flow—the login process itself. We allow users to employ a user-chosen password for login, then piggyback learning of our assigned secret at the end of the login step. We split the 56-bit secret up into three equal-sized chunks to be learned sequentially, to enable a gradual presentation and make it as easy as possible for users to start typing from memory.

3.1 Encoding the secret

Although previous studies have found no significant differences in user's ability to memorize a secret encoded as words or letters [77, 64], we implemented both encodings. For *letters*, we used a string of 12 lowercase letters chosen uniformly at random from the English alphabet to encode a $26^{12} \approx 56.4$ bit secret. The three chunks of the secret were 4 letters each (representing ≈ 18.8 bits each).

For *words*, we chose a sequence of 6 short, common English words. To keep security identical to that of the *letters* case, we created our own list of 676 (26^2) possible words such that 6 words chosen uniformly at random would encode a $676^6 = 26^{12} \approx 56.4$ bit secret. We extracted all 3–5 English nouns, verbs and adjectives (which users tend to prefer in passwords [24, 85]) from Wiktionary, excluding those marked as vulgar or slang words and plural nouns. We also manually filtered out potentially insulting or negative words. From these candidate words we then greedily built our dictionary of 676 words by repeatedly choosing the most common remaining word, ranked by frequency in the Google N-gram

web corpus [27]. After choosing each word we then removed all words within an edit distance of two from the remaining set of candidates to potentially allow limited typo correction. We also excluded words which were a complete prefix of any other word, to potentially allow auto-complete. We present the complete list in Table 3.

3.2 Login form and hinting

Unlike typical login forms, we do not present a button to complete sign-in, but rather automatically submit the password for verification via AJAX each time a character is typed. Above the password field we display the word "verifying" while awaiting a response and "not yet correct" while the current text is not the correct password.

After the user's self-chosen password is verified, a text box for entering the first chunk of the user's assigned code appears to the right of the password field, as we show in Figure 1. On the first login, we display the correct value of the chunk immediately above the field into which users must enter it. In the version used for our study, we included a pop-up introducing the security code and its purpose:

> Due to concerns about stolen accounts and bonuses, we are giving you an additional security code. To finish logging in, simply type the [four letters | two words] above the text box. Your code will not change, so once you have learned it, try to type it before the hint appears.

We color each character a user enters into the security code field green if it is correct and red if incorrect. We replace correct characters with a green circle after 250 ms.

With each consecutive login, we delay the appearance of the hint by $\frac{1}{3}$ of a second for each time the user has previously seen the chunk, up to a maximum of 10 seconds. If the user types a character correctly before the delay expires, we start the delay countdown again. We selected these delay values with the goal of imposing the minimal annoyance necessary to nudge users to start typing from memory.

After a user enters a chunk without seeing the hint on three consecutive logins, we add another chunk. In the version used in our study, we show a pop-up which can be dismissed for all future logins:

> Congratulations! You have learned the first [four letters | two words] of your security code. We have added another [four letters | two words]. Just like the first [four letters | two words], once you have learned them, you can type them without waiting for the hint to appear.

When we detect that a user has finished typing the first chunk of their security code, we automatically tab (moved the cursor) to the text field for the second chunk and then start the delay for that chunk's hint. After typing the second chunk correctly from memory three times

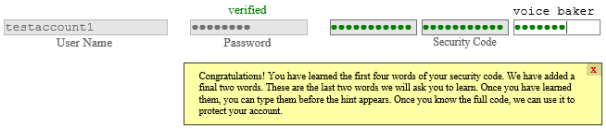

Figure 2: The login form for a user in who has just received the third security code chunk *words*.

in a row, we add the third and final chunk. In the version used in the study, we also displayed one more pop-up:

> Congratulations! You have learned the first [eight letters | four words] of your security code. We have added a final [four letters | two words]. These are the last [four letters | two words] we will ask you to learn. Once you have learned them, you can type them before the hint appears. Once you know the full code, we can use it to protect your account.

We illustrate the login process from our study, using all three chunks, in Figure 2. In a real deployment, once the user is consistently typing the entire security code from memory, entering their self-chosen password would no longer be necessary.

We disable pasting and automatic form-filling for the security code field to encourage users to type from memory. We allow users to type their code in lower or upper case, with all non-letter characters being ignored, including spaces between words as no word is a prefix of any other word. During training we automatically insert a space at the end of any entered code word so users learn that they do not need to type the spaces.

4 Experimental Methodology

We used a remote online study to evaluate our system. To keep participants from realizing the purpose of our study was the security codes and potentially altering their behavior, we presented our study as a psychology study with the security codes a routine part of logging in to participate. We recruited participants using Amazon's Mechanical Turk (MTurk) platform [59] and paid them to participate, which required logging in 90 times in 15 days. For completeness, we provide exact study materials the extended version of this paper [23].

4.1 The distractor task

We intended our distractor task to provide a plausible object of study that would lead us to ask participants to log in to our website repeatedly (distracting participants from the subject of our investigation) and to require a non-trivial mental effort (distracting them from making conscious efforts to memorize their security codes). Yet we also wanted the distractor task to be relatively fast,

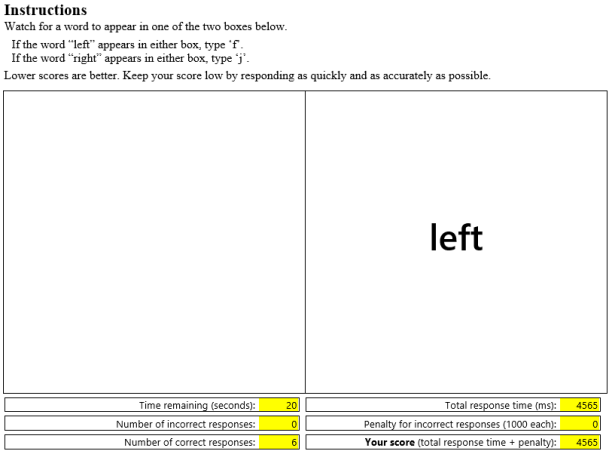

Figure 3: The Attention Game, our distractor task

interesting, and challenging, since we were asking participants to perform a large number of logins.

We designed a game to resemble descendants of the classic psychological study that revealed the Stroop effect [79]. Our game measured participants' ability to ignore where a word appeared (the left or right side of their screen) and respond to the meaning of the word itself. Each 60-second game consisted of 10 trials during which either the word 'left' or 'right' would appear in one of two squares on the screen, as illustrated in Figure 3. The words appeared in a random square after a random delay of 2–4 seconds, after which participants were asked to immediately press the `f` key upon seeing the word 'left' or `j` key upon seeing the word 'right' (corresponding to the left and right sides of a QWERTY keyboard). During the game, participants saw a score based on their reaction time, with penalties for pressing the wrong key.

4.2 Treatments

We randomly assigned participants to three treatments: *letters* (40% of participants), *words* (40%), and *control* (20%). Participants in the *letters* and *words* treatments received security codes consisting of letters and words, respectively, as described in Section 3.1. Participants in the *control* treatment received no security code at all and saw a simple password form for all logins; we included this treatment primarily to gauge whether the additional security codes were causing participants to drop out of the experiment more than traditional authentication would have.

4.3 Recruiting

We recruited participants to our study using Amazon's Mechanical Turk by posting a Human Intelligence Task (HIT) titled "60-Second Attention Study", paying US$0.40, and requiring no login. When participants completed the game, we presented them with an offer to "Earn $19 by being part of our extended study" (a screenshot of the offer is in the extended version of this paper [23]). The offer stated that participants would be required to play the game again 90 times within 15 days, answer two short questions before playing the game, wait 30 minutes after each game before starting a new game session, and that they would have to login for each session. We warned participants that those who joined the extended study but did not complete it would not receive partial payment. Our study prominently listed Microsoft Research as the institution responsible for the study. As we did not want to place an undue burden on workers who were not interested in even reading our offer, we provided a link with a large boldface heading titled "Get paid now for your participation in this short experiment" allowing participants to be paid immediately without accepting, or even reading, our offer.

When workers who had performed the single-game HIT signed up to participate in our 90-game attention study, we presented them with a sign-up page displaying our approved consent form and asking them to choose a username and a password of at least six characters. For the 88 logins following signup (games 2–89), and for login to the final session (in which we did not show the game but instead showed the final survey), we required participants to login using the chosen password and security code (if assigned a non-*control* treatment).

Amazon's policies forbid HITs that require workers to sign up for accounts on websites or to provide their email addresses. These rules prevent a number of abusive uses of Mechanical Turk. They also protect Amazon's business by forbidding requesters from recruiting workers, establishing a means of contact that bypasses Amazon, and then paying hired workers for future tasks without paying Amazon for its role in recruiting the workers. Our HIT was compliant with the letter of these rules because we only required workers to play the attention game, and they were in no way obligated to sign up for the full attention study. We were also compliant with the spirit of the rules, as we were not asking workers to engage in abusive actions and we did not cut Amazon out of their role as market maker—we paid participants for the 90-game attention study by posting a bonus for the HIT they already completed through Amazon.

As in any two-week project, some participants requested extensions to the completion deadline in order to reach 90 completed game. We provided 24-hour extensions to participants who were within 20 games of completing the study at the deadline.

How long has it been since you last slept for at least one hour without interruption?

Please indicate if you have consumed any of the following within the last 60 minutes:

- ☐ Food
- ☐ Beverages
- ☐ Caffeinated substances such as coffee or soft drinks
- ☐ Energy drinks other than caffeine

Figure 4: Participants were asked to fill out this two-question survey before every attention game.

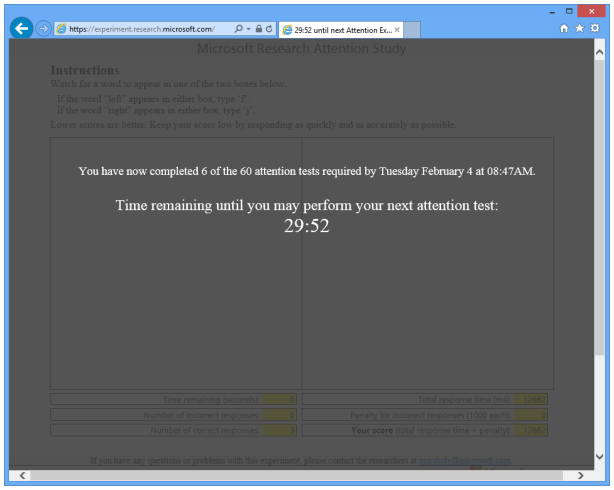

Figure 5: After completing an attention test, participants could not perform another one for 30 minutes.

4.4 Sessions

After each login we presented a very short survey (shown in Figure 4) asking participants about their recent sleep and eating. This was designed solely to support the purported goal of the study and we ignored the responses.

After participants completed the survey we immediately displayed the "Attention Game". When they completed the game, we overlaid a timer on top of the page counting down 30 minutes until they could again fill out the survey and play the game (see Figure 5). The timer also counted down in the title of the page, so that participants would see the countdown when browsing in other tabs and know when they were next allowed to play. If participants tried to log into the website again before the 30-minute waiting period was complete, we displayed the countdown again, starting from the amount of time remaining since they last completed the game.

4.5 Completion survey

When participants logged in for the 90th and final time, we skipped the game and displayed our completion survey. We provide the full text of the survey (with participants' answer counts) in the extended version of this paper [23]. We started the survey with demographic questions and then asked participants if they had written down or stored their passwords or assigned security codes outside of their memory.

We then debriefed participants about the true nature of the study, explaining that the security code was the focus of the study, though we did not reveal that we planned a follow-up study. We could not defer the debriefing to the follow-up study, as participants had not committed to engage with us beyond the end of the study and might not accept invitations for future contact. Indeed, some participants reported discussing the study in forums, but as we had entrusted those who finished the study with the truth, they returned that trust by respecting forum rules against 'spoilers' in all cases we are aware of.

To aid with the follow-up study, we asked participants to provide their email address, stating the question in a manner that we hoped would minimize suspicion that a formal follow-up study was imminent.

> If our analysis raises more questions about your experience during the study, may we contact you and ask you to answer a few questions in return for an additional bonus? If so, provide your email below. (This is optional!)

4.6 Payment

We paid $20 to participants who completed the study, as opposed to the $19 promised, to show extra gratitude for their participation. We informed participants of this only *after* they had completed the 'attention' study and filled out their post-deception ethics questionnaire, so as to not taint their responses about the ethics of the deception. However, this payment came well before the invitation to the follow-up study. Receiving a payment exceeding what we had promised may have increased participants' receptiveness to that invitation.

Despite telling participants they would not be paid unless they completed the study, we did pay $0.20 per login to all participants who logged into the site at least once after signing up. We did so because we couldn't be certain that the extra work of entering a security code didn't cause some participants to drop out. We wanted to ensure that if participants found the security code so arduous as to quit, they would not lose out on payment for the attention tests they did complete. We did not reveal this fact to the participants who completed the study and filled out the ethics survey as we feared they might communicate it to those who had yet to finish.

4.7 Follow-ups

At least 72 hours after a non-control group participant completed the study, we emailed them an invitation to perform an additional HIT for $1 (this email is reproduced in the extended version of this paper [23]). Most

participants provided an email address in the final survey of the attention study; we tried to contact those who didn't via Mechanical Turk. When participants accepted the HIT, we identified them by their Mechanical Turk ID to verify that they'd participated in the main study.[1]

The follow-up study contained only one question:

> Please try to recall and enter the security code that we assigned you during the attention study.
> **If you stored or wrote down your security code, please do not look it up.** We are only interested in knowing what you can recall using *only your memory*. It's OK if you don't remember some or all of it. Just do the best you can.

We presented participants with three text fields for the three chunks of their security code. Unlike the data-entry field used when they logged in for the attention experiment, we used plain text fields without any guidance as to whether the characters typed were correct. We accepted all responses from participants that arrived within two weeks of their completion of the study.

We emailed all participants who completed the first follow-up again 14 days after they completed it with the offer to complete a second identical follow-up for an additional $1 reward.

4.8 Ethics

The experiment was performed by Microsoft Research and was reviewed and approved by the organizations's ethics review process prior to the start of our first pilot.[2]

We employed deception to mask the focus of our research out of concern that participants might work harder to memorize a code if they knew it to be the focus of our study. We took a number of steps to minimize the potential for our deception to cause harm. We provided participants with estimates for the amount of time to complete the study padded to include the unanticipated time to enter the security code. While we told participants they would not be paid if they did not complete the study, we did make partial payments. We monitored how participants responded to the deception, investigating the responses of pilot participants before proceeding with the full study and continued to monitor participants in the full study, using a standard post-deception survey hosted by the Ethical Research Project [82]. We also offered participants the opportunity to withdraw their consent for use data derived from their participants. The vast majority of participants had no objection to the deception and none asked to have their data withdrawn. We provide more detail on participants' ethics responses in the extended version of this paper [23].

[1] We failed to verify that it had been three days since they completed the study, requiring us to disqualify three participants who discovered the follow-up study prematurely (see Section 5.1).

[2] The first author started a position at Princeton after the research was underway. He was not involved in the execution of the study or communications with participants. He did not have access to the email addresses of those participants who volunteered to provide them (the only personally-identifiable information collected).

5 Results

We present overall analysis of the most important results from our study: participant's ability to learn and recall security codes. We present a full accounting of participants' responses to the multiple-choice questions of our final survey and the complete text of that survey in the extended version of this paper [23], including demographics which reflect the typical MTurk population [74].

5.1 Recruitment and completion

We offered our initial attention-game task to roughly 300 workers from February 3–5, 2014. 251 workers accepted the offer to participate in our study by completing the sign-up page and playing the first game. We stopped inviting new participants when we had reached roughly 100 sign-ups for our two experimental groups. Participants' assigned treatment had no effect until they returned after sign-up and correctly entered their username and chosen password into the login page, so we discard the 28 who signed up but never returned. We categorize the 223 participants who did return in Table 1.

5.1.1 Dropouts

Inserting a security-code learning step into the login process creates an added burden for participants. Of participants who completed the study, typing (and waiting for) the security codes added a median delay of 6.9 s per login. To measure the impact of this burden, we tested the hypothesis that participants assigned a security code would be less likely to complete the experiment than those in the *control*. The null hypothesis is that group assignment has no impact on the rate of completion.

Indeed, the study-completion rates in the fourth row of Table 1 are higher for *control* than the experimental groups. We use a two-tailed Fisher's Exact Test to compare the proportion of participants who completed the study between those assigned a security code (the union of the *letters* and *words* treatments, or 133 of 170) to that of the *control* (35 of 41). The probability of this difference occurring by chance under the null hypothesis is $p = 0.2166$. While this is far from the threshold for statistical significance, such a test cannot be used to reject the alternate hypothesis that the observed difference reflects a real percentage of participants who dropped out due to the security code.

Digging into the data further, we can separate out those participants who abandoned the study after exactly

	Control		*Letters*		*Words*		*Total*	
Signed up for the 'attention' study	41		92		90		223	
Quit after 2 or 3 games	0/41	0%	9/92	10%	12/90	13%	21/223	9%
Otherwise failed to finish	6/41	15%	14/92	15%	12/90	13%	32/223	14%
Completed the 'attention' study	35/41	85%	69/92	75%	66/90	73%	170/223	76%
Received full security code	—		63/68	93%	64/65	98%	127/133	95%
Typed entire code from memory	—		62/63	99%	64/64	100%	126/127	99%
Participated in first follow-up	—		56/63	89%	56/64	88%	112/127	88%
Recalled code correctly	—		46/56	82%	52/56	93%	98/112	88%
Participated in second follow-up	—		52/56	93%	52/56	93%	104/112	93%
Recalled code correctly	—		29/52	56%	32/52	62%	61/104	59%

Table 1: Results summary: participants who signed up for the attention study, the fraction of those participants who completed the study, the fraction of the remaining participants who entered the first two chunks of their security code reliably enough to be shown the full security code (all three chunks), the fraction of those remaining who participated in the follow-up studies (after 3 and 17 days, respectively), and the fraction of those who recalled their security code correctly. The *control* group did not receive security codes and hence are excluded from the latter rows of the table.

two or three games from those who failed to finish later (no participant quit after the fourth or fifth games). While no participant in the *control* quit between two or three games, 9 participants assigned to *letters* and 12 assigned to *words* did. For participants who completed more than three games, the rate of failure to finish the study is remarkably consistent between groups. We do not perform statistical tests as this threshold is data-derived and any hypothesis based on it would be post-hoc. Rather, as our study otherwise presents a overall favorable view of random assigned secrets, we present the data in this way as it illustrates to the reader reason for skepticism regarding user acceptance among unmotivated participants.

5.1.2 Participants who appeared not to learn

Six participants completed the study without receiving all three chunks of their security codes, having failed to demonstrate learning by typing the first chunk (one participant from *letters*) or second chunk (five participants, four from *letters* and one from *words*) before the hint appeared. After the conclusion of the study we offered participants $1 to provide insights into what had happened and all replied. Two in the *letters* group, including the one who only received one chunk, reported genuine difficulty with memory. The other four stated quite explicitly (which we provide in the extended version of this paper [23]) that they purposely avoided revealing that they had learned the second chunk to avoid being assigned more to learn.

5.1.3 Excluded participants

We found it necessary to exclude four participants from some of our analysis. Three participants, two in *words* and one in *letters*, discovered and accepted the follow-up HIT before three days had passed since the end of the study, ignoring the admonition not to accept this HIT without an invitation. Though these participants all completed the 90-game attention study, learned and recalled their entire security code, we count them as having not returned for the follow-up. We corrected this bug prior to the second follow-up. We disqualified one additional 'participant' in the *letters* group which appeared to be using an automated script.

After revealing the deceptive nature of the study we gave participants the option to withdraw their consent for us to use our observations of their behavior, while still receiving full payment. Fortunately, none chose to do so.

5.2 Learning rates

Of non-*control* participants completing the study, 93% eventually learned their full security code well enough to type it from memory three times in a row (91% of *letters* and 96% of *words*). Most participants learned their security codes early in the study, after a median of 36 logins (37 for *letters* and 33 of *words*). We show the cumulative distribution of when participants memorized each chunk of their code in Figure 6.

We consider whether participants first typed their codes from memory in fewer logins with either *letters* or *words*, with the null hypothesis that encoding had no impact on this measure of learning speed. A two-tailed Mann-Whitney U (rank sum) test on the distribution of these two sets of learning speeds estimates a probability of $p = 0.07$ ($U = 1616$) of observing this difference by chance, preventing us from rejecting the null hypothesis.

We had hypothesized that, with each subsequent chunk we asked participants to memorize, their learn-

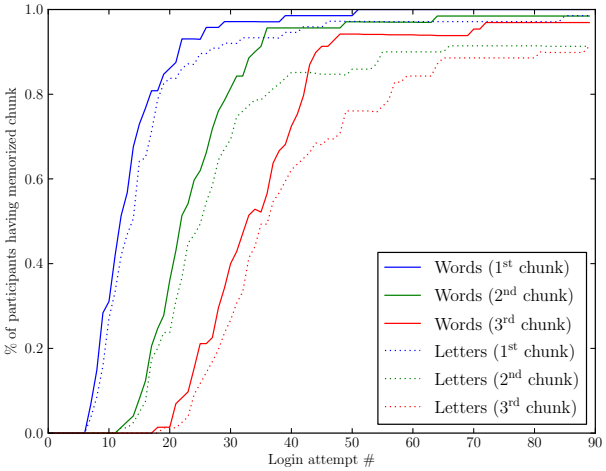

Figure 6: We show the proportion of participants who had memorized each chunk of their security code after a given number of login attempts. We considered a participant to have memorized a chunk after they entered it without a hint in three consecutive logins.

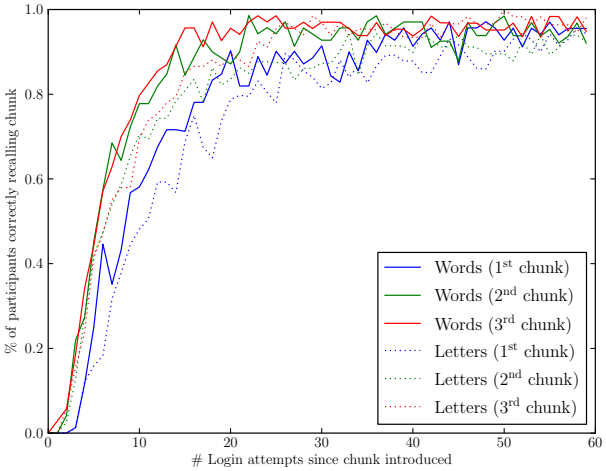

Figure 7: For each of the three chunks in participants' security codes, we show the proportion of participants who entered each chunk without a hint as a function of the number of previous exposures to the chunk (the number of previous logins in which the chunk appeared). On the whole, participants actually memorized their second and third chunks more quickly than the first.

ing speed might decrease due to interference [31] or increase due to familiarity with the system. Learning times decreased. We use a Mann-Whitney U test to compare learning times between the first and final chunks, using times only for participants who learned all three, yielding a significant $p < 0.001$ ($U = 4717$). To remove the impact of the time required to notice the delay and learn that they could enter the code before it appeared, we compare the learning times between the third and second chunks. This difference is much smaller, with a Mann-Whitney U test yielding a probability of $p = 0.39$ ($U = 7646$) of an effect due to chance.

To illustrate the increasing rate of learning we show, in Figure 7, the percent of participants who typed each chunk correctly from memory as a function of the number of previous exposures to that chunk.

5.3 Login speed and errors

Overall, participants in the *words* group took a median time of 7.7 s to enter their security codes, including waiting for any hints to appear that they needed, and participants in the *letters* group took a median time of 6.0 s. Restricting our analysis to those logins in which participants were required to enter all three chunks of the code only increases the median login time to 8.2 s for *words* and 6.1 s for *letters*.[3] The distribution had a relatively long tail, however, with the 95th percentile of logins taking 23.6 s for *words* and 20.5 s for *letters*.

[3]The median login time actually went down for *letters* participants when all three chunks were required, likely because this included more logins typed exclusively from memory with no waiting for a hint.

After computing the median login time for each participant, we compared the set of these values for participants in the two experimental groups using a Mann-Whitney U. We can reject the null hypothesis that the differences between these medians were the result of chance with $p < 0.01$ ($U = 1452$) and conclude that participants in the *letters* group were significantly faster.

Errors in entering security codes (whether typos or genuine memory errors) were relatively rare: over all 90 logins participants in the *words* group made fewer errors (with a median of 5) than participants in the *letters* group (median 7). Using a Mann-Whitney U, we cannot reject the null hypothesis that neither group would make more errors than the other ($p = 0.08$ ($U = 1706$)).

5.4 Recall of security codes in follow-ups

We sent invitations to participants to follow-up studies testing recall of their security codes 3 days after the initial study ended and then 14 more days after they completed the first follow-up. The median time between when participants completed the study and actually took the first follow-up study was 3 days 18 hours (mean 4 days 23 hours). For the second follow-up study the median time was 16 days 0 hours (mean 16 days 13 hours). By comparison, the median time to complete the study itself was 10 days 5 hours (mean 9 days 19 hours).

Overall, 88% of participants recalled their code correctly in the first follow-up and 59% did so in the second. The drop-off at the second follow-up was expected

as memory is believed to decay exponentially with the delay since the information was last recalled [89].

We had hypothesized that participants in the *letters* treatment might be more or less likely to recall their security codes correctly in the follow-ups than participants in the *words* treatment. As seen in Table 1, of participants in the *letters* group 82% recalled their security codes correctly in the first follow-up and 56% did so in the second study, compared to 93% and 62%, respectively, of users in *words*. Using a two-tailed Fisher's Exact Test, we cannot rule out the null hypothesis that participants in either group were equally likely to recall codes correctly, with the observed differences occurring with a $p = 0.15$ chance in the first follow-up and $p = 0.45$ in the second follow-up under the null hypothesis.

5.4.1 Types of errors

We observed 14 participants incorrectly entering their code in the first follow-up and 52 in the second. All 13 users who entered incorrectly in the first follow-up and participated in the second entered their code incorrectly again. This sample is too low to draw firm conclusions about the nature of participants' recall errors, but we did see evidence that users retained partial memory, with 75% of users entering at least one component of their code correctly in the second follow-up and 48% missing only one component or entering components in the wrong order. Re-arranging the order of components, which accounted for 10% of errors, could be corrected by accepting components in any order at a loss of only $\log_2(3!) \approx 2.6$ bits of security. Unfortunately, the majority of other errors could not be corrected without significantly downgrading security. Only 3 participants (6%) in the second-followup (and 2 in the first) entered a code within an edit distance of 2 of the correct code. We present further information on the types of errors observed in the extended version of this paper [23].

5.4.2 Storing security codes

A minority of participants reported storing their security code outside of their memory, as presented in Table 2. We were concerned that participants who had stored their security codes might have been tempted to look them up and thereby inflated the recall rate during the follow-up. However, only 82% of participants storing their security code recalled it correctly on follow-up, whereas 89% of participants not storing the security code did. While it's possible that participants who did not rely on a stored code were better able to remember as a result, we had not hypothesized this in advance nor would the differences we observed have been statistically significant.

We had hypothesized that participants might be more likely to write down or otherwise store codes outside their memory if assigned a code composed of letters as opposed to words, or vice versa. The null hypothesis is that treatment has no impact on the choice to store codes. In the completion survey, 18 of the 69 participants in the *letters* treatment reported having stored their security code, as compared to 10 of the 66 in the *words* treatment. We use a two-sided Fisher's Exact Test to estimate that such a difference would occur with probability $p = 0.14$ under the null hypothesis. Thus we can not conclude that either treatment made participants more likely to write their code down.

6 Limitations

Whenever testing a new approach to security, its novelty alone may be enough to reveal to research participants that it is the focus of the study. Despite our best efforts, of the 133 participants in the experimental groups who completed the study (68 in *letters* and 65 in *words*), only 35 (26%, 24 from *letters* and 11 from *words*) reported that they did not suspect that the security code might be the focus of the study. The majority, 70 (53%, 28 from *letters* and 42 from *words*) reported having some suspicion and 28 (21%, 16 from *letters* and 12 from *words*) reported being 'certain' the security code was the focus of the study. Still, to our knowledge no participants revealed any 'spoilers' on public forums. Participants who suspected we were studying their ability to learn the security code may have tried harder to memorize the code than if they had not, though it's not clear how their effort would compare to that of a real-world user relying on a randomly-assigned code to secure something valuable.

7 Background and related work

7.1 Physiological principles of memory

Human memory has been studied extensively by psychologists (as well as neuroscientists and others). The *spacing effect* describes how people are better able to recall information if it is presented for the same duration, but in intervals spaced over a longer period of time. This effect was first described in the 19$^{\text{th}}$ century [43] and is considered one of the most robust memory effects [10]. It has even been demonstrated in animals. The effect is almost always far more powerful than variations in memory between individual people [35].

The cause of the spacing effect is still under debate, but most theories are based around the *multi-store model* of memory [33] in which short-term (or working memory) and long-term memory are distinct neurological processes [8, 9]. One theory of the spacing effect posits

	Did you store any part of the additional security code for the study website, such as by writing it down, emailing it to yourself, or adding it to a password manager? 'Yes'				'No'			
	Letters		*Words*		*Letters*		*Words*	
Completed the study	18/68	26%	10/65	15%	50/68	74%	55/65	85%
Reported storing password	11/18	61%	6/10	60%	2/50	4%	0/55	0%
Received full security code	16/18	89%	9/10	90%	47/50	94%	55/55	100%
Participated in follow-up	14/16	88%	8/9	89%	42/47	89%	48/55	87%
Recalled code correctly	12/14	86%	6/8	75%	34/42	81%	46/48	96%

Table 2: A minority of participants reported storing their security code outside of their memory. Each row corresponds to an identically-named row in Table 1, separated by participants' response to the code storage question in each column. The first row shows the fraction of all participants who completed the study in each group, and each subsequent row as a fraction of the one above, except for the italicized row which identifies participants who reported storing their self-chosen password (which was much more common amongst participants who stored their security code).

that when information is presented which has left short-term memory, a trace of it is recognized from long-term memory [47] and hence stimulated, strengthening the long-term memory through *long-term potentiation* [14] of neural synapses. Thus, massed presentation of information is less effective at forming long-term memories because the information is recognized from working memory as it is presented. In our case, the natural spacing between password logins is almost certainly long enough for the password to have left working memory.

Early work on spaced learning focused on *expanding presentation* in which an exponentially increasing interval between presentations was considered optimal [70, 62]. More recent reviews have suggested that the precise spacing between presentations is not particularly important [11] or that even spacing may actually be superior [53]. This is fortunate for our purposes as password logins are likely to be relatively evenly spaced in time. Other work has focused on dynamically changing spacing using feedback from the learner such as speed and accuracy of recall [68] which could potentially guide artificial rehearsal of passwords.

7.2 Approaches to random passwords

Many proposals have aimed to produce random passwords which are easier for humans to memorize, implicitly invoking several principles of human memory. Early proposals typically focused on *pronounceable* random passwords [46, 90] in which strings were produced randomly but with an English-like distribution of letters or phonemes. This was the basis for NIST's APG standard [2], though that specific scheme was later shown to be weak [45]. The independently-designed `pwgen` command for generating pronounceable passwords is still distributed with many Unix systems [5].

Generating a random set of words from a dictionary, as we did in our *words* treatment, is also a classic approach, now immortalized by the web comic XKCD [67]. This was first proposed by Kurzban [61] with a very small 100 word dictionary, the popular Diceware project [6] offers 4,000 word dictionaries. Little available research exists on what size and composition of dictionaries is optimal.

Finally, a number of proposals have aimed to enhance memorability of a random string by offering a secondary coding such as a set of images [58], a grammatical sentence [7, 50], or a song [65]. Brown's passmaze protocol was recognition-based, with users simply recognizing words in a grid [29]. None of these proposals has received extensive published usability studies.

7.3 Studies on password recall

A number of studies have examined user performance in recalling passwords under various conditions. These studies often involve users choosing or being assigned a new password in an explicitly experimental setting, and testing the percentage of users who can correctly recall their password later. Surprisingly, a large number of studies have failed to find any statistically significant impact on users' ability to recall passwords chosen under a variety of experimental treatments, including varying length and composition requirements [95, 71, 92, 86, 60] or requiring sentence-length passphrases [55].[4] The consistent lack of impact of password structure on recall rates across studies appears to have gone unremarked in any of the individual studies.

However, several studies have found that stricter composition requirements increase the number of users writing their passwords down [71, 60] and users self-report that they believe passwords are harder to remember when created under stricter password policies [60, 92].

[4] Keith et al. [55] did observe far more typos with sentence-length passwords, which needed correcting to isolate the effective recall rates.

At least three studies have concluded that users *are* more likely to remember passwords they use with greater frequency [95, 28, 42]. This suggests that lack of adequate training may in fact be the main bottleneck to password memorization, rather than the inherent complexity of passwords themselves. Brostoff [28] appears to have made the only study of password *automacity* (the ability to enter a password without consciously thinking about it), and estimated that for most users, this property emerges for passwords they type at least once per day.

A few studies have directly compared recall rates of user-generated passwords to assigned passwords. Interestingly, none has been able to conclude that users were less likely to remember assigned passwords. For example, in a 1990 study by Zviran and Haga [94] in which users were asked to generate a password and then recall it 3 months later, recall was below 50% for all unprompted text passwords and no worse for system-assigned random passwords, though the rate of writing increased. A similar lab study by Bunnell et al. found a negligibly smaller difference in recall rate for random passwords [30]. A 2000 study by Yan et al. [92] found that users assigned random passwords for real, frequently-used accounts actually requested fewer password resets than users choosing their own passwords, though those users were also encouraged to write their passwords down "until they had memorized them." Stobert in 2011 [78] found no significant difference in recall between assigned and user-chosen text passwords.

Two studies have exclusively compared user's ability to recall random passwords under different encodings. The results of both were inconclusive, with no significant difference in recall rate between users given random alphanumeric strings, random pronounceable strings or randomly generated passphrases at a comparable security level of 30 [77] or 38 bits [64]. The results appear robust to significant changes in the word dictionary used for passwords or the letters used in random strings. However, users stated that alphanumeric strings seemed harder to memorize than random passphrases [77].

All of these studies except that of Yan et al. face validity concerns as the passwords were explicitly created for a study of password security. A 2013 study by Fahl et al. [44] compared user behavior in such scenarios and found that a non-trivial proportion of users behave significantly differently in explicit password studies by choosing deliberately weak passwords, while a large number of users re-use real passwords in laboratory studies. Both behaviors bias text passwords to appear more memorable, as deliberately weak passwords may be easy to memorize and existing passwords may already be memorized. Also of concern, all of these studies (again excluding Yan et al.) involved a single enrollment process followed by recall test, with no opportunity for learning.

Spaced repetition for passwords was recently suggested by Blocki et al. [16], who proposed designing password schemes which insert a minimal number of artificial rehearsals to maintain security. After our study, Blocki published results from a preliminary study on mnemonic passwords with formal rehearsals [15]. Compared to our study, participants performed a much lower number of rehearsals spaced (about 10) spaced over a longer period (up to 64 days), prompted by the system at specific times rather than at the participant's convenience. Unlike our study participants were aware that memorization was the explicit goal of the study. Blocki also incorporated additional mnemonic techniques (images and stories). This study provides evidence that spaced repetition and other techniques can be applied more aggressively for motivated users, whereas as our study demonstrates the practicality with few system changes and unmotivated users.

7.4 Alternative authentication schemes

Several approaches have been explored for exploiting properties of human memory in authentication systems. One approach is to query already-held memories using *personal knowledge question* schemes such as "what is your mother's maiden name?" though more sophisticated schemes have been proposed [93, 48] While these schemes typically enable better recall than passwords, they are vulnerable to attacks by close social relations [76], many people's answers are available in online search engines or social networks [73], and many questions are vulnerable to statistical guessing [21, 76]. An advantage of personal knowledge questions is that they represent *cued recall* with the question acting as a cue, which generally increases memory performance over *free recall*.

Graphical passwords aim to utilize humans' strong abilities to recognize visual data [13]. Some schemes employ cued recall only by asking users to recognize a secret image from a set [40, 87, 80]. Others use uncued memory by asking users to draw a secret pattern [49, 81, 12] or click a set of secret points in an image [88, 37]. These schemes are often still vulnerable to guessing attacks due to predictable user choices [39, 83, 84]. The Persuasive Cued Click-Points scheme [36] attempts to address this by forcing users to choose points within a system-assigned region, which was not found to significantly reduce recall. Still, it remains unclear exactly what level of security is provided by most graphical schemes and they generally take longer to authentication than typing a text password. They have found an important niche on mobile devices with touch screens, with current versions of Android and Windows 8 deploying graphical schemes for screen unlock.

Bojinov et al. [17] proposed the use of implicit memory for authentication, training users to type a random key sequence in rapid order using a game similar to one used in psychological research to study implicit memory formation [75]. After a 30–45 minute training period, users were tested 1–2 weeks later on the same game with their trained sequences and random sequences, with about half performing significantly better on trained sequences. Such a scheme offers the unique property that users are unaware of their secret and thus incapable of leaking it to an attacker who doesn't know the correct secret challenge to test on, providing a measure of resistance against "rubber-hose" attacks (physical torture). Without dramatic improvements however this scheme is impractical for normal personal or corporate logins due to the very long enrollment and login times and the low rate of successful authentication.

8 Open questions and future work

As this was our first exploration of spaced repetition for learning random secrets, many of our design choices were best guesses worthy of further exploration. The character set used when encoding secrets as letters, namely 26 lowercase letters, might be inferior to an expanded set such as base-32 with digits included [51]. Our choice of a dictionary of 676 words is almost surely not optimal, since we deliberately chose it for equivalence to the size of our character set. Splitting the secret into three equal-sized chunks was also simply a design heuristic, performance might be better with more or fewer chunks.

We expect spaced repetition to be a powerful enough tool for users to memorize secrets under a variety represenation formats, though the precise details may have important implications. We observed letters to be slightly faster to type and words slightly faster to learn. We also observed double the rate of forgotten codes after three days in the *letters* group and, though this difference was not statistically significant given our sample sizes and the low absolute difference, this is worthy of further study as this difference could be important in practice.

Our system can likely be improved by exploiting additional memory effects, such as dual-coding secrets by showing pictures next to each word or requiring greater depth of processing during each rehearsal. Cued recall could also be utilized by showing users random prompts (images or text) in addition to a random password.

On the downside, interference effects may be a major hindrance if users were asked to memorize multiple random passwords using a system like ours. This is worthy of further study, but suggests that random passwords should only be used for critical accounts.

Changing the login frequency may decrease or increase performance. We aimed to approximate the number of daily logins required in an enterprise environment in which users lock their screen whenever leaving their desks. In this context, the trade-offs appear reasonable if newly-enrolled users can learn a strong password after two weeks of reduced security (to the level of a user-chosen password) with about 10 minutes of aggregate time spent learning during the training period.

In contexts with far fewer logins, such as password managers or private keys which might be used once per day or less, learning might require a larger number of total logins. If a higher total number of logins are needed and they occur at a slower rate, this may lead to an unacceptable period of reduced security. In this case, security-conscious users could use rehearsals outside of authentication events. Further, if codes are used extremely infrequently after being memorized, artificial rehearsals may be desirable even after learning the secret. These are important cases to study, in particular as these are cases in which there is no good alternative defense against offline brute-force attacks.

While the learning rates of our participants did not slow down as the number of chunks they memorized increased, they might have more have trouble as the number of chunks grows further or as they have to associate different codes with different accounts. Fortunately, most users only have a small number of accounts valuable enough to require a strong random secret.

9 Conclusion

For those discouraged by the ample literature detailing the problems that can result when users and security mechanisms collide, we see hope for the human race. Most users *can* memorize strong cryptographic secrets when, using systems freed from the constraints of traditional one-time enrollment interfaces, they have the opportunity to learn over time. Our prototype system and evaluation demonstrate the brain's remarkable ability to learn and later recall random strings—a fact that surprised even participants at the conclusion of our study.

10 Acknowledgments

We thank Janice Tsai for assistance and suggestions on running an ethical experiment, Serge Egelman and David Molnar for help running our experiment on Mechanical Turk, and Arvind Narayanan, Cormac Herley, Paul van Oorschot, Bill Bolosky, Ross Anderson, Cristian Bravo-Lilo, Craig Agricola and our anonymous peer reviewers for many helpful suggestions in presenting our results.

Automatically Detecting Vulnerable Websites Before They Turn Malicious

Kyle Soska and Nicolas Christin
Carnegie Mellon University
{ksoska, nicolasc}@cmu.edu

Abstract

Significant recent research advances have made it possible to design systems that can automatically determine with high accuracy the maliciousness of a target website. While highly useful, such systems are reactive by nature. In this paper, we take a complementary approach, and attempt to design, implement, and evaluate a novel classification system which predicts, whether a given, not yet compromised website will become malicious *in the future*. We adapt several techniques from data mining and machine learning which are particularly well-suited for this problem. A key aspect of our system is that the set of features it relies on is automatically extracted from the data it acquires; this allows us to be able to detect new attack trends relatively quickly. We evaluate our implementation on a corpus of 444,519 websites, containing a total of 4,916,203 webpages, and show that we manage to achieve good detection accuracy over a one-year horizon; that is, we generally manage to correctly predict that currently benign websites will become compromised within a year.

1 Introduction

Online criminal activities take many different forms, ranging from advertising counterfeit goods through spam email [21], to hosting "drive-by-downloads" services [29] that surreptitiously install malicious software ("malware") on the victim machine, to distributed denial-of-service attacks [27], to only name a few. Among those, research on analysis and classification of end-host malware – which allows an attacker to take over the victim's computer for a variety of purposes – has been a particularly active field for years (see, e.g., [6, 7, 16] among many others). More recently, a number of studies [8,15,20,22,36] have started looking into "webserver malware," where, instead of targeting arbitrary hosts for compromise, the attacker attempts to inject code on machines running web servers. Webserver malware differs from end-host malware in its design and objectives. Webserver malware indeed frequently exploits outdated or unpatched versions of popular content-management systems (CMS). Its main goal is usually not to completely compromise the machine on which it resides, but instead to get the victimized webserver to participate in search-engine poisoning or redirection campaigns promoting questionable services (counterfeits, unlicensed pharmaceuticals, ...), or to act as a delivery server for malware.

Such infections of webservers are particularly common. For instance, the 2013 Sophos security threat report [33, p.7] states that in 2012, 80% of websites hosting malicious contents were compromised webservers that belonged to unsuspecting third-parties. Various measurement efforts [20, 25, 36] demonstrate that people engaging in the illicit trade of counterfeit goods are increasingly relying on compromised webservers to bring traffic to their stores, to the point of supplanting spam as a means of advertising [20].

Most of the work to date on identifying webserver malware, both in academia (e.g., [8, 15]) and industry (e.g., [3, 5, 14, 24]) is primarily based on detecting the presence of an *active infection* on a website. In turn, this helps determine which campaign the infected website is a part of, as well as populating blacklists of known compromised sites. While a highly useful line of work, it is by design reactive: only websites that have already been compromised can be identified.

Our core contribution in this paper is to propose, implement, and evaluate a general methodology to identify webservers that are at a high risk of becoming malicious *before* they actually become malicious. In other words, we present techniques that allow to proactively identify likely targets for attackers as well as sites that may be hosted by malicious users. This is particularly useful for search engines, that need to be able to assess whether or not they are linking to potentially risky contents; for blacklist operators, who can obtain, ahead of time, a list of sites to keep an eye on, and potentially warn these

sites' operators of the risks they face ahead of the actual compromise; and of course for site operators themselves, which can use tools based on the techniques we describe here as part of a good security hygiene, along with practices such as penetration testing.

Traditional penetration testing techniques often rely on ad-hoc procedures rather than scientific assessment [26] and are greatly dependent on the expertise of the tester herself. Different from penetration testing, our approach relies on an online classification algorithm ("classifier") that can 1) automatically detect whether a server is likely to become malicious (that is, it is probably vulnerable, and the vulnerability is actively exploited in the wild; or the site is hosted with malicious intent), and that can 2) quickly adapt to emerging threats. At a high level, the classifier determines if a given website shares a set of features (e.g., utilization of a given CMS, specifics of the webpages' structures, presence of certain keywords in pages, ...) with websites known to have been malicious. A key aspect of our approach is that the feature list used to make this determination is automatically extracted from a training set of malicious and benign webpages, and is updated over time, as threats evolve.

We build this classifier, and train it on 444,519 archives sites containing a total of 4,916,203 webpages. We are able to correctly predict that sites will eventually become compromised within 1 year while achieving a true positive rate of 66% and a false positive rate of 17%. This level of performance is very encouraging given the large imbalance in the data available (few examples of compromised sites as opposed to benign sites) and the fact that we are essentially trying to predict the future. We are also able to discover a number of content features that were rather unexpected, but that, in hindsight, make perfect sense.

The remainder of this paper proceeds as follows. We review background and related work in Section 2. We detail how we build our classifier in Section 3, describe our evaluation and measurement methodology in Section 4, and present our empirical results in Section 5. We discuss limitations of our approach in Section 6 before concluding in Section 7.

2 Background and related work

Webserver malware has garnered quite a bit of attention in recent years. As part of large scale study on spam, Levchenko et al. [21] briefly allude to search-engine optimization performed my miscreants to drive traffic to their websites. Several papers [17, 19, 20, 22] describe measurement-based studies of the "search-redirection" attacks, in which compromised websites are first being used to link to each other and associate themselves with searches for pharmaceutical and illicit products; this allows the attacker to have a set of high-ranked links displayed by the search engine in response to such queries. The second part of the compromise is to have a piece of malware on the site that checks the provenance of the traffic coming to the compromise site. For instance, if traffic is determined to come from a Google search for drugs, it is immediately redirected—possibly through several intermediaries—to an illicit online pharmacy. These studies are primarily empirical characterizations of the phenomenon, but do not go in great details about how to curb the problem from the standpoint of the compromised hosts.

In the same spirit of providing comprehensive measurements of web-based abuse, McCoy et al. [25] looks at revenues and expenses at online pharmacies, including an assessment of the commissions paid to "network affiliates" that bring customers to the websites. Wang et al. [36] provides a longitudinal study of a search-engine optimization botnet.

Another, recent group of papers looks at how to detect websites that have been compromised. Among these papers, Invernizzi et al. [15] focuses on automatically finding recently compromised websites; Borgolte et al. [8] look more specifically at previously unknown web-based infection campaigns (e.g., previously unknown injections of obfuscated JavaScript-code). Different from these papers, we use machine-learning tools to attempt to detect websites that have not been compromised yet, but that are likely to become malicious in the future, over a reasonably long horizon (approximately one year).

The research most closely related to this paper is the recent work by Vasek and Moore [35]. Vasek and Moore manually identified the CMS a website is using, and studied the correlation between that CMS the website security. They determined that in general, sites using a CMS are more likely to behave maliciously, and that some CMS types and versions are more targeted and compromised than others. Their research supports the basic intuition that the content of a website is a coherent basis for making predictions about its security outcome.

This paper builds on existing techniques from machine learning and data mining to solve a security issue. Directly related to the work we present in this paper is the data extraction algorithm of Yi et al. [38], which we adapt to our own needs. We also rely on an ensemble of decision-tree classifiers for our algorithm, adapting the techniques described by Gao et al. [13].

3 Classifying websites

Our goal is to build a classifier which can predict with high certainty if a given website will become malicious in the future. To that effect, we start by discussing the properties our classifier must satisfy. We then elaborate on the learning process our classifier uses to differentiate between benign and malicious websites. Last, we de-

scribe an automatic process for selecting a set features that will be used for classification.

3.1 Desired properties

At a high level, our classifier must be efficient, interpretable, robust to imbalanced data, robust to missing features when data is not available, and adaptive to an environment that can drastically change over time. We detail each point in turn below.

Efficiency: Since our classifier uses webpages as an input, the volume of the data available to train (and test) the classifier is essentially the entire World Wide Web. As a result, it is important the the classifier scale favorably with large, possibly infinite datasets. The classifier should thus use an online learning algorithm for learning from a streaming data source.

Interpretability: When the classifier predicts whether a website will become malicious (i.e., it is vulnerable, and likely to be exploited; or likely to host malicious content), it is useful to understand why and how the classifier arrived at the prediction. Interpretable classification is essential to meaningfully inform website operators of the security issues they may be facing. Interpretability is also useful to detect evolution in the factors that put a website at risk of being compromised. The strong requirement for interpretability unfortunately rules out a large number of possible classifiers which, despite achieving excellent classification accuracy, generally lack interpretability.

Robustness to imbalanced data: In many applications of learning, the datasets that are available are assumed to be balanced, that is, there is an equal number of examples for each class. In our context, this assumption is typically violated as examples of malicious behavior tend to be relatively rare compared to innocuous examples. We will elaborate in Section 5 on the relative sizes of both datasets, but assume, for now, that 1% of all existing websites are likely to become malicious, i.e., they are vulnerable, and exploits for these vulnerabilities exist and are actively used; or they are hosted by actors with malicious intent. A trivial classifier consistently predicting that all websites are safe would be right 99% of the time! Yet, it would be hard to argue that such a classifier is useful at all. In other words, our datasets are imbalanced, which has been shown to be problematic for learning—the more imbalanced the datasets, the more learning is impacted [30].

At a fundamental level, simply maximizing accuracy is not an appropriate performance metric here. Instead, we will need to take into account both false positives (a benign website is incorrectly classified as vulnerable) and false negatives (a vulnerable website is incorrectly classified as benign) to evaluate the performance of our classifier. For instance, the trivial classifier discussed above, which categorizes all input as benign, would yield 0% false positives, which is excellent, but 100% of false negatives among the population of vulnerable websites, which is obviously inadequate. Hence, metrics such as receiver-operating characteristics (ROC) curves which account for both false positive and false negatives are much more appropriate in the context of our study for evaluating the classifier we design.

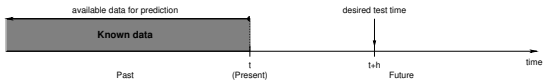
Robustness to errors: Due to its heterogeneity (many different HTML standards co-exist, and HTML engines are usually fairly robust to standard violations) and its sheer size (billions of web pages), the Web is a notoriously inconsistent dataset. That is, for any reasonable set of features we can come up with, it will be frequently the case that some of the features may either be inconclusive or undetermined. As a simple example, imagine considering website popularity metrics given by the Alexa Web Information Service (AWIS, [1]) as part of our feature set. AWIS unfortunately provides little or no information for very unpopular websites. Given that webpage popularity distribution is "heavy-tailed [9]," these features would be missing for a significant portion of the entire population. Our classifier should therefore be robust to errors as well as missing features.

Another reason for the classifier to be robust to errors is that the datasets used in predicting whether a website will become compromised are fundamentally noisy. Blacklists of malicious websites are unfortunately incomplete. Thus, malicious sites may be mislabeled as benign, and the classifier's performance should not degrade too severely in the presence of mislabeled examples.

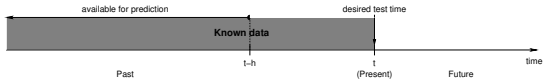
Adaptive: Both the content on the World Wide Web, and the threats attackers pose vary drastically over time. As new exploits are discovered, or old vulnerabilities are being patched, the sites being attacked change over time. The classifier should thus be able to learn the evolution of these threats. In machine learning parlance, we need a classifier that is adaptive to "concept drift" [37].

All of these desired properties led us to consider an ensemble of decision-tree classifiers. The method of using an ensemble of classifiers is taken from prior work [13]. The system works by buffering examples from an input data stream. After a threshold number of examples has been reached, the system trains a set of classifiers by resampling all past examples of the minority class as well as recent examples of the majority class. While the type of classifier used in the ensemble may vary, we chose to use C4.5 decision trees [31].

The system is efficient as it does not require the storage or training on majority class examples from the far past. The system is also interpretable and robust to errors as the type of classifier being used is a decision-tree in



(a) Using the present to predict the future



(b) Using the past to predict the present

Figure 1: **Prediction timeline.** Attempting to predict the future makes it impossible to immediately evaluate whether the prediction was correct (a). A possible alternative (b) is to use past data to simulate a prediction done in the past (at $t-h$) that can then be tested at the present time t.

an ensemble [13]. Periodically retraining our classifiers makes them robust to concept drift as long as retraining occurs sufficiently often. Finally, the system handles class imbalance by resampling the input stream, namely, it resamples from the set of all minority class training examples from the past as well as recent majority class examples.

3.2 Learning process

The type of classification we aim to perform presents unique challenges in the learning process.

Lack of knowledge of the future: Assume that at a given time t, our classifier predicts that a given website w is likely to become compromised in the future. Because the website has not been compromised yet—and may not be compromised for a while—we cannot immediately know whether the prediction is correct. Instead, we have to wait until we have reached a time $(t+h)$ to effectively be able to verify whether the site has become compromised between t and $(t+h)$, or if the classifier was in error. This is particularly problematic, since just training the classifier—let alone using it—would require to wait at least until $(t+h)$. This is the situation illustrated in Figure 1(a).

A second, related issue, is that of defining a meaningful "time horizon" h. If h is too long, it will be impossible to even verify that the classifier was right. In an extreme case, when $h \to \infty$, the performance of the classifier cannot be evaluated.[1] Selecting a time horizon too short (e.g., $h = 0$) would likewise reduce to the problem of determining whether a website is already compromised or not—a very different objective for which a rich literature already exists, as discussed earlier.

[1] Given the complexity of modern computer software, it is likely that exploitable bugs exist in most, if not all webservers, even though they might have not been found yet. As a result, a trivial classifier predicting that all websites will be compromised over an infinite horizon ($h \to \infty$) may not even be a bad choice.

We attempt to solve these issues as follows. First, deciding what is a meaningful value for the horizon h appears, in the end, to be a design choice. Unless otherwise noted, we will assume that h is set to one year. This choice does not affect our classifier design, but impacts the data we use for training.

Second, while we cannot predict the future at time t, we can use the past for training. More precisely, for training purposes we can solve our issue if we could extract a set of features, and perform classification on an archived version of the website w as it appeared at time $(t-h)$ and check whether, by time t, w has become malicious. This is what we depict in Figure 1(b). Fortunately, this is doable: At the time of this writing, the Internet Archive's Wayback Machine [34] keeps an archive of more than 391 billion webpages saved over time, which allows us to obtain "past versions" of a large number of websites.

Obtaining examples of malicious and benign websites: To train our classifier, we must have ground truth on a set of websites—some known to be malicious, and some known to be benign. Confirmed malicious websites can be obtained from blacklists (e.g., [28]). In addition, accessing historical records of these blacklists allows us to determine (roughly) at what time a website became malicious. Indeed, the first time at which a compromised website appeared in a blacklist gives an upper bound on the time at which the site became malicious. We can then grab older archived versions of the site from the Wayback Machine to obtain an example of a site that was originally not malicious and then became malicious.

We obtain benign websites by randomly sampling DNS zone files, and checking that the sampled sites are not (and have never been) in any blacklist. We then also cull archives of these benign sites from the Wayback machine, so that we can compare *at the same time in the past* sites that have become malicious to sites that have remained benign.

We emphasize that, to evaluate the performance of the classifier at a particular time t, training examples from the past (e.g., $t-h$) may be used; and these examples can then be used to test on the future. However, the converse is not true: even if that data is available, we cannot train on the present t and test on the past $(t-h)$ as we would be using future information that was unknown at the time of the test. Figure 1(b) illustrates that data available to build predictions is a strict subset of the known data.

Dealing with imbalanced datasets: As far as the learning process is concerned, one can employ class re-balancing techniques. At a high level, class re-balancing has been studied as a means to improve classifier performance by training on a distribution other than the naturally sampled distribution. Since we sample only a random subset of sites which were not compromised, we

already perform some resampling in the form of a one-sided selection.

3.3 Dynamic extraction of the feature list

Any classifier needs to use a list of features on which to base its decisions. Many features can be used to characterize a website, ranging from look and feel, to traffic, to textual contents. Here we discuss in more details these potential features. We then turn to a description of the dynamic process we use to update these features.

3.3.1 Candidate feature families

As potential candidates for our feature list, we start by considering the following families of features.

Traffic statistics. Website statistics on its traffic, popularity, and so forth might be useful in indicating a specific website became compromised. For instance, if a certain website suddenly sees a change in popularity, it could mean that it became used as part of a redirection campaign. Such statistics may be readily available from services such as the aforementioned Alexa Web Information Service, if the website popularity is not negligible.

Filesystem structure. The directory hierarchy of the site, the presence of certain files may all be interesting candidate features reflecting the type of software running on the webserver. For instance the presence of a `wp-admin` directory might be indicative of a specific content management system (WordPress in that case), which in turn might be exploitable if other features indicate an older, unpatched version is running.

Webpage structure and contents. Webpages on the website may be a strong indicator of a given type of content-based management system or webserver software. To that effect, we need to distill useful page structure and content from a given webpage. The user-generated content within webpages is generally not useful for classification, and so it is desirable to filter it out and only keep the "template" the website uses. Extracting such a template goes beyond extraction of the Document Object Model (DOM) trees, which do not provide an easy way to differentiate between user-generated contents and template. We discuss in the next section how extracting this kind of information can be accomplished in practice.

Page content can then distilled into features using several techniques. We chose to use binary features that detect the presence of particular HTML tags in a site. For instance, "is the keyword *joe's guestbook/v1.2.3* present?" is such a binary feature. Of course, using such a binary encoding will result in a rather large feature set as it is less expressive than other encoding choices. However the resulting features are extremely interpretable and, as we will see later, are relatively straightforward to extract automatically.

Perhaps more interestingly, we observed that features on filesystem structure can actually be captured by looking at the contents of the webpages. Indeed, when we collect information about internal links (e.g., *<a href="../top.html">*) we are actually gathering information about the filesystem as well. In other words, features characterizing the webpage structure provide enough information for our purposes.

3.3.2 Dynamic updates

We consider traffic statistics as "static" features that we always try to include in the classification process, at least when they are available. On the other hand, all of the content-based features are dynamically extracted. We use a statistical heuristic to sort features which would have been useful for classifying recent training examples and apply the top performing features to subsequent examples.

4 Implementation

We next turn to a discussion of how we implemented our classifier in practice. We first introduce the data sources we used for benign and soon-to-be malicious websites. We then turn to explaining how we conducted the parsing and filtering of websites. Last we give details of how we implemented dynamic feature extraction.

4.1 Data sources

We need two different sources of data to train our classifier: a ground truth for soon-to-be malicious websites, and a set of benign websites.

Malicious websites. We used two sets of blacklists as ground truth for malicious websites. First, we obtained historical data from PhishTank [28]. This data contains 11,724,276 unique links from 91,155 unique sites, collected between February 23, 2013 and December 31, 2013. The Wayback machine contained usable archives for 34,922 (38.3%) of these sites within the required range of dates.

We then complemented this data with a list of websites known to have been infected by "search-redirection attacks," originally described in 2011 [20, 22]. In this attack, miscreants inject code on webservers to have them participate in link farming and advertise illicit products—primarily prescription drugs. From a related measurement project [19], we obtained a list, collected between October 20, 2011 and September 16, 2013, of 738,479 unique links, all exhibiting redirecting behavior, from 16,173 unique sites. Amazingly, the Wayback machine contained archives in the acceptable range for 14,425 (89%) of these sites.

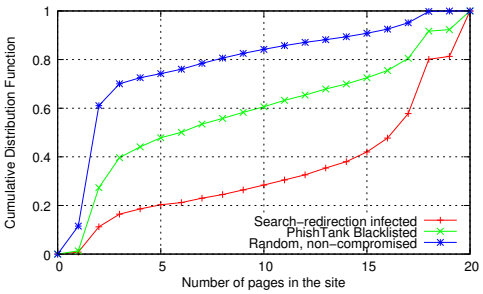


Figure 2: **Cumulative distribution function of the number of pages scraped.** Benign websites very frequently contain only a handful of pages.

We use these two blacklists in particular because we determined, through manual inspection, that a large percentage of sites in these lists have either been compromised by an external attacker or are maliciously hosted. On the other hand, various other blacklists often label sites that are heavily spammed or contain adult content as malicious, which we do not think is appropriate.

Benign websites. We randomly sampled the entire `.com` zone file from January 14th, 2014. For each domain, we enumerated the available archives in the Wayback machine. If at least an archive was found, we selected one of the available archives in the range of February, 20, 2010 to September 31, 2013. This yielded 337,191 website archives. We then removed all archives that corresponded to sites known as malicious. We removed 27 of them that were among the set of sites known to have been infected by search-redirection attacks, and another 72 that matched PhishTank entries. We also discarded an additional 421 sites found in the DNS-BH [2], Google SafeBrowsing [14], and hpHosts [23] blacklists, eventually using 336,671 websites in our benign corpus.

Structural properties. Figure 2 shows some interesting characteristics of the size of the websites we consider. Specifically, the cumulative distribution function of the number of pages each website archive contains differs considerably between the datasets. For many benign sites, that were randomly sampled from zone files, only a few pages were archived. This is because many domains host only a parking page or redirect (without being malicious) to another site immediately. Other sites are very small and host only a few different pages.

On the other hand, malicious sites from both of our blacklists contain more pages per site, since in many cases they are reasonably large websites that had some form of visibility (e.g., in Google rankings), before becoming compromised and malicious. In some other cases, some of the blacklisted sites are sites maliciously registered, that do host numerous phishing pages.

4.2 Parsing and filtering websites

We scraped web pages from the Wayback Machine using the Scrapy framework [4], and a collection of custom Python scripts.

Selecting which archive to use. The scripts took in a URL and a range of dates as inputs, and then navigated The WayBack Machine to determine all the archives that existed for that URL within the specified range.

Sites first appear in a blacklist at a particular time t. If a site appears in multiple blacklists or in the same blacklist multiple times, we use the earliest known infection date. We then search for snapshots archived by the Wayback machine between $t-12$ months and to $t-3$ months prior to the site being blacklisted. The choice of this range is to satisfy two concerns about the usefulness of the archive data. Because compromised sites are not generally instantaneously detected, if the date of the archive is chosen too close to the first time the site appeared in a blacklist, is is possible that the archived version was already compromised. On the other hand, if the archived version was chosen too far from the time at which the site was compromised, the site may have changed dramatically. For instance, the content management system powering the site may have been updated or replaced entirely.

If multiple archives exist in the range $t-3$ months–$t-12$ months, then we select an archive as close to $t-12$ months as possible; this matches our choice for $h=1$ year described earlier. We also download and scrape the most recent available archive, and compare it with the the one-year old archive to ensure that they are using the same content management system. In the event that the structure of the page has changed dramatically (defined as more than 10% changes) we randomly select a more recent archive (i.e., between zero and one year old), and repeat the process.

Scraping process. We scrape each archived site, using a breadth-first search. We terminate the process at either a depth of two links, or 20 pages have been saved, and purposefully only download text (HTML source, and any script or cascading style sheets (CSS) embedded in the page, but no external scripts or images). Using a breadth-first search allows us to rapidly sample a large variety of web pages. It is indeed common for websites to contain multiple kinds of webpages, for example forums and posts, blogs and guestbooks, login and contact pages. A breadth-first search provides an idea of the amount of page diversity in a site without requiring us to scrape the entire site. Limiting ourselves to 20 pages allows us to quickly collect information on a large number of websites, and in fact allows us to capture the vast majority of websites in their entirety, according to Figure 2,

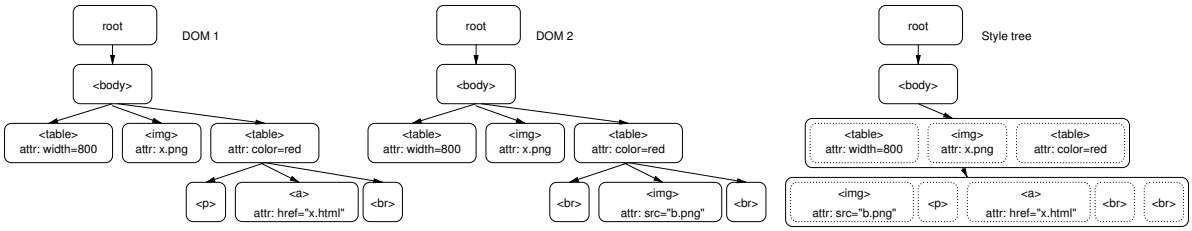

Figure 3: **DOM and style trees**. The figure, adapted from Yi et al. [38], shows two DOM trees corresponding to two separate pages, and the resulting style tree.

while—as we will see later—providing enough information to our classifier to be able to make good decisions.

Filtering. Once a batch of webpages has been saved for a given website, we filter each of them to remove user-generated content. We define user-generated content as all data in webpage, visible and invisible, which is not part of the underline template or content-management system. This includes for instance blog posts, forum posts, guestbook entries, and comments. Our assumption is that user-generated content is orthogonal to the security risks that a site a priori faces and is therefore simply noise to the classifier. User-generated content can, on the other hand, indicate that a site has *already* been compromised, for instance if blog posts are riddled with spam links and keywords. But, since our objective is to detect vulnerable (as opposed to already compromised) sites, user-generated content is not useful to our classification.

The process of extracting information from webpages is a well-studied problem in data mining [10, 11, 32, 38, 39]. Generally the problem is framed as attempting to isolate user-generated content which otherwise would be diluted by page template content. We are attempting to do the exact opposite thing: discarding user-generated content while extracting templates. To that effect, we "turn on its head" the content-extraction algorithm proposed by Yi et al. [38] to have it only preserve templates and discard contents.

Yi et al. describes an algorithm where each webpage in a website is broken down into a Document Object Model (DOM) tree and joined into a single larger structure referred to as a style tree. We illustrate this construction in Figure 3. In the figure, two different pages in a given website produce two different DOM trees (DOM 1 and DOM 2 in the figure). DOM trees are essentially capturing the tags and attributes present in the page, as well as their relationship; for instance, *¡table¿* elements are under *¡body¿*.

The style tree incorporates not only a summary of the individual pieces of content within the pages, but also their structural relationships with each other. Each node in a style tree represents an HTML tag from one or possibly many pages within the site and has a derived property called *composite importance* (CompImp), which is an information-based measure of how important the node is. Without getting into mathematical details—which can be found in Yi et al. [38]—nodes which have a CompImp value close to 1 are either unique, or have children which are unique. On the other hand, nodes which have a CompImp value closer to 0 typically appear often in the site.

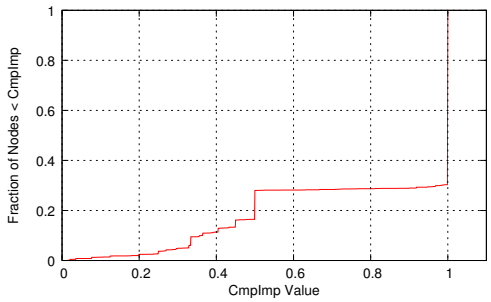

Figure 4: **C.d.f. of CompImp over the style tree generated for `dailyshotofcoffee.com`**. We use 1,000 pages to generate the style tree.

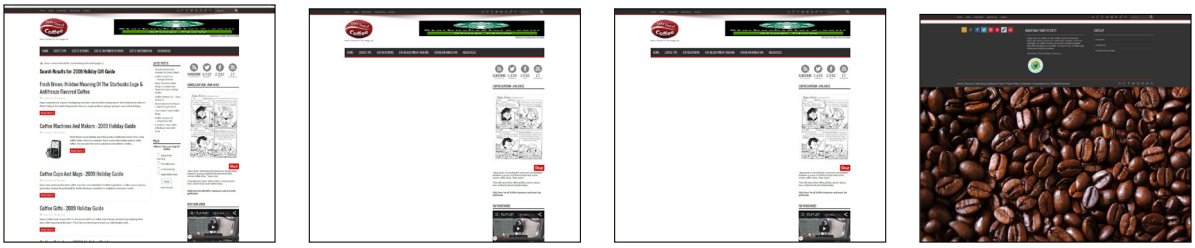
While Yi et al. try to filter out nodes with CompImp below a given threshold to extract user content, we are interested in the exact opposite objective; so instead we filter out nodes whose CompImp is *above* a threshold.

We provide an illustration with the example of `dailyshotofcoffee.com`. We built, for the purpose of this example, a style tree using 1,000 randomly sampled pages from this website. We plot the CompImp of nodes in the resulting style tree in Figure 4. A large portion of the nodes in the style tree have a CompImp value of exactly 1 since their content is completely unique within the site. The jumps in the graph show that some portions of the site may use different templates or different variations of the same template. For example, particular navigation bars are present when viewing some pages but not when viewing others.

We illustrate the effect of selecting different values as a threshold for filtering in Figure 5. We consider a ran-



(a) Original (b) CompImp > 0.99 (c) CompImp > 0.6 (d) CompImp > 0.1

Figure 5: **Impact of various thresholds on filtering.** The figure shows how different CmpInt thresholds affect the filtering of the webpage shown in (a). Thresholds of 0.99 and 0.6 produce the same output, whereas a threshold of 0.1 discards too many elements.

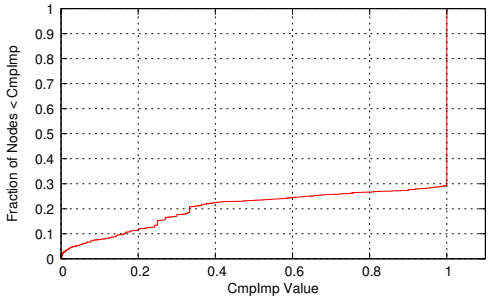


Figure 6: **C.d.f. of CompImp over all style trees generated for 10,000 random sites**. We use 1,000 pages per website to generate the style tree.

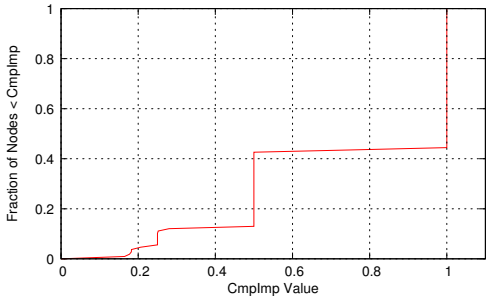

Figure 7: **C.d.f. of CompImp over the style tree generated for `dailyshotofcoffee.com` using only 5 pages.** The plot represents the fraction of nodes less than a threshold in the style tree generated from only five random pages from `dailyshotofcoffee.com`.

dom page of `dailyshotofcoffee.com` showed in Figure 5(a). In Figures 5(b), (c), and (d), we show the result of filtering with a threshold value of 0.99, 0.6 and 0.1 respectively. There is no difference between using 0.99 and 0.6 as a threshold since there are very few nodes in the style tree that had a CompImp between 0.6 and 0.99, as shown in Figure 4. There is a notable difference when using 0.1 as a threshold since portions of the page template are present on some but not all pages of the site.

In general, style trees generated for other sites seem to follow a similar distribution, as shown in Figure 6 where we plot the aggregated CompImp c.d.f. over all style trees generated for 10,000 sites. The aggregation does have a slight curve around the CompImp value 1 which indicates that a few sites do have style trees with nodes in this space. Such sites typically use a fixed template with the exception of a few pages such as 404 error pages, login, and registration pages.

A concern with applying style trees for filtering in this setting occurs in instances where there are only a few examples of pages from a particular site. Trivially, if there is only a single page from the site, then the style tree is just the page itself, and if only a few examples are found then the estimates of nodes in the style tree will be highly dependent on where in the site those pages were sampled from. In Figure 7, we plot the cumulative distribution function for CompImp over the style tree generated for `dailyshotofcoffee.com`, but this time, only using five random pages from the site. Compared to Figure 4, we see that the particular cutoffs are slightly different from when we used 1,000 pages; but the general shape still remains the same. Manual inspection over many sites has indicates that this approach still works well with as few as five pages. This serves as further justification to our design decision of only scraping 20 pages at most from each website.

With all of these experiments in mind, we selected a thresholding value of 0.99 for our system, and eliminated from our filtering process sites where we could only scrape less than five pages.

4.3 Feature extraction

We derived the set of features used in classification from two main sources, the Alexa Web Information Service

Feature	Discretization fn.	Values
AWIS Site Rank	$\lceil \log(\text{SiteRank}) \rceil$	$[0 \ldots 8]$
Links to the site	$\lceil \log(\text{LinksIn}) \rceil$	$[0 \ldots 7]$
Load percentile	$\lfloor \text{LoadPercentile}/10 \rfloor$	$[0 \ldots 10]$
Adult site?	(Boolean)	$\{0,1\}$
Reach per million	$\lceil \log(\text{reachPerMillion}) \rceil$	$[0 \ldots 5]$

Table 1: **AWIS features used in our classifier and their discretization.** Those features are static—i.e., they are used whenever available.

(AWIS) and the content of the saved web pages. Features generated from the pages content are dynamically generated during the learning process according to a chosen statistic. For the classification process we use an ensemble of decision trees so that the input features should be discrete. In order to obtain useful discrete features (i.e., discrete features that do not take on too many values relative to the number of examples), we apply a mapping process to convert continuous quantities (load percentile) and large discrete quantities (global page rank) to a useful set of discrete quantities. The mappings used are shown in Table 1.

4.3.1 AWIS features

For every site that was scraped, we downloaded an entry from AWIS on Feb 2, 2014. While the date of the scrape does not match the date of the web ranking information, it can still provide tremendous value in helping to establish the approximate popularity of a site. Indeed, we observed that in the overwhelming majority of cases, the ranking of sites and the other information provided does not change significantly over time; and after discretization does not change at all. This mismatch is not a fundamental consequence of the experiment design but rather a product retrospectively obtaining negative training examples (sites which did not become compromised) which can be done in real time.

Intuitively, AWIS information may be useful because attackers may target their resources toward popular hosts running on powerful hardware. Adversaries which host malicious sites may have incentives to make their own malicious sites popular. Additionally, search engines are a powerful tool used by attackers to find vulnerable targets (through, e.g., "Google dorks [18]") which causes a bias toward popular sites.

We summarize the AWIS features used in Table 1. An AWIS entry contains estimates of a site's global and regional popularity rankings. The entry also contains estimates of the reach of a site (the fraction of all users that are exposed to the site) and the number of other sites which link in. Additionally, the average time that it takes users to load the page and some behavioral measurements such as page views per user are provided.

The second column of Table 1 shows how AWIS information is discretized to be used as a feature in a decision-tree classifier. Discretization groups a continuous feature such as load percentile or a large discrete feature such as global page rank into a few discrete values which make them more suitable for learning. If a feature is continuous or if too many discrete values are used, then the training examples will appear sparse in the feature space and the classifier will see new examples as being unique instead of identifying them as similar to previous examples when making predictions.

For many features such as AWIS Site Rank, a logarithm is used to compress a large domain of ranks down to a small range of outputs. This is reasonable since for a highly ranked site, varying by a particular number of rankings is significant relative to much lower ranked site. This is because the popularity of sites on the Internet follows a long tailed distribution [9].

Dealing with missing features. Some features are not available for all sites, for example information about the number of users reached by the site per million users was not present for many sites. In these cases, there are two options. We could reserve a default value for missing information; or we could simply not provide a value and let the classifier deal with handling missing attributes.

When a decision-tree classifier encounters a case of a missing attribute, it will typically assign it either the most common value for that attribute, the most common value given the target class of the example (when training), or randomly assign it a value based on the estimated distribution of the attribute. In our particular case, we observed that when a feature was missing, the site also tended to be extremely unpopular. We asserted that in these cases, a feature such as reach per million would probably also be small and assigned it a default value. For other types of missing attributes such as page load time, we did not assign the feature a default value since there is likely no correlation between the true value of the attribute and its failure to appear in the AWIS entry.

4.3.2 Content-based features

The content of pages in the observed sites provides extremely useful information for determining if the site will become malicious. Unlike many settings where learning is applied, the distribution of sites on the web and the attacks that they face vary over time.

Many Internet web hosts are attacked via some exploit to a vulnerability in a content-management system (CMS), that their hosted site is using. It is quite common for adversaries to enumerate vulnerable hosts by looking for CMSs that they can exploit. Different CMSs and even different configurations of the same CMS leak information about their presence through content such as tags associated with their template, meta tags, and com-

ments. The set of CMSs being used varies over time: new CMSs are released and older ones fall out of favor, as a result, the page content that signals their presence is also time varying.

To determine content-based features, each of the pages that survived the acquisition and filtering process described earlier was parsed into a set of HTML tags. Each HTML tag was represented as the tuple (type, attributes, content). The tags from all the pages in a site were then aggregated into a list *without repetition*. This means that duplicate tags, i.e., tags matching precisely the same type, attributes and content of another tag were dropped. This approach differs from that taken in typical document classification techniques where the document frequency of terms is useful, since for example a document that uses the word "investment" a dozen times may be more likely to be related to finance than a document that uses it once. However, a website that has many instances of the same tag may simply indicate that the site has many pages. We could balance the number of occurrences of a tag by weighting the number of pages used; but then, relatively homogeneous sites where the same tag appears on every page would give that tag a high score while less homogeneous sites would assign a low score. As a result, we chose to only use the existence of a tag within a site but not the number of times the tag appeared.

During the training phase, we then augmented the lists of tags from each site with the sites' classification; and added to a dictionary which contains a list of all tags from all sites, and a count of the number of positive and negative sites a particular tag has appeared in. This dictionary grew extremely quickly; to avoid unwieldy increase in its size, we developed the following heuristic. After adding information from every 5,000 sites to the dictionary, we purged from the dictionary all tags that had appeared only once. This heuristic removed approximately 85% of the content from the dictionary every time it was run.

Statistic-based extraction. The problem of feature extraction reduces to selecting the particular tags in the dictionary that will yield the best classification performance on future examples. At the time of feature selection, the impact of including or excluding a particular feature is unknown. As a result, we cannot determine an optimal set of features at that time. So, instead we use the following technique. We fix a number N of features we want to use. We then select a statistic $\hat{s}$, and, for each tag t in the dictionary, we compute its statistic $\hat{s}(t)$. We then simply take the top-N ranked entries in the dictionary according to the statistic $\hat{s}$.

Many statistics can be used in practice [12]. In our implementation, we use $N = 200$, and $\hat{s}$ to be ACC2. ACC2 is the balanced accuracy for tag x, defined as:

$$\hat{s}(x) = \left| \frac{|\{x : x \in w, w \in \mathscr{M}\}|}{|\mathscr{M}|} - \frac{|\{x : x \in w, w \in \mathscr{B}\}|}{|\mathscr{B}|} \right|,$$

where $\mathscr{B}$ and $\mathscr{M}$ are the set of benign, and malicious websites, respectively; the notation $x \in w$ means (by a slight abuse of notation) that the tag x is present in the tag dictionary associated with website w. In essence, the statistic computes the absolute value of the difference between the tag frequency in malicious pages and the tag frequency in benign pages.

A key observation is that these top features can be periodically recomputed in order to reflect changes in the statistic value that occurred as a result of recent examples. In our implementation, we recomputed the top features every time that the decision tree classifiers in the ensemble are trained.

As the distribution of software running on the web changes and as the attacks against websites evolve, the tags that are useful for classification will also change. A problem arises when the dictionary of tags from previous examples is large. For a new tag to be considered a top tag, it needs to be observed a large number of times since $|\mathscr{M}|$ and $|\mathscr{B}|$ are very large. This can mean that there is a significant delay between when a tag becomes useful for classification and when it will be selected as a top feature, or for example in the case of tags associated with unpopular CMSs, which will never be used.

A way of dealing with this problem is to use windowing, where the dictionary of tags only contains entries from the last K sites. By selecting a sufficiently small window, the statistic for a tag that is trending can rapidly rise into the top N tags and be selected as a feature. The trade-off when selecting window size is that small window sizes will be less robust to noise but faster to capture new relevant features while larger windows will be more robust to noise and slower to identify new features.

An additional strategy when calculating the statistic value for features is to weight occurrences of the feature differently depending on when they are observed. With windowing, all observations in the window are weighted equally with a coefficient of 1, and all observations outside of the window are discarded by applying a coefficient of 0. Various functions such as linear and exponential may be used to generate coefficients that scale observations and grant additional emphasis on recent observations of a feature.

5 Experimental results

We evaluate here both our dynamic feature extraction algorithm, and the overall performance of our classifier, by providing ROC curves.

Table 2: **Selection of the top features after processing the first 90,000 examples.** These features are a chosen subset of the top 100 features determined by the system after 90,000 examples had been observed and using windowing with a window size of 15,000 examples and linear attenuation.

5.1 Dynamic Feature Extraction

We analyzed dynamic features by logging the values of the statistic AAC2 after adding every example to the system. We selected a few particular features from a very large set of candidates to serve as examples and to guide intuition regarding dynamic feature extraction. The process of feature extraction could be performed independently of classification and was run multiple times under different conditions to explore the effect of different parameters such as the use of windowing and attenuation.

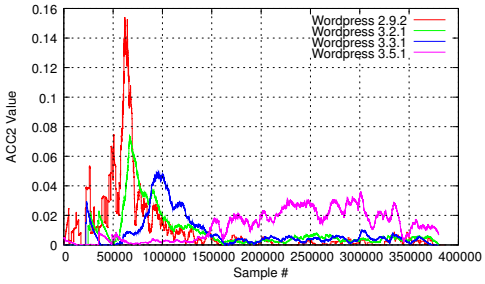

Figure 8: **Statistic value for various tags corresponding to different version of the Wordpress content management system.**

Dynamic feature extraction is essential, as it allows the system to automatically identify features useful in predicting if a domain will become malicious; this automation is imperative in a concept-drifting domain. For example, Figure 8 shows the computed statistic value for various features that correspond directly to different versions of the Wordpress CMS. Over time, the usefulness of different features changes. In general, as new versions of a CMS are released, or new exploits are found for existing ones, or completely new CMSs are developed, the set of the features most useful for learning will be constantly evolving.

Table 2 shows a selection of the 200 tags with highest statistic value after 90,000 examples had been passed to the system using a window size of 15,000 examples and a linear weighting scheme. A meaningful feature, i.e., with a large statistic value, is either a feature whose presence is relatively frequent among examples of malicious sites, or whose presence is frequent among benign sites. Of the 15,000 sites in the window used for generating the table, there were 2,692 malicious sites, and 12,308 benign ones. The feature *ul{'class': ['xoxo', 'blogroll']}* was observed in 736 malicious sites and 1,027 benign ones (461.34 malicious, 538.32 benign after attenuation) making it relatively more frequent in malicious sites. The feature *div{'id': 'content_disclaimer'}* was observed in no malicious sites and 62 benign ones (47.88 benign after attenuation) making it more frequent in benign sites. After manual inspection, we determined that this feature corresponded to a domain parking page where no other content was hosted on the domain.

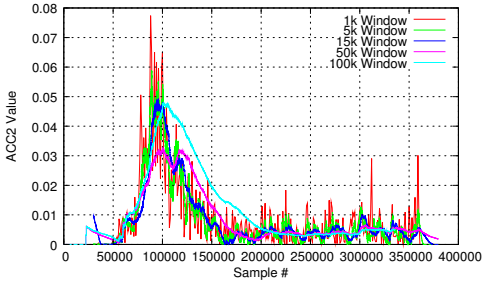

Figure 9: **Statistic value for *meta{'content': 'WordPress 3.3.1', 'name': 'generator'}* over time.** The statistic was computed over the experiment using window sizes of 1,000, 5,000, 15,000, 50,000 and 100,000 samples and uniform weighting.

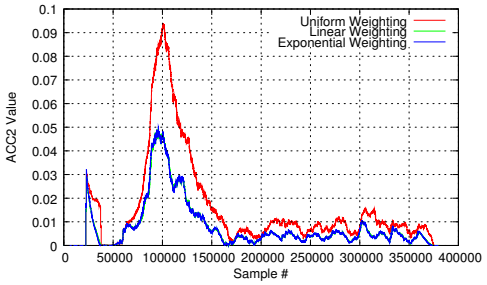

Figure 10: **Statistic value for *meta{'content': 'WordPress 3.3.1', 'name': 'generator'}* over time.** The statistic was computed over the experiment using a window size of 15,000 samples and various weighting techniques.

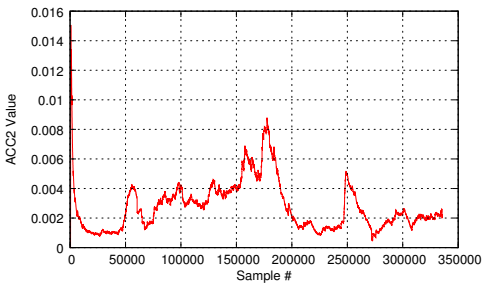

Figure 11: **Statistic value for *div{'id': 'content_disclaimer'}* over time.** The statistic was computed over the experiment using a window of size 15,000 samples and linear attenuation.

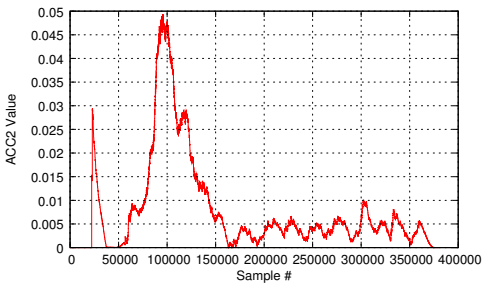

Figure 12: **Statistic value for *meta{'content': 'WordPress 3.3.1', 'name': 'generator'}* over time.** The statistic was computed over the experiment using a window of size 15,000 samples and linear attenuation.

The calculation of the ACC2 statistic for a feature at a particular time is parameterized by the window size and by a weighting scheme. As an example, Figure 9 shows the value of the statistic computed for the tag *meta{'content': 'WordPress 3.3.1', 'name': 'generator'}* over the experiment using different window sizes. When using a window, we compute the statistic by only considering examples that occurred within that window. We made passes over the data using window sizes of 1,000, 5,000, 15,000, 50,000 and 100,000 samples, which approximately correspond to 3 days, 2 weeks, 7 weeks, 24 weeks, and 48 weeks respectively.

A small window size generates a statistic value extremely sensitive to a few observations whereas a large window size yields a relatively insensitive statistic value. The window size thus yields a performance trade-off. If the statistic value for a feature is computed with a very small window, then the feature is prone to being incorrectly identified as meaningful, but will correctly be identified as meaningful with very low latency as only a few observations are needed. A large window will result in less errors regarding the usefulness of a feature but will create a higher latency.

Figure 10 shows the effect of varying the weighting scheme with a constant window size. Using a weighting scheme gives higher weight to more recent examples and the effect is very similar to simply decreasing the window size. There is almost no difference between exponential and linear decay.

Features belonging to positive (malicious) and negative (benign) examples often carry with them their own characteristics. The statistic values of negative examples tend to be relatively constant and time-invariant as the example in Figure 11 shows. These are generally features that indicate a lack of interesting content and therefore a lack of malicious content—for instance, domain parking pages. Conversely, the statistic value of positive examples tend to contain a large spike as evidenced by the example in Figure 12. The features correspond to vulnerable software and spike when an attack campaign exploiting that vulnerability is launched. Occasionally, additional spikes are observed, presumably corresponding to subsequent campaigns against unpatched software.

A design consideration when working with dynamic features is whether or not it is appropriate to use features that were highly ranked at some point in the past in addition to features that are currently highly ranked. As discussed above, negative features tend to be relatively constant and less affected, unlike positive features which fluctuate wildly. These positive features tend to indicate the presence of software with a known vulnerability that may continue to be exploited in the future.

Since it may happen that a feature will be useful in the future, as long as computational resources are available, better classification performance can be achieved by including past features in addition to the current top performing features. The result of including past features is that in situations where attack campaigns are launched against previously observed CMSs, the features useful for identifying such sites do not need to be learned again.

5.2 Classification performance

We ran the system with three different configurations to understand and evaluate the impact that different configurations had on overall performance. We send input to our ensemble of classifiers as "blocks," i.e., a set of websites to be used as examples. The first configuration generated content features from the very first block of the input stream but did not recompute them after that. The second configuration recomputed features from every block in the input stream but did not use past features which did not currently have a top statistic value. The third configuration used dynamic features in addition to all features that had been used in the past.

For all configurations, we used a block size of 10,000 examples for retraining the ensemble of C4.5 classifiers.

We also used a window size of 10,000 samples when computing the statistic value of features, and we relied on features with the top 100 statistic values. We generated ROC curves by oversampling the minority class by 100% and 200% and undersampling the majority class by 100%, 200%, 300%, and 500%. We ran each combination of over- and undersampling as its own experiment, resulting in a total of 10 experiments for each configuration. The true positive rate and false positive rate[2] for each experiment is taken as the average of the true positive and false positive rates for each block, that is, each block in the input stream to the system is tested on before being trained on, and the rates are taken as the average over the tested blocks.

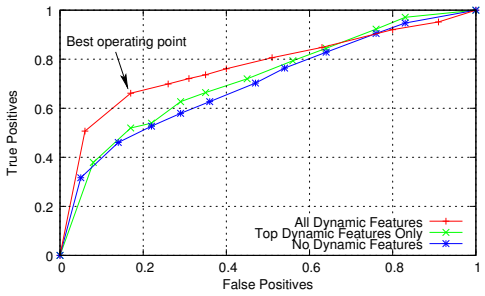

Figure 13: **ROC plot for three different strategies of dynamic features.** The classifier was run using three different configurations for dynamic features. The first configuration corresponds to classifiers trained on both current and past top features; the second corresponds to classifiers trained using only current top features; the third corresponds to classifiers trained using the top features from the first 5,000 samples.

Figure 13 shows the ROC curves generated for the three configurations described. The points resulting from the experiments have been linearly connected to form the curves. One can see that the configuration which used past features performed the best, followed by the configuration which used only current top dynamic features and the configuration which did not use dynamic features at all. The best operating point appears to achieve a true positive rate of 66% and a false positive rate of 17%.

The configuration which did not use dynamic features ended up selecting a feature set which was heavily biased by the contents of first block in the input data stream. While the features selected were useful on learning the first block, they did not generalize well to future examples since the distribution of pages that were observed had changed. This is a problem faced by all such systems in this setting that are deployed using a static set of features, unless the features set is fully expressive of the page content, i.e., all changes in the page content are able to be uniquely identified by a corresponding change in the feature values, then the features will eventually become less useful in classification as the distribution of pages changes.

The configuration which only used the current top dynamic features also performed relatively poorly. To understand why this is the case, we can see that in Figures 11 and 12 some features have a statistic value which oscillates to reflect the change in usefulness of the feature due to the time varying input distribution. One can also see that when a feature becomes useful, the corresponding increase in the statistic value lags behind since a few instances of the feature need to be observed before the statistic can obtain a high value again. During this transient period, the system fails to use features that would be useful in classification and so performance suffers. This problem may be partially addressed by shrinking the input block size from the data streams well as the window for computing the static value to a smaller value to reduce the transient. However such a strategy will still be outperformed by the strategy which remembers past features.

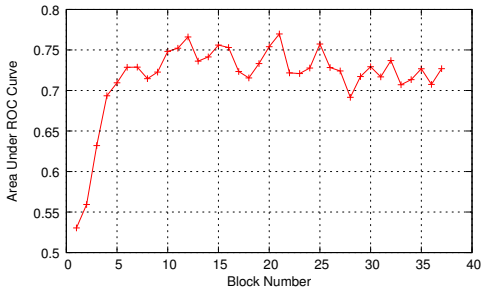

Figure 14: **AUC plot for the system over time using current and past dynamic features.** The system was run using both current and past top dynamic features. ROC curves were generated for each block of examples that was processed and the corresponding AUC value was computed.

For each input block in the experiments using past features, we recorded the true positive and false positive rates and used them to generate an ROC curve. We then used the ROC curve to approximate the area under the curve (AUC) which is a value that gives some intuitive understanding of how well the classifier performed on that block. Figure 14 shows the AUC values for each block in the experiment. The system performed relatively poorly until a sufficient number of blocks had been processed at which point the performance increased to a threshold value. We believe that the difficulty in achiev-

[2]The false negative rate and true negative rates are simple complements of the respective positive rates.

ing better performance is due to the nature of the problem, specifically it is not always the case that the content of a site and its traffic statistics are a factor in whether or not it will become compromised. We discuss this issue in more details in the limitations section.

Finally, we observed that when classification yielded a prediction that a site would become compromised, the reasoning can be read as the conjunction of conditions from the decision tree. For example the classification of `www.bisoft.org` which appeared in the search redirection data set was described as (Global Site Rank = 8) $\wedge$ (*<META NAME="Generator" CONTENT="EditPlus">= 1*) $\wedge$ (*<script type="text/javascript" src="/static/js/analytics.js">* = 1). The classification of benign examples was generally less obvious.

The conditions resulting in incorrect classification tended to follow a few main types. The first type are instances where a website would in the future become malicious, but very few examples like it exist at classification time. These sites contained content that would eventually yield prominent features for identifying sites that would become malicious but were not classified correctly due to latency in the dynamic feature extraction. As an example, consider in Figure 12 the samples that occurred just before the first significant spike.

The second type of instance that was incorrectly classified were examples that did not become malicious, but were classified as becoming so based on some strong positive content features that they contained. It is likely that after an initial attack campaign, vulnerable CMSs are less targeted due to the incremental number of compromises that could be yielded from them.

The third type of instance that was incorrectly classified were examples that would be become malicious for seemingly no apparent reason. These examples that would become malicious did not follow the general trend of large spikes corresponding to attack campaigns against a CMS, and have been observed with positive features both before and after its initial spike as well as with strong negative features. It is believed that these examples are cases where a site is becoming malicious for reasons completely independent of its content or traffic profile. It could be the case that an attack is launched where default login credentials for many CMSs are being attempted resulting in a few seemingly random breaks. It could also be the case that the domain in question was sold or rebuilt after observing it causing the system to erroneously predict its future malicious status from its old content.

6 Limitations

The limits on the classification performance of the system can be attributed to the following few difficulties in predicting if a site will become malicious.

Our system assumes the factors responsible for whether or not a site will become compromised can be summarized by its content and its traffic statistics. This assumption is sometimes violated, since for example sites may be compromised and become malicious due to weak administrator passwords being guessed or being retrieved via social engineering. Other examples may include adversaries who host their own sites with malicious intent. While it is often the case that such actors use similar page templates due to their participation in affiliate networks or out of convenience, such sites may introduce examples where the factors for the site being malicious are independent of its content. In such situations, the system will fail to perform well since the factors for site becoming malicious are outside its domain of inputs.

The nature of adversaries who compromise sites may also be perceived as a limitation on what our system can do. It has been observed that attack campaigns are launched where adversaries appear to enumerate and compromise sites containing a similar vulnerability. While adversaries do attack many sites which contain a particular vulnerability, it is generally not a reasonable assumption that they will systematically attack all sites containing this vulnerability both at the time of the campaign and in the future. The impact of this behavior on the system is that sites which contain similar content to those which were compromised in the campaign will be classified as becoming malicious in the future, when they actually may not since attackers have chosen to ignore them. While this does deteriorate the performance of the system, we argue that this does not take away its usefulness since these misclassifications represent sites which are still at considerable security risk and need attention.

The dynamic feature extraction system also presents at least two main limitations. The first is a correlation of features that are selected as top features at any given point in time. Tags often rise to the top of the list because they are part of some page template which has come up frequently. There may be multiple tags associated with a particular page template which all rise at the same time, and so a few of the top tags are redundant since they are identifying the same thing. It would be desirable to measure the correlation of the top features in order to select a more diverse and useful set however no attempt to do this was made in our experiments.

Another limitation of the dynamic features is that for system configurations which use past features in addition to the current top features, the size of the feature set is monotonically increasing. Thus, it will take longer over time train the classifiers and run the system. It would be

useful to further investigate the trade-offs between classification performance and limited feature lists.

Last, dynamic features introduce a unique opportunity for adversarial machine learning approach to poison the performance of the system. Adversaries which control a website may attempt to remove, change, or insert tags into their pages in order to damage the effectiveness of feature generation. For example, adversaries that host or control sites that have distinguishing tags may either try to remove them or rewrite them in semantically equivalent ways to prevent the system from using them for classification. Since the sites examined by the system are typically not under adversarial control at the time of evaluation, we believe that the impact of such attacks should be minimal; but it deserves further analysis.

7 Conclusions

We discussed a general approach for predicting a websites propensity to become malicious in the future. We described a set of desirable properties for any solution to this problem which are interpretability, efficiency, robustness to missing data, training errors, and class imbalance, as well as the ability to adapt to time changing concepts. We then introduced and adapted a number of techniques from the data mining and machine learning communities to help solve this problem, and demonstrated our solution using an implementation of these techniques. Our implementation illustrates that even with a modest dataset, decent performance can be achieved since we are able to operate with 66% true positives and only 17% false positives at a one-year horizon. We are currently working on making our software publicly available.

Abstract

We present Hulk, a dynamic analysis system that detects malicious behavior in browser extensions by monitoring their execution and corresponding network activity. Hulk elicits malicious behavior in extensions in two ways. First, Hulk leverages *HoneyPages*, which are dynamic pages that adapt to an extension's expectations in web page structure and content. Second, Hulk employs a *fuzzer* to drive the numerous event handlers that modern extensions heavily rely upon. We analyzed 48K extensions from the Chrome Web store, driving each with over 1M URLs. We identify a number of malicious extensions, including one with 5.5 million affected users, stressing the risks that extensions pose for today's web security ecosystem, and the need to further strengthen browser security to protect user data and privacy.

1 Introduction

All major web browsers today support broad extension ecosystems that allow third parties to install a wide range of modified behavior or additional functionality. Internet Explorer has binary add-ons (Browser Helper Objects), while Firefox, Chrome, Opera, and Safari support JavaScript-based extensions. Some browsers have online web stores to distribute extensions to users. For example, the most popular extension in Chrome's Web Store, AdBlock, has over 10 million users. Other popular extensions serve a variety of functions, such as preserving privacy, changing the aesthetics of the browser's UI, or integrating with web services such as Google Translate.

The amount of critical and private data that web browsers mediate continues to increase, and naturally this data has become a target for criminals. In addition, the web's advertising ecosystem offers opportunities to profit by manipulating a user's everyday browsing behavior. As a result, malicious browser extensions have become a new threat, as criminals realize the potential to monetize a victim's web browsing session and readily access web-related content and private data.

Our work examines extensions for Google Chrome that are designed with malicious intent—a threat distinct from that posed by attackers exploiting bugs in benign extensions, which has seen prior study [6, 5]. Extensions for Google Chrome are primarily distributed through the Chrome Web Store.[1] Like app stores for other platforms, such as Android or iOS, inherent risks arise when downloading and executing programs from untrusted sources. Reports have documented not only malicious extensions [27], but miscreants *purchasing* extensions (and thereby access to their userbases via update mechanisms) to add malicious functionality [2, 25]. In addition to the web store, extensions can also be directly installed by users and other programs. Installed by a process called *sideloading*, these extensions pose a recognized risk that browser vendors have attempted to prevent through modifications to the browser [22]. Sideloaded extensions are especially problematic since they can be installed without user knowledge, and are not subject to review by a web store. Despite efforts to stifle sideloaded extensions, they remain a significant problem [12].

In this paper we present Hulk, a tool for detecting malicious behavior in Google Chrome extensions. Hulk relies on dynamic execution of extensions and uses several techniques to trigger malicious functionality during execution. One technique we developed to elicit malicious behavior is the use of *HoneyPages*: specially-crafted web pages designed to satisfy the structural conditions that trigger a given extension. We interpose on all queries and modifications to the DOM tree of the HoneyPage to automatically create elements and mimic DOM tree structures for extensions on the fly. Using this technique, we can readily observe malicious behavior that inserts new `iframe` or `div` elements.

In addition, we built a fuzzer to drive the execution

[1] https://chrome.google.com/webstore/category/extensions

of event handlers registered by extensions. In our experiments, we use the fuzzer to trigger all event handlers associated with web requests, exercising each with 1 million URLs. Although we undertook extensive efforts to trigger malicious behavior, the possibility remains that Hulk lacks the mechanisms to satisfy all of the conditions necessary for eliciting an extension's malicious behavior.

Our analysis of 48,332 Chrome extensions found that malicious extensions pose a serious threat to users. By developing a set of rules that label execution logs from Hulk, we identified 130 malicious extensions and 4,712 "suspicious" extensions, most of which appear in the Chrome Web Store. Several large classes of malicious behavior appear within our set of extensions: affiliate fraud, credential theft, ad injection or replacement, and social network abuse. In one case, an extension performing ad replacement had nearly 2 million users, similar in size to some of the largest botnets.

In summary, we frame our contributions as follows:

- We present Hulk, a system to perform dynamic analysis for Chrome extensions.
- We demonstrate the effectiveness of HoneyPages and event handler fuzzing to elicit malicious behavior in browser extensions.
- We perform the first broad study of malicious Chrome extensions.
- We characterize several classes of malicious Chrome extensions, some with very large footprints (up to 5.5M installations) and propose solutions to eliminate entire classes of malicious behavior.

2 Background

We begin by reviewing the Google Chrome extension model and the opportunities this model provides to malicious extensions.

2.1 Chrome Extension Composition

Google Chrome supports extensions written in JavaScript and HTML (distributed as a single `zip` file). A small number of extensions also include binary code plugins, although these are subject to a manual security review process [15]. Each extension contains a (mandatory) manifest that, along with other extension parameters, describes the permissions the extension uses and the list of resources that the browser should load.

The permission system is designed in the spirit of least privilege, with the goal of limiting the resources available to an extension in case it has exploitable vulnerabilities [5]. The threat model does not attempt to address malicious extensions accessing sensitive content or performing other actions. The permission system determines which sites an extension can access, the allowed API calls, and the use of binary plugins. We describe relevant parts of the permission system later in this section. See Barth et al. for a more detailed description of Chrome's extension architecture [5].

2.2 Installing Extensions

The Chrome Web Store is the official means for users to find and install extensions. The web store is similar to other app stores, such as those for iOS and Android, in that developers create extensions and upload them to the store for users to download. Extension developers can also push out updates without requiring any action by the end-user.

In addition to the Chrome Web Store, extensions can also be installed manually by a user or an external program. We refer to the installation of extensions outside the web store as *sideloading*. Chrome version 25 (released February, 2013) included changes to prevent silent installation of Chrome extensions and require that the user indicate consent for installation [22]. In May, 2014, Chrome took further steps to prevent sideloading by requiring *all* installed extensions to be hosted in the Chrome Web Store [18]. While these changes increase the difficulty of sideloading, it is still possible for programs to force silent installation of extensions, since the attacker already has control of the machine. For our study we obtained a set of extensions that are sideloaded into Chrome by other Windows programs, many of which are known malware.

2.3 Extension Permissions

Permissions. Chrome requires extensions to list the permissions needed to access the different parts of the extension API. For example, Figure 1 shows a portion of a manifest file requesting permission to access the `webRequest` and `cookies` API. The `webRequest` permission allows the extension to "observe and analyze traffic and to intercept, block, or modify requests in-flight" by allowing the extension to register callbacks associated with different parts of the HTTP stack [15]. Similarly, the cookies API allows the extension to get, set, and be notified of changes to cookies.

The extension API permissions operate in conjunction with the optional *host permissions*, which limit the API permissions to access resources only for the specified URLs. For example, in Figure 1 the extension requests host permissions for `https://www.google.com/`, which allows it to access `cookies` and `webRequest` APIs for the specified domains. Host permissions also support wildcarding

```
...
"permissions": [
  "cookies",
  "webRequest",
  "*://*.facebook.com/",
  "https://www.google.com/"
],
...
"content_scripts": [
  {
    "matches": ["http://www.yahoo.com/*"],
    "js": ["jquery.js", "myscript.js"]
  }
],
...
"background": {
  "scripts": ["background.js"]
},
...
"content_security_policy": "script-src 'self'
      http://www.foo.com 'unsafe-eval';"
...
```

Figure 1: Example of a manifest that shows API permissions for two hosts, followed by content scripts that run on `http://www.yahoo.com`, followed by a background script that runs on all pages. Finally, the CSP specifies the ability to include and `eval` scripts in the extension from `foo.com`.

URLs. In Figure 1, the extension requests access to `*://*.facebook.com`. This permission allows for access to all subdomains of `facebook.com` requested via any URL scheme. In addition to wildcards, the special token `<all_urls>` matches any URL.

Besides the permissions described above, we found that extensions request a variety of other permissions. In Section 4 we summarize the permissions requested for all of the extensions we examined, and we discuss the permissions relevant to various types of abuse in Section 5. Other resources provide a thorough analysis of the Chrome permission system [5, 6].

Content Scripts. In addition to permissions for accessing various resources associated with a page, extensions can also specify a list of `content_scripts` to indicate JavaScript files that will run inside of the web page. Figure 1 shows an example of including two JavaScript files, `jquery.js` and `myscript.js` that will be run in the context of the page for any URLs matching the specified URL patterns (all pages on `http://www.yahoo.com/` in this example). Inside of each JavaScript file the author can include further logic to decide if and when to execute.

The ability to run in the context of a page is a powerful feature. Once a content script executes, any resulting actions become indistinguishable from actions performed by JavaScript provided by the web server. Not only can the scripts modify the DOM tree or other scripts, but they can also issue authenticated web requests (such as POST with proper cookies).

Background Pages. Besides the content scripts that allow an extension to interact with a given page, Chrome also allows extensions to run scripts in a "background page". Figure 1 shows an example manifest file that specifies `background.js` as a background page. Background pages often contain the logic and state an extension needs for the entirety of the browser session and do not have any visibility to the user. For example, an extension requesting `webRequest` permissions may use the background script to attach a listener to read outgoing requests using the `chrome.webRequest.onBeforeRequest.addListener()` call. After filtering on the *host permissions*, Chrome will send the extension a notification for every outgoing request. We detail further examples in the context of the extensions in the following sections.

Content Security Policy. In general, servers can specify a Content Security Policy (CSP) header that the browser uses to determine the sources from which it can include objects on the page. CSP can also specify other options, such as whether to allow the page to perform an `eval` or to embed inline JavaScript [29]. Extensions can use the same syntax to express their CSP in the manifest file. For example, an extension that wishes to include source from `foo.com` and to execute `eval` can specify its CSP as shown in Figure 1.

3 Architecture

In this section, we describe the architecture of Hulk, our dynamic analysis system that identifies malicious behavior in Chrome extensions. Hulk dynamically loads extensions in a monitored environment and observes the interaction of extensions with the loaded web pages. Using a set of heuristics to identify potentially dangerous behavior, it labels extensions as *malicious*, *suspicious*, or *benign*. In the rest of this section we describe how Hulk works and the challenges that arise in analyzing browser extensions.

3.1 Profiling Extensions

At the core of our dynamic analysis system is an instrumented browser and extension loader that enables us to automatically install extensions and instrument activity during web browsing. Our monitoring hooks collect data

from multiple vantage points within Hulk as it visits web pages and triggers a range of extension behavior.

URL Extraction. Before we dynamically analyze an extension we need to ensure that we can trigger the extension's functionality. Most extensions interact with the content of web pages, so we need to choose which URLs to load for our analysis. To this end, we use three sources of URLs: the manifest, the source code, and a list of popular sites. First, using the manifest file of the extension we construct valid URLs that match the permissions and content scripts specified. In some cases, the host permissions of an extension are restrictive—for example, `https://*.facebook.com`—so we can generate URLs that will match the pattern. It is more difficult to pick URLs to visit in cases where the extension requests host permissions on all URLs (Section 2.3), because the malicious behavior may only trigger on a small subset of sites. Therefore, we search the source code for any static URLs and visit those as well. Finally, for every extension we also visit a set of popular sites targeted by malicious extensions. We constantly strive to improve this list as we detect malicious extensions attacking particular domains. We however note that although we use multiple sources of URLs to determine the appropriate pages to visit, our approach is not complete; we discuss the limitations further in Section 7.

HoneyPages. Some extensions activate based on the content of a web page instead of the URL. To analyze such extensions we use specially crafted pages that attempt to satisfy the conditions that an extension looks for on a page before performing an action. We call these *HoneyPages*. HoneyPages contain JavaScript functions that overload built-in functions that query the DOM tree of the web page. As a result, when an extension queries for the presence of a specific element we can automatically create it and insert it into the page. For example, if the extension queries an `iframe` DOM element with the intention to alter it, then our HoneyPage will create an `iframe` element, inject it in the DOM tree, and return it to the extension.

HoneyPages enable us to supplement the URL extraction phase and dynamically create an environment for the extension to perform as many actions as it needs. The on-demand nature of a HoneyPage does not restrict us to a specific DOM tree structure, but enables us to determine what an extension looks for in a page during execution, since we can record all interactions within a HoneyPage. By using HoneyPages we can better understand how the extension will behave on arbitrary pages that are otherwise difficult to generate prior to analysis.

3.2 Event-Based Execution

The Chrome browser offers to extensions an event-based model to register callbacks that respond to certain browser-level events. For example, extensions use the `chrome.webRequest.onBeforeRequest` callback to intercept all outgoing HTTP requests from the browser. HoneyPages will not trigger callbacks for network events that require special properties, such as a specific URL or HTTP header. Therefore, we complement HoneyPages with event handler fuzzing. Specifically, we invoke all event callbacks that an extension registers in the `chrome.webRequest` API with mock event objects. We point to a HoneyPage loaded in the active tab while invoking the callbacks, enabling us to monitor the changes that the extension attempts to make on that page. Our approach allows us to test for every extension the extension's callbacks on the top 1 million Alexa domains in under 10 seconds on average.

3.2.1 Monitoring Hooks

Browser Extension API. Depending on the permissions included in the manifest (Section 2.3), an extension can use the Chrome extension API to perform actions not available to JavaScript running in a web page. As such, monitoring the extension API captures a subset of the total JavaScript activity that results from an extension, but gives us a detailed picture of what the extension attempts to do. For example, we monitor the extension API and log if the extension registers a callback to intercept all HTTP requests performed by the browser, and then track the changes that the extension makes to the HTTP requests. To do this, we leverage the current logging infrastructure offered by Chrome for monitoring the activity of extensions. We build upon the JavaScript function call logging provided by the browser to identify malicious behavior, such as tampering of security-related HTTP headers.

Content Scripts. We intercept and log all additional code introduced by the extension in the context of the visited page. Doing so provides a more complete picture of the extension's functionality, since it can include remote scripts from arbitrary locations and inject them into the page. Remote scripts can compromise the page's security similar to third-party JavaScript libraries [23], and make the analysis of the extension more difficult. Using remote scripts gives miscreants the ability to blacklist IP addresses of our analysis system (i.e., cloaking [17, 28]) or return code without the malicious components. Remote JavaScript inclusion also renders static analysis on the extension's code fundamentally incomplete since parts of the extension's codebase are not available until execution.

Network Logging. We use a transparent proxy that intercepts all browser HTTP and DNS traffic to log the requests made during extension execution. A browser extension has a set of files available as resources loaded by the browser, and it can also download and execute content from the web. Since the URLs retrieved can be computed at runtime, monitoring the network activity of the extension is critical for a complete analysis of its source code and included components. In addition to identifying remote content, we log all domains contacted by monitoring the DNS requests generated by the browser. Doing so enables us to identify extensions that contact nonexistent domains, which can occur because the extension is no longer operational or up-to-date. In these cases, our analysis was necessarily incomplete, since when the domain was active the extension could have fetched more remote code from it.

3.3 Detecting Malicious Behavior

As described in the previous section, our dynamic analysis system can provide detailed information about all browser and extension activity performed while visiting web pages. We combine this data to label the extension as either *benign*, *suspicious*, or *malicious* by applying a set of labeling heuristics based on the behavior. Labeling an extension as malicious indicates we identified behavior harmful to the user. Suspicious indicates the presence of potentially harmful actions or exposing the user to new risks, but without certainty that these represent malicious actions. Finally, when we do not find any suspicious activity, we label the extension as benign.

3.3.1 JavaScript Attributes

We use our monitoring modules described in Section 3.2.1 to identify malicious JavaScript execution. Below we detail actions that we consider malicious or suspicious in our post-processing analysis.

Extension API. As described earlier, Chrome's extension API offers privileged access to additional functionality of the browser besides native JavaScript, using permissions specified in the manifest file. While there are benign uses for every permission, we found several extensions that abuse the API. Specifically, for reasons described below, we consider the following actions available only through the extension API as malicious: uninstalling other extensions, preventing uninstallation of the current extension, and manipulating HTTP headers.

We consider uninstalling other extensions as malicious because some extensions uninstall cleaner extensions, such as the extension Facebook created to remove harmful extensions on its blacklist.[2] We detect this behavior by monitoring the `chrome.management.uninstall` API calls. To avoid false positives, we can differentiate cleaners from malicious extensions because, to the best of our knowledge, cleaners operate in a different fashion than Antivirus does: they clean up malicious extensions and then remove themselves from the browser. This differs from the behavior of malicious extensions, which remain persistent on the system.

Besides attempting to uninstall other extensions, malicious extensions often prevent the user from uninstalling the extension itself. More specifically, we found extensions that prevent the user from opening Chrome's extension configuration page where a user can conveniently uninstall any extension. To prevent uninstallation, malicious extensions interfere with tabs that point to the extension configuration page, `chrome://extensions`, either by replacing the URL with a different one, or by removing the tab completely. For analysis, we load a tab with `chrome://extensions` in the browser during our dynamic analysis and monitor any interactions to identify such behavior.

Lastly, using callbacks in the `webRequest` API, a malicious extension can manipulate HTTP headers. Extensions can use the `webRequest` API to effectively perform a man-in-the-middle attack on HTTP requests and responses before they are handled by the browser. This behavior is often malicious (or at least dangerous) since we found extensions that remove security-related headers, such as Content-Security-Policy or X-Frame-Options, through the use of callbacks such as `webRequest.onHeadersReceived` and `webRequestInterval.eventHandled`. By monitoring the use of this API, we can log events that reveal state of HTTP headers before and after the request. Upon manipulation of any security-related headers, we label the extension as malicious.

Interaction with visited pages. In addition to the extension API, we also monitor an extension's use of content scripts to modify web content loaded in the browser. In our analysis, we flag two kinds of interaction: sensitive information theft as malicious and injection of remote JavaScript content as suspicious.

There are many ways an extension can steal personal information from the user. For example, it can act as a JavaScript-based keylogger by intercepting all keystrokes on a page. Extensions can also access form data, such as a password field, before it is encrypted and sent over the network. Finally, extensions can also steal sensitive information from third parties by accessing sites with which the user has a valid session, and ei-

[2] `https://chrome.google.com/webstore/detail/facebook-malicious-extens/mhkafblddkepdhhjpmedkngigkjjknoa`

ther issuing requests to exfiltrate data, or simply stealing valid authentication tokens.

We label any extension that injects remote JavaScript content into a web page as suspicious. We define this activity as adding a `script` element with a `src` attribute pointing to a domain that is different from the one of the web page. Including these scripts complicates analysis since the JavaScript content can change without any corresponding change in the extension. We have observed changes to JavaScript files that substantially alter the functionality of an extension, possibly due to a server compromise.

3.3.2 Network Level

By monitoring network requests, including DNS lookups and HTTP requests, we identify other types of suspicious/malicious behavior. Using a manual analysis of network logs we have identified two attributes that indicate malicious or suspicious behavior: request errors and modification of HTTP requests. To detect HTTP modifications, we examine if the network response that we observe on the wire differs from the network response finally processed by the browser.

As we discussed earlier, the extension API offers callbacks to give extensions the ability to intercept and manipulate web requests. Not only can extensions drop security-related headers, but extensions can change or add parameters in URLs before the HTTP request is sent. We find such suspicious behavior common, especially among extensions that request permissions on shopping-related sites such as Amazon, EBay, and others. In these cases, the extension adds parameters to the URL that indicate that the site should credit a particular affiliate for any resulting sales. We discuss this behavior in more detail in Section 5. At the network level, we have the complete view of how the requests originally appeared. We combine that knowledge with our `chrome.*` API monitoring to identify the exact changes made to the request.

We also look for errors during domain name resolution to identify extensions that contact domains since taken down. As with drive-by downloads, we expect that malicious code dynamically loaded into an extension will eventually become blacklisted. In such cases, the extension will fail to introduce more code during its execution. We detect this behavior and mark it as suspicious.

3.4 Injected Content Analysis

A Chrome extension can also manipulate the visited pages of the browser by injecting a content script. The injected script runs in the context of the visited page and thus has full access to its DOM tree. The injected code can vary significantly, and, with the dynamic nature of JavaScript, can prove difficult to analyze statically. The use of HoneyPages enables us to understand the injected code's full intentions. Instead of trying to infer what the code will do, we actually run it to observe its effects on the DOM tree and classify it accordingly. For example, if the injected code looks for a form field with the name "password," we classify it as malicious, since it can potentially hijack the user's credentials on the page. Another example concerns injecting additional code, where the injected code is part of a two-stage process that fetches yet more code from the web and dynamically executes it in the context of the visited page. By relying on HoneyPages to understand the code's intentions by the effect that the code has on a given page, we obtain a more precise view of what the code attempts do than we can using only static analysis.

Analysis result	Count
Malicious	130
Suspicious	4,712
Benign	43,490
Total	48,332

Table 1: Classification distribution of extensions.

Detection class	Count
[s] Injects dynamic JavaScript	2,672
[s] Produces HTTP 4xx errors	2,322
[s] Evals with input >128 chars long	451
[m] Prevents extension uninstall	56
[m] Steals password from form	39
[s] Performs requests to non-existent domain	26
[m] Contains keylogging functionality	23
[m] Injects security-related HTTP header	11
[m] Steals email address from form	10
[m] Uninstalls extensions	8

Table 2: Distribution of detected suspicious/malicious behavior from analyzed extensions. Notice that an extension might have more than one detections and that we mark with [m] detections classified as malicious and with [s] detections classified as suspicious.

4 Results

To evaluate Hulk we use two sources of extensions: the official Chrome Web Store (totaling 47,940 extensions), and extensions sideloaded by binaries. We obtained the latter based on binaries executed in Anubis [1], which, after removing a large number of duplicates, resulted in

a set of 392 unique extensions. As shown in Table 1, in total we analyzed 48,332 distinct extensions, of which Hulk labeled 130 as *malicious* and 4,712 as *suspicious*. Table 2 summarizes all of the detected behaviors, which we analyze in more detail in the following sections.

4.1 Permissions Used

In this section we characterize the extensions we executed by identifying the most popular permissions, content scripts, and API calls that they performed.

Permissions. Table 3 shows the top 10 permissions from 30,392 unique extensions that use the Chrome Extension API (excluding the host permissions). The most commonly used, the `tabs` permission, allows an extension to interact with the browser's tabs, including navigating a tab to a specified URL and registering callbacks to react to changes in the address bar. The second most popular permission, `notifications`, allows an extension to generate custom notifications that alert the user. The `storage` and `unlimitedStorage` permissions allow storing of permanent data in the user's browser. The `contextMenus` permission allows an extension to add additional items on the context menu of the browser. Context menus appear when the user right clicks on a page. To manipulate the browser's cookies, an extension needs to ask for the `cookies` permission. The permissions `webRequest`, `webRequestBlocking` and `webNavigation` allow an extension to inspect, intercept, block, or modify web requests from the browser. Finally, an extension can get a list of other extensions installed in the browser—and even disable or unistall them—with the `management` permission.

We also computed permission statistics independently for the set of benign extensions and the set of malicious or suspicious ones. To our surprise, we found that permissions for benign extensions do not differ significantly from permissions requested by malicious/suspicious ones, indicating that often attackers do not need to target different APIs to perform their attacks; maliciousness instead manifests in the way they use the API.

Table 4: The top 25 host permissions used by extensions. Extensions can include more than one host permission per manifest.

We found 18,313 extensions that use host permissions to restrict on which pages the extension can use the privileged `chrome.*` API. Table 4 shows the top 25 hosts appearing in host permissions. As seen in the table, extensions typically request broad permissions using wildcards in URL patterns. In addition these, we examined the hosts that extensions specified as targets for injecting content scripts, per Table 5, finding similar broad declarations. In practice, extension authors often use content scripts and host permissions in an unrestricted fashion.

API calls. Table 6 shows the top 15 Chrome Extension API calls made during by extensions during our experiments. There are several measurement artifacts introduced by our methodology. To load an extension for testing, we install the extension on a clean

Table 5: The top 25 hosts used in extensions' content script permissions.

browser each time we start an analysis. This causes `runtime.onInstalled` to appear in every analysis independent of the extension's activities. We also open the `chrome://extensions` tab from inside the extension to determine if the extension interferes with the management of extensions. This causes Hulk to record a large number of `tabs.create` calls. In Table 6 the `tabs` API is by far the most used API, which matches the popularity of `tabs` permissions observed in Table 3.

4.2 Network Level

Using network activity alone we identified 24 malicious extensions. These extensions were labeled as malicious by Hulk because they tampered with security-related HTTP headers. By removing HTTP response headers like *Content-Security-Policy*, the malicious extensions can inject JavaScript into pages that specifically do not allow scripts from external sources (according to the CSP policies provided by the web server). For example, Hulk found multiple variants of an active extension on the Chrome Web Store targeting users that seek to cheat in online games; these extensions, generally going by the name "*Cheat in your favorite games*", affect over 20K users.

14	runtime.sendMessage	5,847
15	extension.sendRequest	5,454

Table 6: The top 15 chrome.* APIs called by extensions during dynamic analysis.

During our experiments we encountered cases where our analysis could not obtain the full set of information needed to make a decision regarding the maliciousness of an analyzed extension. This problem arose due extensions performing HTTP requests that either returned errors, such as an HTTP 404 responses, or having domain names that no longer resolved. In such cases, given our inability to exercise the extension's full set of capabilities, and because the failed requests might correspond to fetching additional code, we mark these extensions as suspicious.

4.3 Extensions Management

Using signals tailored to detect the manipulation of the `chrome://extensions` page (as described in Section 3.3), we found several extensions on the Chrome Web Store that prevent uninstallation. Two of of these extensions claim to be video players (each with thousands of user) and completely replace Chrome's extensions management with a page that prevents users from uninstalling them. These are "HD Video Player" with 7,173 users and "SmartScreen Video Plugin" with 11,012 users. These signals also generated a false positive: the "No Tab Left Behind" extension (with only 8 users) allows only one tab at a time to be open. Thus, during our execution this extension prevented us from opening the extension settings tab.

4.4 Code Injection

Code injection was the most commonly detected "suspicious" feature in our dataset. In principle injection need not occur at all, since Chrome extensions can come packaged with all the code needed to operate. In total, we found more than 3,000 extensions that dynamically introduced remotely-retrieved code either through script injections or by evoking `eval`. As we noted earlier, using remote code renders static analysis on the extension's code fundamentally incomplete. However, Hulk can identify code injections and pinpoint the remote locations from which an extension fetches code. Although not necessarily malicious, we found many cases of dangerous code injection. For example, our system identified an extension named "Bang5TaoShopping assistant" from the Chrome Web Store that has been installed in 5.6 million (!) browsers and injects code into every visited page. Several extensions perform this same activity, while others insert tracking pixels for similar purposes. One instance sends cleartext HTTP request to a server controlled by the extension that encodes the URL visited by the user along with a unique identifier, leaking users browsing behavior and thus compromising their privacy.

5 Profiting from Maliciousness

In this section, we discuss five categories of malicious behavior in extensions, and describe their characteristics and the methods they employ to carry out their goals. We base each of these categories on examples we found in our feeds. When the extension is available on the Chrome Web Store, we also when possible include the number of users prior to reporting the extension to Google for review.

We have reported to Google any extension that performs behavior that is clearly abusive or malicious, and several of our reports have lead to removals of extensions from the web store.

5.1 Ad Manipulation

Advertisement manipulation falls in a grey area in that it does not subvert the user, but rather manipulates an external ecosystem. Replacing ads might appear benign to end users, but removes the potential for monetary credit for website owners (publishers) and instead fraudulently credits the extension owner. We include in this category the addition of new ads as well as the replacement of existing ads or identifiers. We find a range of behaviors in extensions, such as replacing banner ads with different identically-sized banners; inserting banners and text ads into well-known sites (such as Wikipedia); changing affiliate IDs for ads; or simply overlaying ads on top of

```
"content_scripts": [{
  "matches": ["http://*/*", "https://*/*"],
  "js": ["js/content.js"]
}],
"permissions": ["http://*/*",
  "https://*/*", "tabs"],
```

Figure 2: Permission-related JSON from the manifest file of an extension performing ad replacement.

content. Each instance aims to profit from impressions or clicks on the substituted advertisements.

As one striking example of ad manipulation we found an extension on the Chrome Web Store that had 1.8M users at the time we detected it. The extension, named "SimilarSites Pro" used primarily unobfuscated JS to perform benign functionality as advertised on the Chrome Web Store; however, it also inserted a script element into the content of web pages that downloads another, fully-obfuscated script (using `eval` and `unescape`) from a web server. At the time of analysis, this script contained a large conditional block that looked for `iframe` elements of particular sizes, such as 728x90 pixels, and replaced them with new banners of the same size. Since our first analysis, we have seen several new versions of the script available from the same URL. In addition, the extension contains a blacklist of sites and meta keywords where it should *not* change the banners, which appears due to many ad networks prohibiting the display of their ads on porn sites.

We find the same JavaScript included in five other extensions from the Chrome Web Store, as well as one sideloaded extension. Based on manual analysis, these extensions are primarily produced by a single company called "SimilarGroup" that engages in dubious behavior through the Chrome Web Store.

To perform banner replacement, the extension requests the permissions shown in Figure 2. Such exceptionally wide permissions are not uncommon [6]. Therefore, their presence alone provides little insight into the functionality of the extension. The most significant permission in Figure 2 is the broad use of content scripts that allow the extension to inject dynamic JavaScript files from a remote location. Following injection, execution continues as though the page had included it. Such content scripts provide an exceptionally powerful feature to enable a variety of malicious behaviors, as further discussed in this Section.

5.2 Affiliate Fraud

Many major merchant web sites such as `amazon.com`, `godaddy.com`, and `ebay.com` run affiliate programs that

credit affiliates with a fraction of the sales made as a result of customers referred by the affiliates. Usually merchant programs assign unique identifiers to affiliates, which affiliates then include in the URL that refers customers to the merchant site. Furthermore, affiliate programs usually associate a cookie with the user's browser so that they can attribute a sale to an affiliate within several hours after a user originally visited the merchant site with an affiliate identifier.

As an example, when a user reads product reviews on an Amazon affiliate's blog and clicks on a link to Amazon, the link includes an Amazon affiliate ID specified with the `tag` parameter in the URL, such as `http://www.amazon.com/dp/0961825170/?tag=affiliateID`. When Amazon receives this request, it returns a `Set-Cookie` header with a cookie that associates the user with the affiliate. When the customer returns to Amazon within 24 hours and makes a purchase, Amazon credits the affiliate with a small percentage of the transaction amount.

Such programs expect affiliates to bring potential customers to their sites via affiliate pages that advertise the merchant products. However, we found examples of several extensions involved in *cookie stuffing*—a technique that causes the user's browser to visit the merchant URLs without the user clicking on affiliate URLs. Doing so causes the merchant to deliver a cookie associated with the fraudulent affiliate, who then receives credit for any future, unrelated purchase made by the customer on the merchant site. Besides defrauding the merchant, the fraudulent affiliate also causes an over-write of the cookie associated with any legitimate affiliate who might have genuinely influenced the user to buy the product.

In our study, we found two kinds of extensions that defrauded affiliate programs. The first group includes extensions that provide some utility to users—such as refreshing pages automatically every few seconds, or changing the theme of popular sites like Facebook—but do not inform users of the extension author profiting from the user's web browsing. Generally, these activities involve monitoring visited URLs for merchant sites where the extension can earn a commission and modifying the outgoing requested URLs to include the affiliate ID, or by injecting `iframe`'s that include affiliate URLs.

For example, we found an extension named "*Split Screen*" (with 52K users) that allows users to show two tabs in a single window, while also stealthily monitoring the URLs visited by the user. It then silently replaces the requested URL with the affiliate's URL for sites such as `amazon.com`, `amazon.co.uk`, `hotelscombing.com`, `hostgator.com`, `godaddy.com`, and `booking.com`. For some merchants, it also sets the referrer header for outgoing requests to falsely imply a visit through the affiliate's site. The extension is able to make these changes using `tab` and `webRequest` permissions, as well as by registering callbacks on `chrome.tabs.onUpdated` to identify changes in the URL as a user types, and `chrome.webRequest.onBeforeSendHeaders` to modify the referrer header before the browser sends a request to a merchant site. We found four other extensions created by the same developer that similarly provided some small utility to the user while defrauding merchant programs in the background. Overall this developer's extensions have nearly 70K users.

Another extension we found named "Facebook Theme: Basic Minimalist Black Theme" (2.5K users) allows users to change the appearance of Facebook. Besides its stated intent, however, it also monitors browsing and appends an affiliate identifier to 7 different Amazon sites. By using its Content Security Policy (Section 2.3) to perform `eval`, it runs a highly-obfuscated hexadecimal and base64-encoded background script that stores all affiliate identifiers in Chrome's storage (using `storage` permissions), and registers callbacks on tab update events using `tab` permissions. When the user visits any URL, Chrome notifies the extension, and the extension uses regular expressions to identify target Amazon URLs for which to add an affiliate identifier. The extension then updates the URL before the browser sends the request. The creator of the extension appears well aware that the extension violates Amazon's Conditions of Use [3] and has heavily used obfuscation, evidently to evade any static analysis for detecting affiliate fraud.

As another example, we found an extension named "Page Refresh" (200 installations) that allows users to refresh tabs periodically and only requests `tabs` permission. By using the background page to listen on all tab update events, if a user visits a merchant site it sets the URL in the tab to a URL shortener that redirects the user to the same merchant page but with the affiliate identifier included in the URL, thereby stuffing a cookie into the user's browser. This extension abuses 40 different merchants, again including Amazon.

This approach has the advantage that it capitalizes on organic traffic to merchant sites, which can make fraud detection difficult because merchants see visit behavior highly similar to that they would otherwise see as a result of legitimate affiliate referrals.

The second group of extensions includes extensions that clearly state in their descriptions that the extension monetizes the user's online purchases—generally for charitable causes or donations to organizations. The intent or legitimacy of such programs is difficult to ascertain. For example, the extension "Give as you Live" [8] has over 11K users, and forms part of a larger campaign [7] to raise funds for charities from user purchases online. The extension works by adding a list of stores for which the extension author has signed up as an affil-

iate to the results of major search engines. It also adds a script on merchant sites such as `amazon.co.uk` to redirect users via its own URL. While it does bring legitimate and likely well-intentioned traffic to Amazon, the legitimate affiliates can lose out if users choose to read product reviews on affiliate sites and then make the purchase via this extension.

In fact, a plethora of extensions exists allowing users to donate to charity simply by shopping online. Another such extension uses `webRequest` permissions to modify the requested URL to the affiliate URL, including over-writing the existing affiliate URL. While this clearly constitutes cookie-stuffing, the extension advertises itself as "Help support our charity by shopping at amazon.co.uk".[3]

5.3 Information Theft

Information theft clearly reflects malicious behavior that has the potential to harm the user in a number of ways, from disclosing private information to financial loss. This broad category of abuse in many ways replicates the functionality of some malware families. Within the browser, we observe stealing of: keypresses, passwords and form data, private in-page content (e.g., bank balances), and authentication tokens such as cookies. We do not include extensions that simply re-use existing authentication tokens already present, such as extensions that spam on social networks; we discuss these in Section 5.4.

One example of keylogging we found in the Chrome Web Store, "Chrome Keylogger", is an experimental extension from researchers [14] that is now removed. Keyloggers use content scripts to register callbacks for key press events, recording the pressed key by using the messaging API to communicate with a background page. The background page then queues up data to send to a remote server. This behavior has similarities with that of extensions that steal form data, although the specific event handlers differ. Both form field theft and keylogging require the extension to specify a content script but do not require other permissions.

5.4 OSN Abuse

Online social network abuse constitutes the final category of prevalent malicious extensions we found. These extensions typically target Facebook, and spread via both the Chrome Web Store and sideloading. These extensions use existing authentication data to interact with the APIs and websites of online social networks. Previous work identified and reported Chrome extensions that abuse social networks, reporting that thousands of users had installed extensions from the Chrome Web Store that spam on Facebook [4].

[3] The extension creator also helpfully marked the JavaScript code that adds the affiliate identifier as something to obfuscate in the future.

```
"content_scripts": [{
  "js":["BlobBuilder.js", ... ],
  "matches":["http://*/*", "https://*/*" ],
  "run_at": "document_end"
}],
"permissions":["http://*/*", "https://*/*",
"*://*.facebook.com/",
"tabs", "cookies", "notifications",
"contextMenus", "webRequest", ...],
```

Figure 3: Permissions and content script excerpts from the manifest for an extension that spams on Facebook and creates Tumblr accounts.

We found a number of extensions that post spam messages and use other features provided by social networks, such as the ability to upload and comment on photos or query the social graph. When we execute these extensions with Hulk, the HoneyPage features allows the extensions to create elements and insert them into the DOM tree. While we do not typically inspect the visual results of our executions, in one case we observed an extension creating `div` elements to mimic Facebook status updates and inserting them into a page. The HoneyPage acted as a sink for the spam status messages resulting in a page full of spam for the infected user.

One extension of interest, *WhasApp* (a name closely resembling the popular *WhatsApp*, a mobile chat application), has since been removed from the Chrome Web Store, but we also found evidence of the same extension being sideloaded from malware. The extension targets both Facebook and Tumblr. At Facebook, the extension uploads images to Facebook and then comments on them with messages containing URLs. In some cases the links are used to spread the malicious extension to a wider audience, while other URLs sought to monetize users as part of a spam campaign to advertise products. At Tumblr, the extension creates new Tumblr accounts and verifies them in the background.

The manifest file contains permissions and content scripts that request broad access, as shown in Figure 3. The extension is in fact over-privileged, since the extension in fact does not use some of the API permissions the manifest includes. Prior work has identified over-privileging as not uncommon, even among benign extensions [13]. Figure 3 shows the extension specifically requesting access for permissions and content scripts on `facebook.com` in addition to all other sites, which provides a hint as to the sites targeted. To carry out spamming on Facebook and Tumblr account creation,

the extension actually only requires the use of content scripts. The abusive component of the extension is 15 lines of JavaScript that downloads a much larger remote JavaScript file containing the spamming functionality.

6 Recommendations

In this section, we frame changes to make Chrome's extension ecosystem safer. Extensions should not have the ability to manipulate browser configuration pages, such as `chrome://extensions`, that govern how users manage and uninstall extensions. Extensions should also not be allowed to uninstall other extensions unless they are from the same author or a trusted source (such as Google or Antivirus vendors). We also recommend preventing extensions from manipulating HTTP requests by **removing security-related headers** that compromise the security of web pages. This change will require modifications to several extension APIs to comprehensively address this issue, the primary one being `webRequest`.

To address cloaking and other changes in remotely included content, we suggest that Google should encourage **local inclusion of static files** in the context of a web page. Chrome supports pushing automatic updates of extensions to users, so remotely including additional JavaScript code is not necessary to support rapid changes in an extenion's code. This change will make it possible to have a more complete analysis of extension behavior, since the analysis engine—Hulk or otherwise[4]—will have the complete extension code available. To encourage developers to write completely self-contained extensions and not load additional code from the network, one could introduce a new policies, such as: if an extension loads code from a remote site, it loses permissions such as the ability to inject that new code into the visited pages.

Finally, extensions should not have the ability to **hook all keyboard events** on a given site. The *window.onkey** API that exists in JavaScript has utility for pages that want to intercept the keyboard events of their users, but in the context of extensions it provides too much power. An experimental API (*chrome.commands*) exists that allows extensions to register keyboard shortcuts; this strikes us as a step in the right direction, as this covers the common use-case for requiring access to these events.

These suggestions will not eliminate malicious extensions, but can prevent classes of attacks, and significantly facilitate the analysis of extensions.

[4] In particular, ultimately an extension store operator such as Google needs to undertake such analysis as part of its curation of the store contents.

7 Limitations

Our system uses dynamic analysis for analyzing extensions, and, as with every dynamic analysis system, the correct classification of an extension relies on triggering the malicious activity. Hulk employs HoneyPages and event handler fuzzing on the extension's web request listeners to enhance dynamic analysis, but does not provide a complete view of extension behavior. For example, we do not attempt to address cloaking that loads different code based on the client's location or time. We also will not observe behavior that depends on specific targets, such as those that require user interaction with a visited page to take effect. Similarly, pages that require sign-in pose difficulties. Hulk has a pre-set list of sites and credentials to use while visiting pages, but does not perform account creation on the fly.

Hulk's Honeypages do not currently support multi-step querying of DOM elements. While we can place elements in the DOM tree that an extension looks for, if the extension expects elements to have additional properties in order to trigger its malicious behavior, we will fail to adapt to the extension's expectations. We plan on improving HoneyPages to support multi-step querying, and for many element types and attributes this appears possible.

We currently also lack data flow analysis in the Chrome browser, a feature that would substantially improve the depth of behavior available for analysis. One example where this would prove particular useful regards keystroke interception. Without data flow tracking, we cannot automatically derive whether this information ultimately becomes transmitted to a third party via a network request.

Another difficult concern for Hulk is analysis evasion by extensions that specifically look for HoneyPages. A determined adversary with knowledge of the system could try to evade Hulk by querying for random elements in the DOM tree first, and, if found, avoid malicious activity. A similar type of evasive behavior arose for in submissions to Wepawet [17]. One way to counter this is by introducing non-deterministic HoneyPages for which DOM tree queries only succeed with a given probability. We could further enhance this approach by crawling a few million sites and building models of the existing elements to assign apt probabilities weights for different queries. This approach may also require analysis of an extension's DOM queries in case the extension repeatedly performs these in an effort to detect randomized queries. Finally, we can consider measuring code coverage to examine the impact that each DOM query has on the amount of code executed by an extension, as the extension will skip executing the malicious code when it detects the presence of an analysis system.

8 Related Work

Browser extensions have been available for Internet Explorer and Firefox for over a decade. As a result of a study of vulnerabilities in Firefox extensions, Barth et al. designed an extension architecture that promotes least privilege and isolation of components to prevent a compromised extension from gaining full access to a user's browser [5], an architecture subsequently adopted by Google Chrome. Since then, further work has examined the success of the Chrome extension architecture at preventing damage [6] and the ability of developers to correctly request privileges for their extensions [13]. Similar studies have examined the Firefox extension system to limit the potential damage arising from exploitation of extension vulnerabilities, and to improve the defenses the browser provides [27]. These works have a focus mostly tangential to our work, since the principle of least privilege does not prevent an overtly malicious extension from executing malicious code.

The security industry has documented malicious extensions in ways similar to malware reports and other new threats [2, 4]. Liu et al. examined Google Chrome extensions and, based on malicious extensions the authors built, suggested refined privileges to make detecting malicious extensions easier [21]. In our work, we build a system that performs dynamic analysis and classification of extensions, and present an analysis of malicious extensions that we found in the wild.

JavaScript-based program analysis has particular promise for benefiting our work, and in light of our current limitations we will be exploring techniques that we can adapt to improve our system's detection capabilities. Research has applied information flow analysis to Firefox extensions [10], performed taint-based tracking of untrusted data within the browser [11], used symbolic execution to detect vulnerabilities [26], applied static verification to extensions [16], contained extensions in privacy-preserving environments [20], and used supervised learning of browser memory profiles to detect privacy-sensitive events [14].

Our work has similarities to that of other malware detection and execution systems. While our implementation and requirements significantly differ from systems that execute Windows binary malware (such as Anubis [1]), at a high level we share common goals of executing and extracting data from samples. Like Anubis, Wepawet, the GQ honeyfarm, and other malware execution platforms, we share the difficult problem of triggering malicious behavior in a synthetic environment [9, 19]. Other research in this area has focused on classification and discerning malware from goodware [24].

9 Summary

In this paper we presented Hulk, a system to dynamically analyze Chrome browser extensions and identify malicious behavior. Our system monitors an extension's actions and creates a dynamic environment that adapts to an extension's needs in order to trigger the intended behavior of extensions, classifying the extension as malicious or benign accordingly. In total, we identified 130 malicious and 4,712 suspicious extensions that have up to 5.5 million browser installations, many of which remain live in the Chrome Web Store. Based on these results, we developed a detailed characterization of the malicious behavior that we found, targeted at determining the motivation behind the extension. Finally, we propose several changes for the Chrome browser ecosystem that could eliminate classes of extension-based attacks and aid with analysis.

Acknowledgments

We would like to thank our shepherd David Evans for his insightful comments and feedback. We would also like to thank Niels Provos, Adrienne Porter Felt, Nav Jagpal and the rest of the Safebrowsing team at Google for their insight and discussions throughout this project. Abstract

The current generation of client-side Cross-Site Scripting filters rely on string comparison to detect request values that are reflected in the corresponding response's HTML. This coarse approximation of occurring data flows is incapable of reliably stopping attacks which leverage non-trivial injection contexts. To demonstrate this, we conduct a thorough analysis of the current state-of-the-art in browser-based XSS filtering and uncover a set of conceptual shortcomings, that allow efficient creation of filter evasions, especially in the case of DOM-based XSS. To validate our findings, we report on practical experiments using a set of 1,602 real-world vulnerabilities, achieving a rate of 73% successful filter bypasses. Motivated by our findings, we propose an alternative filter design for DOM-based XSS, that utilizes runtime taint tracking and taint-aware parsers to stop the parsing of attacker-controlled syntactic content. To examine the efficiency and feasibility of our approach, we present a practical implementation based on the open source browser Chromium. Our proposed approach has a low false positive rate and robustly protects against DOM-based XSS exploits.

1 Introduction

Ever since its initial discovery in the year 2000 [6], Cross-Site Scripting (XSS) is an ever-present security concern in Web applications. Even today, more than ten years after the first advisory, XSS vulnerabilities occur in high numbers [39] with no signs that the problem will be fundamentally resolved in the near future. Furthermore, in recent years, DOM-based XSS, a subtype of the vulnerability class that occurs due to insecure client-side JavaScript, has gained traction, probably due to the shift towards rich, JavaScript heavy Web applications. In a recent study, we have shown that approximately 10% of the Alexa Top 5000 carry at least one DOM-based XSS vulnerability [18].

The design of protection measures against XSS has received considerable attention. In its core, XSS is a client-side security problem: The malicious code is executed in the client-side context of the victim, affecting his client-side execution environment. Hence, a well-suited place to protect end users against XSS vulnerabilities is the Web browser. Following this concept, several client-side XSS filters have been developed over the years.

These contemporary client-side XSS filtering mechanisms rely on string-based comparison of outgoing HTTP requests and incoming HTTP responses to detect reflected XSS attack payloads. In essence, this string comparison is an approximation of server-side data flows that might result in direct inclusion of request data in the HTTP response. While this approximative approach is valid for server-based XSS vulnerabilities – the browser has no insight on the server-side logic – it is unnecessarily imprecise for client-side XSS issues.

In contrast to server-side problems, the complete data flow within the browser from attacker-controlled sources to the security-sensitive sinks into the browser's JavaScript engine occurs within one system and thus can be tracked seamlessly and precisely. Based on this observation, we propose a different protection approach: A client-side XSS filtering mechanism relying on precise dynamic taint tracking and taint-aware parsers within the browser.

To demonstrate the current limitations of the established approaches – which focus mainly on stopping reflected XSS attacks – we first conduct an in-depth analysis of the current state-of-the-art in client-side XSS filtering, with focus on the capabilities of thwarting DOM-based XSS attacks (see Section 3). In course of this analysis, we uncover a set of conceptual weaknesses which, taken together, render the existing techniques incapable of protecting against the majority of client-side XSS attacks (see Section 4). To practically validate our analysis, we report on a fully automatic system to create XSS attacks which evade the current protection mechanism:

Using a data set of 1,602 real-life DOM-based XSS vulnerabilities, we successfully created XSS vectors that bypassed client-side filtering in 73% of all cases, affecting 81% of all vulnerable domains we found.

Motivated by the results of our experiments, we propose an alternative approach for client-side prevention of DOM-based XSS: Using character-level taint tracking in the browser we can precisely detect cases in which attacker-controlled values end up in a syntactic parsing context which might lead to the browser executing the injected data as JavaScript. By enhancing the browser's HTML and JavaScript parsers to identify tokens that carry taint markers, we can efficiently and robustly stop injection attempts. To summarize, we make the following contributions:

- *Systematic analysis of conceptual shortcomings of current client-side XSS filters:* We report on a systematic investigation on the current state-of-the-art client-side XSS filter, the XSS Auditor, and identify a set of conceptual flaws that render the filter incapable of effectively protecting against DOM-based XSS attacks.
- *Automatic filter bypass generation:* To validate our findings and to demonstrate the severity of the identified filter limitations, we built a fully automated system to generate XSS payloads which bypass the string comparison based XSS filter. Our system leverages the precise flow information of our taint-enhanced JavaScript engine and our detailed knowledge on the Auditor's functionality to create exploit payloads that are tailored to a vulnerability's specific injection context and the applicable filter weakness. By practically applying our system to a set of 1,602 real-world DOM-based XSS vulnerabilities, we achieved a success rate of 73% successful filter bypasses.
- *Robust protection approach, utilizing client-side taint propagation:* Based on the identified weaknesses in the established XSS filtering approaches, we propose an alternative protection measure which is designed to address the specific characteristics of DOM-based XSS. Through combining a taint-enhanced browsing engine with taint-aware JavaScript and HTML parsers, we are able to precisely track the flow of attacker-controlled data into the parsers. This in turn enables our system to reliably detect and stop injected code on parse time.

2 Technical Background

In the following, we briefly discuss DOM-based Cross-Site Scripting and shed light on the technical basis used for this work, namely a taint-aware browsing engine.

2.1 DOM-based Cross-Site Scripting

Cross-Site Scripting (XSS) is a term describing attacks where the adversary is able to inject his own script code into a vulnerable application, which is subsequently executed in the browser of the victim in the context of this application. In contrast to the server-side variants of XSS, namely reflected and persistent, the term DOM-based Cross-Site Scripting (or DOM-based XSS) subsumes all classes of vulnerabilities which are caused by insecure client-side code. The term itself was coined by Klein in 2005 [16]. These issues come to light when untrusted data is used in a security-critical context, such as a call to `eval`. In the context of DOM-based XSS, this data might originate from different sources such as the URL, postMessages [38] or the Web Storage API.

2.2 Browser-level Taint Tracking

One of the underlying technical cornerstones of this paper is the taint-enhanced browsing browsing engine we developed for CCS 2013 [18]. This engine allows precise tracking of data flows from attacker-controlled sources, such as `document.location`, to sinks, such as `eval`.

Our implementation, based on the open source browser Chromium, provides support for tracking information flow on the granularity of single characters by attaching a numerical value to identify the origin of the character's taint. This taint marker is propagated whenever string operations are conducted and is also persisted between the two realms of the rendering component, i.e., Blink, and the V8 JavaScript engine.

As this part of our system is not one of the paper's major contributions, we omit further details for brevity reasons and refer the reader to the aforementioned paper.

3 Current Approaches for Client-side XSS Filtering

In this section we investigate the current in-browser techniques used to detect and prevent XSS attacks. More specifically, we describe the concepts of the Firefox plugin NoScript [20], Internet Explorer's XSS Filter [29] and Chrome's XSS Auditor [2].

3.1 Regular-expression-based Approaches: NoScript and Internet Explorer

One of the first mechanisms on the client side to protect against XSS attacks was introduced by the NoScript Firefox Plugin [22] in 2007. NoScript utilizes regular expressions to filter outgoing HTTP *requests* for potentially malicious payloads. If one of the regular expressions matches, the corresponding parts are removed from the HTTP request. The malicious payload will thus never

reach the vulnerable application and hence an attack is thwarted. Nevertheless, as described in NoScript's feature list, this potentially leads to false positives [21] due to its aggressive filtering approach. NoScript works around this issue by prompting the user whether to repeat the request, this time disabling the protection mechanism. While this seems to be a valid approach for NoScript's security-aware users, it is not acceptable as a general Web browser feature, as many studies have shown that an average user is not able to properly react to such security warnings [9, 13, 34].

In order to tackle this problem Microsoft slightly extended NoScript's approach and integrated it into Internet Explorer [29]. Similar to NoScript, IE's XSS filter utilizes regular expressions to identify malicious payloads within outgoing HTTP requests. Instead of removing the potentially malicious parts from a request, the filter generates a signature of the match and waits for the HTTP response to arrive at the browser. If the signature matches anything inside the response, i.e., if the payload is also contained within the response, the filter removes the parts it considers to be suspicious. Thus, attacks are only blocked if the payload is indeed contained in the response and, hence, depending on the situation, false positives are less frequent. In fact, avoiding false positives is one of the filter's many design goals [30], even if this results in a higher false negative rate, as Microsoft's David Ross states: "Thus, the XSS Filter defends against the most common XSS attacks but it is not, and will never be, an XSS panacea." [30].

In 2010, Bates et al. [2] demonstrated that regular-expression-based filtering systems have severe issues and proposed a superior approach in the form of the XSS Auditor, which has been adopted by the WebKit browser family (Chrome, Safari, Yandex).

3.2 State-of-the-Art: The XSS Auditor

Based on the identified weaknesses of regular-expression-based XSS defenses, Bates et al. proposed the XSS Auditor – a new system that is "faster, protects against more vulnerabilities, and is harder for attackers to abuse" [2]. Up to now, the XSS Auditor constitutes the state-of-the art in client-side XSS mitigation, albeit focusing mainly on reflected XSS.

As we will demonstrate in this paper, the XSS Auditor also has shortcomings, especially related to DOM-based XSS attacks. Before we explore the limitations of the system in the next section, we provide an overview of the Auditor's protection mechanism.

One of the key differences between Chrome's XSS Auditor and previous filter designs is the filter's placement within the browser architecture. Instead of applying regular expressions on the string representations of the HTTP requests or responses, the Auditor is placed between the HTML parser and the JavaScript engine [2]. The idea behind this placement is, that an attacker's payload has to be parsed by the HTML parser to be transferred to the JavaScript engine where the injected payload is being executed.

In order to block XSS attacks, the Auditor receives each token generated by the HTML parser and checks whether the token itself or some of its attributes are contained in either the request URL or the request body. If so, the filter considers the token to be injected and replaces JavaScript or potentially harmful HTML attributes with a benign value. Such a benign value is a payload that has no effect, such as `about:blank`, `javascript:void(0)` or an empty string. The injected fragments will thus not be passed to the JavaScript engine and hence attacks are prevented.

The main design goals of the filter are to avoid false positives and to minimize performance impact. Before demonstrating that these goals severely impact the filter's detection capabilities, we will first provide details on the detection algorithm (simplified to satisfy space and readability constraints):

1. **Initialization (For document fragments)**
   (a) Deactivate the filter
2. **Initialization (For each full document)**
   (a) Fully decode the request URL
   (b) Fully decode the request body
   (c) Check if request could contain an injection
      i. If not, deactivate the filter
      ii. Otherwise continue
3. **For each start token in the document do...**
   (a) Check and delete dangerous attributes
      i. Delete injected event handlers
      ii. Delete injected JavaScript URLs
   (b) Conduct tag specific checks
4. **For each script token in the document do...**
   (a) Check and delete injected inline code

As soon as the so-called *HTMLDocumentParser* is spawned by Chrome, an initialization routine of the XSS Auditor is called. The parser can either be invoked for parsing document fragments or complete documents. While the XSS filter is deactivated for document fragments, it guesses whether an injection attack is likely to be present for full documents. If either the URL or the request body contains one of the characters shown in Listing 1, the filter is activated. If none of these characters is found, the filter assumes the browser not being under attack and skips the complete filtering process.

If, on the other hand, one of the characters mentioned in Listing 1 is present in the request the Auditor investigates every token within the document for injected values that might cause script execution. This process

Listing 1 Required characters to activate the filter

```
static bool isRequiredForInjection(UChar c)
{
    return (c == '\'' || c == '"' ||
            c == '<'  || c == '>');
}
```

is threefold: First the Auditor looks for dangerous attributes, second it conducts tag specific checks for certain attributes and third it filters injected inline scripts.

Dangerous Attributes are, in the view of the Auditor, attributes that either contain a JavaScript URL or have the name of an inline event handler (`onclick`, `onload`, etc.) as these attributes can enable XSS attacks. If such an attribute is found, the Auditor searches for it within the corresponding request. If a match is found, the filter assumes the attribute to be injected and either deletes the complete attribute value in case of event handlers or replaces the JavaScript URL with a benign URL.

Tag-specific filtering Besides event handlers and attributes containing JavaScript URLs, other tag specific attributes that need to be filtered exist. An attacker could, for example, inject a script tag and use the `src` attribute to load an external script file. Hence, for any script token, the Auditor additionally checks the legitimacy of the `src` attribute. In total, the Auditor conducts such checks for 18 additional attributes contained in 11 tokens (script, object, param, embed, applet, iframe, meta, base, form, input and button).

Filter inline scripts Whenever the Auditor encounters a script tag, it also validates whether the content between opening and closing tag has been injected. If the content can be found in the request, it is replaced with an empty string.

4 Limitations of String-based XSS Filters

In this section we report on a detailed analysis we conducted to assess the XSS Auditor's protection capabilities with a focus on DOM-based XSS. Although the XSS Auditor was designed to stop reflected Cross-Site Scripting attacks, it is also the most advanced and deployed filter against DOM-based XSS attacks. In the following, we therefore analyze issues related to the concept of the Auditor, which impair its capabilities of stopping DOM-based XSS attacks. In doing so, we show the arising need for a filter capable of stopping DOM-based XSS attacks.

4.1 Scope-related Issues

In general, the Auditor is called whenever potentially dangerous elements are encountered during the initial parsing of the HTTP response. These are, however, not the only situations in which attacker-controlled data might end up being interpreted as code. In this section, we explore situations in which the filter is not active and hence does not protect against attacks.

eval As mentioned earlier, the Auditor is placed between the HTML parser and the JavaScript engine to intercept potential XSS payloads. Still, not every DOM-based XSS attack needs to go through the HTML parser. If a Web site invokes the JavaScript function `eval` with user-provided data, the execution will never pass the HTML parser. Therefore, the Auditor will never see a malicious payload that an attacker injected into a call to `eval`. As we will demonstrate later, `eval` is commonly used in Web applications.

innerHTML While script tags inserted via `innerHTML` are not executed, it is still possible to execute JavaScript via inline event handlers. Hence, `innerHTML` is also prone to XSS attacks. In earlier versions of the Auditor content parsed via `innerHTML` was also filtered. Google later experienced some performance drawbacks in innerHTML-heavy applications [17] and as a consequence, the Auditor is nowadays disabled for document fragment parsing which is invoked upon an assignment to `innerHTML`.

Direct assignment to dangerous DOM properties Besides `eval` and `innerHTML` it is also possible to trigger the execution of scripts without invoking a HTML parsing process as a few examples in Listing 2 show. As no HTML parsing takes place in these cases, the XSS Auditor is never invoked. Hence, if a Web application assigns a user-controlled value to such a DOM property, an attacker is able to evade the filter.

Listing 2 Examples for dangerous DOM properties

```
var s = document.createElement("script");
s.innerText = "myFunction(1)";        // 1.
s.src = "http://example.org/script.js"// 2.

var i = document.createElement("iframe");
i.src = "javascript:myFunction(1)"    // 3.

var a = document.createElement("a");
a.href = "javascript:myFunction(1)"   // 4.
```

Second order flows When investigating a token, the Auditor always validates whether a suspicious value was contained within the preceding HTTP request's URL or body. As demonstrated by Hanna et al. [10], second order flows are relevant for DOM-based XSS. So, for example, if a value is written into LocalStorage within one request/response cycle, it can be used to cause a DOM-based XSS attack in another request/response pair. As the Auditor only investigates the last request, it will not find the value sent with the second-last request. LocalStorage is only one of many ways to persist data across multiple HTTP requests as Cookies, WebStorage or the File API exist nowadays.

Alternative attack vectors It is not sufficient to only check the URL and the request body in order to prevent DOM-based XSS attacks. Multiple other sources of attacker-controllable data exist which could be abused to inject malicious content into an application. Examples are the PostMessage API, the `window.name` attribute, or the `document.referer` attribute. As the Auditor does not take these sources into account, they can be used to evade the filter.

Furthermore, Bojinov et al. demonstrated that data can be injected by an attacker via alternative communication channels [4]. Thus, so-called cross-channel scripting attacks also bypass the XSS Auditor.

Unquoted attribute injection During initialization, the Auditor checks whether filtering is necessary by verifying the presence of the characters shown in Listing 1. In doing so, it implicitly assumes that an attack is not possible without these characters. This assumption, however, is wrong. In Listing 3 we show a common vulnerability and the corresponding attack (note: the value of the id attribute is not surrounded by quotes). In this example, the payload does not make use of the required characters. Normally, the XSS Auditor would block the `src` attribute containing the JavaScript URL. In this case, however, it does not conduct any checks as it is deactivated.

Listing 3 Unquoted Attribute injection

```
var id = location.hash.slice(1);
var code = "<iframe id=" + id + " [...]>";
    code += "</iframe>";
document.write(code);

// attack payload within URL
"//example.org/#1 src=javascript:eval(name)"
```

4.2 String-matching-related Issues

In the following we explore the limits of the implemented string matching algorithms. Whenever the Auditor finds a potentially dangerous element or attribute, it verifies whether the corresponding string representation can be found in the request. If an attacker is able to mislead the string-matching algorithm, the filter can be bypassed. Hence, the precision of this process determines the filter's effectiveness and as a result its false positive and false negative rates.

4.2.1 Partial Injections

One of the assumptions the Auditor makes is that an attacker has to inject a complete tag or attribute to successfully launch an attack. As a consequence the filter always aims to find the complete tag or the complete attribute within the request. While this approach reduces false positives as it is very unlikely that an application contains an existing tag or attribute in its URL legitimately, it does not regard application-specific scenarios. This assumption leads to potential problems in three different cases:

Attribute Hijacking One of the first things the Auditor does is to check whether a dangerous attribute was injected into the application. Hence, whenever it discovers a dangerous attribute during the parsing process it regenerates the string representation of the attribute and matches it against the URL and the request body. Listing 4 shows the string generation process:

Listing 4 Attribute string matching

```
// current start token
<iframe [...] onload="alert('example')">
// Step 1: extract the dangerous attribute
onload="alert('example')"
// Step 2: Truncate after 100 characters
onload="alert('example')"
// Step 3: Truncate at a terminating char
onload="alert('
```

After detecting a potentially dangerous attribute the Auditor extracts its decoded string representation. Then, it truncates the attribute at 100 chars to avoid the comparison of very long strings. It finally truncates the string at one of seven so-called terminating characters (this is done to detect attacks, that we will cover later). The resulting string is then matched against the URL. Obviously, the resulting string always contains the name of the potentially dangerous attribute. Hence, the underlying assumption here is that the attacker always has to inject the attributes herself. In real-world applications, however, attributes can often be hijacked by an attacker as shown in Listing 5. Although the `onload` attribute is a dangerous event handler attribute, the Auditor will not discover it within the URL as the `onload` attribute's name is hardcoded within the application and not injected by the attacker.

Listing 5 Attribute & Tag hijacking vulnerability

```
var h = location.hash.slice(1);
var code = "<iframe onload='" + h + "'"
    code += "[...]></iframe>";
document.write(code);

//attack for attribute hijacking
"//example.org/#alert('example')"
//attack for tag hijacking
"//example.org/#' srcdoc='...'"
```

Tag Hijacking After checking for dangerous attributes the Auditor conducts tag specific attribute checks. Matching all attributes of all tokens within an HTML

document against the URL and request body, however, can be a very time consuming and error-prone task. Therefore, the auditor only matches an attribute against the URL if it can find the tag's name in the URL. For example, if the filter investigates an iframe token it validates whether the sequence <iframe is contained in the request before matching the src or srcdoc attribute [1]. Hence, if the injection point of a vulnerability lies within such a tag, the attacker can hijack the tag and inject additional attributes to it. As the tag itself is hardcoded the Auditor will skip any of its checks for specific attributes. An example of this attack is provided in Listing 5.

In-Script Injections Another vulnerability that is not detectable by the XSS Auditor is an injection inside of an existing inline script. As described in Section 3.2, whenever the filter encounters a script tag, it matches the *complete* inline content of the script against the request. Real-world Web applications however often make use of dynamically generated inline scripts made up from user-controllable input mixed with hardcoded values. Hence, instead of injecting a script tag via the URL an attacker is able to simply inject code into an existing dynamic inline script. As a consequence searching for the complete script content within sources of user input will not be successful.

4.2.2 Trailing Content

A very similar problem to partial injections is trailing content. When real-world Web applications write input to the document, they do not simply write one single value coming from the user but rather use a string that was constructed from hardcoded values as well as potentially attacker-controlled values. Listing 6 shows a real-world example.

Listing 6 An example of String construction

```
var code = "<iframe src='//example.org/";
    code += getParamFromURL("page_name");
    code += ".html'></iframe>";;
document.write(code);

// attack payload:
"' onload='alert(1);foo"
// resulting code
"<iframe src='//example.org/'
       onload='alert(1);foo.html'>"
```

Note, that the injection point is inside the src attribute of the iframe tag. Within this src attribute, the attacker-controllable input starts in the middle of the attribute (after //example.org/) and some more content is following the injection point (.html). When crafting an attack, the attacker is able to use the trailing content within the payload to confuse the string matching process. Despite the fact that the Auditor is aware of this issue (source code comments indicate this) and defends against it, the current defenses are not able to reliably detect which parts are actually injected by the attacker and which parts are hardcoded within the Web application. We found four bypasses which allow an attacker to exploit this problem in different and partly unexpected ways. Due to the high complexity and the limited space, we omit a detailed explanation here.

4.2.3 Double Injections

Another conceptional flaw of string-matching-based approaches is the inability to discover concatenated values coming from more than one source of user input. As we have shown in previous work [18], a call to a security sensitive function contains on average three potentially attacker provided substrings. Listing 7 shows an example for such a double injection.

Listing 7 An example of double injection

```
var id = getParamFromURL("id");
var name = getParamFromURL("name");
var code = "<iframe id='" + id + "'";
    code += " name='" + name +"'";
    code += "[...]></iframe>";
document.write(code);

// attack
id="'/><script>void('"
name="');alert(1)</script>"
// resulting code
<iframe id=''/>
<script>void(' name=');alert(1)</script>
[...]></iframe>
```

As the call to document.write contains two injection points (id, name) an attacker is able to split the payload. A specially crafted set of inputs, as shown in the Listing, therefore leads to the creation of a valid script tag that is a combination of both attacker inputs. In this case, the Auditor's string matching algorithm would search for void('name=');alert(1) within the request. Finding this value in the URL, however, is not possible as the ' name =' part is hardcoded and not originating from the URL. Furthermore, the attacker is able to arbitrarily change the order in which the values appear within the URL. Hence, double injections are a severe conceptional problem for string-matching-based approaches. In total, we identified three different classes of double injection. The first class has been explained in the example above. A call to document.write contains two injection points

[1] For iframe.srcdoc the tag hijacking attack is not possible anymore, as concurrent research discovered this issue and reported it to Google. Upon the report Google changed the behavior for srcdoc. Nevertheless, for any other of the 18 special attributes, tag hijacking still is an issue

and the injected values are independent from each other. Very similar to this approach, the double injection pattern also applies to situations in which a single value is used twice within a single call to a security sensitive function. Finally, double injection attacks can be conducted if subsequent calls to `document.write` are made containing attacker-controllable values.

4.2.4 Application-specific Input Mutation

Another assumption of the XSS Auditor is that input of the user always reaches the parser without any modifications. If even one character of the input changed, the string matching algorithm will fail to find the payload and hence is not able to block the resulting attack. Application-specific encoding functions or data formats, therefore, lead to situations in which the filter can be bypassed.

4.3 Practical Experiments

As previously demonstrated we found numerous conditions under which the protection mechanisms of the XSS Auditor can be evaded, especially with respect to DOM-based Cross-Site Scripting. In order to assess the severity of the identified issues for real-world applications, we conducted a practical experiment. We used the methodology applied for our previous paper [18] to collect a set of 1,602 unique real-world DOM-based XSS vulnerabilities on 958 domains. We then built a bypass generation engine to verify whether a certain vulnerability allows employing one of the bypassing techniques described above.

Using our taint-aware infrastructure we are able to determine the exact injection context of a vulnerability. As soon as our infrastructure detects a call to a security sensitive sink such as `document.write`, `eval`, or `innerHTML`, it stores the string value and the exact taint information. Using a set of patched HTML and JavaScript parsers, we can exactly determine the location of the injection point. Using this data, we cannot only give an indication for a filter evasion possibility, but also generate an exact bypass that takes the injection point's context as well as the specific flaws of the Auditor into account. Applying this technique we compiled a set of bypasses that we evaluated against the vulnerabilities.

In doing so, we were able to bypass the filter for 73% of the 1,602 vulnerabilities, successfully exploiting 81% of the 958 domains in our initial data set.

4.4 Analysis & Discussion

As demonstrated by our practical experiments, the XSS Auditor – which aims at stopping reflected Cross-Site Scripting – can not stop DOM-based XSS attacks in the aforementioned cases. We therefore believe that additional defenses are necessary to combat this type of Cross-Site Scripting. Furthermore, the results of our analysis lead us to believe that the design of the XSS Auditor is prone to being bypassed in certain reflected XSS attack scenarios which are related to string-based matching issues. Since the focus of our work is on DOM-based XSS, we leave the investigation of this assumption to future work.

In our analysis, we identified two conceptual issues that limit the Auditor's approach in detecting and stopping DOM-based XSS attacks.

Placement One of the Auditor's strengths compared to Internet Explorer's and NoScript's approach is its placement between the HTML parser and the JavaScript engine. This way the Auditor does not need to approximate the browser's behavior during the filtering process. As we have shown in Section 4.1 the current placement is prone to different attack scenarios which are not taken into account by the filter. Currently the Auditor is not able to catch JavaScript-based injection attacks and situations in which HTML parsing is not conducted prior to a script execution.

String matching Even if it would be possible to extend the Auditor's reach to the JavaScript engine and the so-called *DOM bindings*, the string matching algorithm is another conceptual problem that will be very difficult if not impossible to solve. In order to cope with the situation the XSS Auditor introduced many additional checks and optimizations to thwart attacks. Nevertheless and despite the fact that a lot of bug hunters regularly investigate the filter's inner workings, we were able to find 13 bypasses targeting the string matching algorithm. All the mentioned problems will not disappear as employing string matching is inherently imprecise.

5 Preventing Client-side Injection Attacks during Parse-time

As the previous section has shown, current concepts of Cross-Site Scripting filters are not designed to thwart DOM-based XSS and, thus, are not sufficient to protect users against these kinds of attacks. In this section, we discuss the methodology behind our newly proposed filter as well as the corresponding policy considerations. We then go into detail on the issue of handling postMessages in our filter and finally outline the technical challenges we had to overcome to implement the concept into a real-world browser.

5.1 Methodology Overview

As we have demonstrated in Section 4.2, client-side XSS filters relying on string comparison lack the required precision for robust attack mitigation. String comparison

as an approximation of occurring data flows is a necessary evil for flows that traverse the server. For DOM-based XSS, this is not the case: The full data flow occurs within the browser's engines and can thus be observed precisely. For this reason, we propose an alternative protection mechanism that relies on runtime tracking of data-flows and taint-aware parsers and makes use of two interconnected components:

- A taint-enhanced JavaScript engine that tracks the flow of attacker-controlled data.
- Taint-aware JavaScript and HTML parsers capable of detecting generation of code from tainted values.

This way our protection approach reliably spots attacker-controlled data during the parsing process and is able to stop cases in which tainted data alters the execution flow of a piece of JavaScript. In the following, we discuss the general concept and security policy, whereas we go into more detail on the implementation in Section 5.4 and investigate the implications of our proposed filtering approach in Section 6.1.

5.2 Precise Code Injection Prevention

As we outlined in the previous section our protection approach relies on precise byte-level taint tracking.

In the following we give a detailed overview on the necessary changes we performed in order to implement our filtering approach. More specifically, we made changes to the browser's rendering engine, the JavaScript engine and the DOM bindings, which connect the two engines.

JavaScript Engine When encountering a piece of JavaScript code, the JavaScript engine first tokenizes it to later execute it according to the ECMAScript language specification.

While it is a totally valid use case to utilize user-provided data within data values such as String, Boolean or Integer literals, we argue that such a value should never be turned into tokens that can alter a program's control flow such as a function call or a variable assignment. We therefore propose that the tokenization of potentially attacker-provided data should never result in the generation of tokens other than literals. As our JavaScript engine is taint-aware, the parser is always able to determine the origin of a character or a token. Hence, whenever the parser encounters a token that violates our policy, execution of the current code block can be terminated immediately.

Rendering Engine Besides injecting malicious JavaScript code directly into an application, attackers are able to indirectly trigger the execution of client-side code. For example, the attacker could inject an HTML tag, such as the script or object tag, to make the browser fetch and execute an external script or plugin applet. Hence, only patching the JavaScript engine is not sufficient to prevent DOM-based XSS attacks. To address this issue we additionally patched the HTML parser's logic on how to handle the inclusion of external content. When including active content we again validate the origin of a script's or plugin applet's URL based on our taint information. One possible policy here is to reject URL containing tainted characters. However, as we assess later, real-world applications commonly use tainted data within URLs of dynamically created applets or scripts. Therefore, we allow tainted data within such a remote URL, but we do not allow the tainted data to be contained either in the protocol or the domain of the URL. The only exemption to this rule is the inclusion of external code from the same origin. In these cases, similar to what the Auditor does, we allow the inclusion even if the protocol or domain is tainted. This way, we make sure that active content can only be loaded from hosts trusted by the legitimate Web application.

DOM bindings Very similar to the previous case the execution of remote active content can also be triggered via a direct assignment to a script or object tag's src attribute via the DOM API. This assignment does not take place within the HTML parser but rather inside the DOM API. We therefore patched the DOM bindings to implement the same policy as mentioned above.

Intentional Untainting As our taint-aware browser rejects the generation of code originating from a user-controllable source, we might break cases in which such a generation is desired. A Web application could, for example, thoroughly sanitize the input for later execution. In order to enable such cases we offer an API to taint and untaint strings. If a Web application explicitly wants to opt-out of our protection mechanism, the API can be used to completely remove taint from a string.

5.3 Handling Tainted JSON

While our policy effectively blocks the execution of attacker-injected JavaScript, only allowing literals causes issues with tainted JSON. Although JavaScript provides dedicated functionality to parse JSON, many programmers make use of `eval` to do so. This is mainly due to the fact that `eval` is more tolerant whereas `JSON.parse` accepts only well-formed JSON strings. Using our proposed policy we disallow tokens like braces or colons which are necessary for parsing of JSON. In a preliminary crawl, we found that numerous applications make use of postMessages to exchange JSON objects across origin boundaries. Hence, simply passing on completely tainted JSON to the JavaScript parser would break all these applications whereas allowing the additional tokens to be generated from parsing tainted JSON might jeopardize our protection scheme. In order to combat

these two issues we implemented a separate policy for JSON contained within postMessages. Whenever our implementation encounters a string which heuristically matches the format of JSON, we parse it in a tolerant way and deserialize the resulting object. In doing so, we only taint the data values within the JSON string. This way incompatible Web applications are still able to parse JSON objects via `eval` without triggering a taint exception. Since we validated the JSON's structure, malicious payloads cannot be injected via the JSON syntax. If a deserialized object's attributes are used later to generate code, they are still tainted and attacks can be detected. If for some reason our parser fails, we forward the original, tainted value to the postMessage's recipient to allow for backwards compatibility.

5.4 Implementation

To practically validate the feasibility of our protection approach we conducted a prototypical implementation based on the open source browser, Chromium, version 30.0.1561.0. This section will provide details on a selection of issues we encountered when implementing the desired protection capabilities.

Equality problem for tainted strings: We had to decide when a tainted string should be considered equal to an untainted version as this requirement is dependent on the situation at hand. Under certain circumstances we do want to consider them as being equal but there are also conditions under which equality should not be given. For example, when creating DOM elements from tainted strings, we do want a tainted string to be equal to an untainted version because the tainted string should match the untainted version for the correct element to be created. If the strings would not match, the correct element could not be looked up and hence an unknown (or custom) element would be created. On the other hand, when looking up a string in a cache, we do not want the tainted version to be equal to an untainted one. If that were the case, we might loose taint as we retrieve the untainted version. For performance reasons WebKit uses addresses of certain strings it considers to be unique to perform an equality check. We thus needed to implement a fallback method for the equality check on tainted strings if we desire a tainted string to be equal to its untainted version.

Attaching taint to JavaScript Tokens: To prevent code strings from untrusted sources to generate code, we needed to forward taint information from strings to these generated tokens. We thus needed to broaden the interface not only leading to the JavaScript lexer but also to the parser. V8 not only has a parser for the JavaScript language but also for JSON to efficiently read serialized data. While it was conceptually easy to attach another bit to the generated tokens, a sophisticated buffering logic inside V8 needed to be made taint aware. A variety of `CharacterStream` classes buffer characters of an input stream to be consumed by the scanner and also enables it to push back characters if it did not accept them. To enable taint propagation all classes of an inheritance hierarchy at least three levels deep needed to be changed.

6 Practical Evaluation

After the implementation of our modified engine as well as the augmented HTML and JavaScript parsers we evaluated our approach in three different dimensions. In this section we shed light on the compatibility of our approach with the current Web, discuss its protection capabilities, and evaluate its performance in comparison to the vanilla implementation of Chromium as well as other commonly used browsers. Finally, we summarize the results of said evaluation and discuss their meaning.

6.1 Compatibility

While a secure solution seems desirable, it will not be accepted by users if it negatively affects existing applications. Therefore, in the following, we discuss the compatibility of our proposed defense to real-world applications. We differentiate between the two realms in which our approach is deployed – namely the JavaScript parser and the HTML/DOM components – and answer the questions:

1. In what fraction of the analyzed applications do we break at least one functionality?
2. How big is the fraction of all documents in which we break at least one functionality?
3. How many of these false positives are actually caused by vulnerable pieces of code which allow an attacker to execute a Cross-Site Scripting attack?

6.1.1 Analysis methodology

To answer these questions for a large body of domains, we conducted a shallow crawl of the Alexa Top 10,000 domains (going down one level from the start page) with our implemented filter enabled. Rather than just blocking execution we also sent a report back to our backend each time the execution of code was blocked. Among the information sent to the backend were the URL of the page that triggered the exception, the exact string that was being parsed as well as the corresponding taint information. Since we assume that we are not subject to a DOM-based XSS attack when following the links on said start pages, we initially count all blocked executions of JavaScript as false positives. In total, our crawler visited 981,453 different URLs, consisting of a total of

9,304,036 frames. The percentages in the following are relative to the number of frames we analyzed.

6.1.2 Compatibility of JavaScript Parsing Rules

In total, our crawler encountered and subsequently reported taint exceptions, i.e., violations of the aforementioned policy for tainted tokens, in 5,979 frames. In the next step, we determined the Alexa ranks for all frames which caused exceptions, resulting in a total of 50 domains. Manual analysis of the data showed that on each of these 50 domains, only one JavaScript code snippet was responsible for the violation of our parsing policy. Out of these 50 issues, 23 were caused by data stemming from a postMessage, whereas the remaining 27 could be attributed to data originating from the URL. With respect to the analyzed data set this means that the proposed policy for parsing tainted JavaScript causes issues on 0.50% of the domains we visited, whereas in total only 0.06% of the analyzed frames caused issues.

To get a better insight into whether these false positive were in fact caused by vulnerable JavaScript snippets, we manually tried to exploit the flows which had triggered a parsing violation. Out of the 23 issues related to data from postMessages, we found that one script did not employ proper origin checking, allowing us to exploit the insecure flow. Of the 27 other scripts which were not using data from postMessages, we were able to exploit 21 scripts and hence 21 additional domains. This constitutes a total number of 50 domain on which one functionality caused a false positive, while 22 domains contained an actual vulnerability in just the functionality our filter blocked.

Importance of JSON-handling policy As we outlined in Section 5.3, we do allow for postMessages to contain tainted JSON which is automatically selectively untainted by our prototype. To motivate the necessity for this decision, we initially also gathered taint exceptions caused by tainted JSON (stemming from postMessages) being parsed by `eval`. This analysis showed that next to the 5,979 taint exceptions we had initially encountered, 90,937 additional documents utilized tainted JSON from postMessages in a policy-violating manner. Albeit, with respect to our data set, this only caused issues with less than 1% of all documents we analyzed, it puts emphasis on the necessity for our proposed selective untainting, whereas on the other hand, it also shows that programmers utilize `eval` quite often in conjunction with JSON exchanged via postMessages.

6.1.3 Compatibility of HTML Injection Rules

As discussed in the Section 5.2, our modified browser blocks the execution of external scripts if any character in the domain name of the external script resources is tainted – only exempting those scripts that are located on the same domain as the including document. Analogous to what we had investigated with respect to the JavaScript parsing policy, we wanted to determine in how many applications we would potentially break functionality when employing the proposed HTML parsing policy. We therefore implemented a reporting feature for *any* tainted HTML and a blocking feature for policy-violating HTML. This feature would always send a report containing the URL of the page, the HTML to be parsed, as well as the exact taint information to the backend. We will go into further detail on injected HTML in Section 7 and will now focus on all those tainted HTML snippets which violate the policy we defined in Section 5.2.

During our crawl, 8,805 out of the 9,304,036 documents we visited triggered our policy of tainted HTML, spreading across 73 domains. Out of these, 8,667 violations (on 67 domains) were caused by script elements with `src` attributes containing one or more tainted characters in the domain of the included external script. Out of the remaining six domains, we found that three utilized `base.href` such that the domain name contained tainted characters and thus, our prototype triggered a policy exception on these pages. Additionally, two domains used policy-violating `input.formaction` attributes and the final remaining domain had a tainted domain name in an `embed.src` attribute. In total, this sums up to a false positive rate of 0.09% with respect to documents as well as 0.73% for the analyzed domains.

Subsequently, we analyzed the 73 domains which utilized policy violation HTML injection to determine how many of them were susceptible to a DOM-based XSS attack. In doing so, we found that we could exploit the insecure use of user-provided data in the HTML parser in 60 out of 73 cases.

6.1.4 Compatibility of DOM API Rules

As we discussed previously we also examine assignments to security-critical DOM properties like `script.src` or `base.href` and block them according to our policy. In our compatibility crawl, our engine blocked such assignments on 60 different domains in 182 documents, whereas the largest amount of blocks could be attributed to `script.src`. Noteworthy in this instance is the fact that 45 out of these 60 blocks interfered with third-party advertisement by only two providers.

After having counted the false positive, we yet again tried to exploit the flows that had been flagged as malicious by our policy enforcer. Out of the 60 domains our enforcer had triggered a block on, we verified that eight constitute exploitable vulnerabilities. In compari-

	documents	domains	exploitable domains
JavaScript	5,979	50	22
HTML	8,805	73	60
DOM API	182	60	8
Sum	14,966	183	90

Table 1: False positives by blocking component

son to the amount of exploitable blocks we had encountered for the JavaScript and HTML injection polices this number seems quite low. This is due to the fact that both the aforementioned advertisement providers employed whitelisting to ensure that only script content hosted on their domains could be assigned. In total, this sums up to 0.60% false positives with respect to domains and just 0.002% of all analyzed documents.

6.1.5 Summary

In this section we evaluated the false positive rate of our filter. In total, the filtering rules inside the JavaScript parser, the HTML parser and the security-sensitive DOM APIs caused issues on 14,966 document across 183 domains. Considering the data set we analyzed this amounts to a false positive ratio of 0.16% for all analyzed documents and 1.83% for domains. Noteworthy in this instance is however the fact that out of the 183 domains on which our filter blocked a single functionality, 90 contained actual verified vulnerabilities in just that functionality. Table 1 shows the number of documents and domains on which our policy caused false positive, also denoting in which of the different policy-enforcing components the exception was generated as well as the amount of domains in which the blocked functionality caused an exploitable vulnerability.

6.2 Protection

To ensure that our protection scheme does not perform worse than the original Auditor, we re-ran all exploits that successfully triggered when the Auditor was disabled. All exploits were caught by the JavaScript parser, showing that our scheme is at least as capable of stopping DOM-based Cross-Site Scripting as the Auditor.

To verify the effectiveness of our proposed protection scheme, we ran all generated exploits and bypasses against our newly designed filter. To minimize side-effects, we also disabled the XSS Auditor completely to ensure that blocking would only be conducted by our filtering mechanism. As we discussed in Section 4.2, alongside the scoping-related issues that were responsible for the successful bypassing of the Auditor by the first generation of exploits, other issues related to string matching arose. In the following, we briefly discuss our protection scheme with respect to stopping these kinds of exploits.

Scoping: eval and innerHTML In contrast to the XSS Auditor our filtering approach is fully capable of blocking injections into `eval` due to the fact that it is implemented directly in the JavaScript parser. In the XSS Auditor, innerHTML is not checked for performance reasons. To check whether a given token was generated from a tainted source, a simple boolean flag has to be checked, therefore we do not have these performance-inhibiting issues.

Injection attacks targeting DOM APIs In our experiments, we did not specifically target the direct assignment to security-critical DOM API properties. Inside the API, analogous to the HTML parser, assignment to one of these critical properties might cause direct JavaScript execution (such as a `javascript:` URL for an `iframe.src`) or trigger loading of remote content. For the first case, our taint tracking approach is capable of persisting the taint information to the execution of the JavaScript contained in the URL and hence, the DOM API does not have to intervene. For the loading of remote content, the rules of the HTML parser are applied, disallowing the assignment of the property if the domain name contains tainted characters.

Partial injection One of the biggest issues, namely partial injection, was stopped at multiple points in our filter. Depending on the element and attribute which could be hijacked, the attack vector either consisted of injected JavaScript code or of an URL attribute used to retrieve foreign content (e.g. through `script.src`). For the direct injection of JavaScript code, the previously discussed JavaScript parser was able to stop all exploit prototypes whereas for exploits targeting URL attributes the taint-aware HTML parser successfully detected and removed these elements, thus stopping the exploit.

Trailing content and double injection The bypasses which we categorized as trailing content are targeting a weakness of the Auditor, specifically the fact that it searches for completely injected tags whereas double injection bypasses take advantage of the same issue. Both trailing content and double injections can be abused to either inject JavaScript code or control attributes which download remote script content. Hence, analogous to partial injection, the filtering rules in the HTML and JavaScript parsers could in conjunction with the precise origin information stop all exploits.

Second order flows and alternative attack vectors Similar to injection attacks targeting the direct assignment of DOM properties through JavaScript, we did not generate any exploits for second order flows. Nevertheless, we persist the taint information through intermedi-

ary sources like the WebStorage API. Therefore, our prototype is fully capable of detecting the origin of data from these intermediary source and can thus stop these kinds of exploits as well. As for postMessages, `window.name` and `document.referer`, our implementation taints all these sources of potentially attacker-controlled data and is hence able to stop all injection attacks pertaining to these sources.

Application-specific input mutation Our engine propagates taint information through string modification operations. Therefore, it does not suffer the drawbacks of current implementations based on string matching. All exploits targeting vulnerabilities belonging to this class were caught within our HTML and JavaScript parsers.

6.3 Performance

In order to evaluate the performance of our implementation we conducted experiments with the popular JavaScript benchmark suites Sunspider, Kraken, and Octane as well as the browser benchmark suite Dromaeo. Sunspider was developed by the WebKit authors to "focus on short-running tests [that have] direct relevance to the web" [28]. Google has developed Octane which includes "5 new benchmarks created from full, unaltered, well-known web applications and libraries" [5]. Mozilla has developed Kraken which "focuses on realistic workloads and forward-looking applications" [15]. Dromaeo, which is a combination of several JavaScript and HTML/DOM tests, finally serves as a measure of the overall impact our implementation has on the everyday browsing experience.

All tests ultimately lead to a single numerical value, either being a time needed for a run (the lower the better) or a score (the higher the better), reflecting the performance of the browser under investigation. For runtime (score) values the results were divided by the values obtained for the unmodified version of the Web browser (vice versa). These serve as the baseline for our further comparisons. With the obtained results we computed a slowdown factor reflecting how many times slower our modified version is. To set these numbers into context, we also evaluated other popular Web browsers, namely Internet Explorer 11 and Firefox 26.0. To eliminate side effects of, e.g., the operating system or network latency, we ran each of the benchmarking suites locally for ten times using an Intel Core i7 3770 with 16GB of RAM. All experiments, apart from Internet Explorer, were conducted in a virtual machine running Ubuntu 13.04 64-bit on that system whereas IE was benchmarked natively running Windows 7.

Table 2 shows the results of our experiments. To ascertain a baseline for our measurements we ran all benchmarks on a vanilla build of Chromium. The table shows the mean results (in points or milliseconds) as well as the standard error and the slowdown factor for each test and browser. Internet Explorer employs an optimization to detect and remove dead code, causing it to have significantly better performance under the Sunspider benchmark than the other Web browsers [40]. As the results generated by all browsers under the Kraken benchmark were varying rather strongly, we ran the browsers in our virtual machines 50 times against the Kraken benchmark. Regardless, we still see a rather high standard error of the mean for all the browsers.

We chose the aforementioned tests because they are widely used to evaluate the performance of both JavaScript and HTML rendering engines. Nevertheless, these tests are obviously not designed to perform operations on tainted strings. As we discussed in Section 5.4, our engine usually only switches to this runtime implementation if the operation is conducted on a tainted string. In the initial runs, which is denoted in Table 2 as *Tainted Best*, our engine incurred slowdown factors of 1.08, 1.01, 1.16 and 1.05, resulting in an average slowdown factor of 7%. Since the tests are not targeting the usage of tainted data, we conducted a second run. This time we modified our implementation to treat *all* strings as being tainted, forcing it to use as much of our new logic as possible. In this, the performance was naturally worse than in the first run. More precisely, by calculating the average over the observed slowdown factors for our modified (denoted as *Tainted Worst*) version, we see that our implementation incurs, in the worst case, an overhead of 17% compared to the vanilla version. While the performance hit is significant, we will elaborate on possible performance improvements in the next section.

6.4 Discussion

In this section we evaluated compatibility, protection capability as well as performance of our proposed filter against DOM-based Cross-Site Scripting. In the following we will briefly discuss the implications of these evaluations.

In our compatibility crawl we found that 183 of the 10,000 domains we analyzed had one functionality that was incompatible with our policies for the JavaScript parser, the HTML parser and the DOM APIs. Although this number appears to be quite high at first sight it also includes 90 domains on which we could successfully a vulnerability in just the functionality that was blocked by our filter. On the other hand, the total number of domains, which our approach protected from a DOM-based XSS attack amounts to 958. Although the XSS Auditor is not designed to combat DOM-based XSS attacks, it is the only currently employed defense for Google Chrome against such attacks. As we discussed in Section 4.3, the Auditor could be bypassed on 81% of these domains, protecting users on only 183 domains in our initial data

	Dromaeo			Octane			Kraken (ms)			Sunspider (ms)		
Baseline	1167.4	*1.89*	–	20177.9	*64.47*	–	1418.9	*94.29*	–	169.02	*0.37*	–
Tainted Best	1082.6	*2.40*	**1.08**	19851.0	*54.54*	**1.01**	1653.1	*59.84*	**1.16**	178.03	*0.70*	**1.05**
Tainted Worst	1015.6	*1.93*	**1.15**	18168.7	*70.24*	**1.11**	1814.4	*64.55*	**1.27**	192.66	*0.26*	**1.14**

IE 11	607.0	*2.13*	**1.92**	17247.2	*47.15*	**1.17**	1858.5	*4.16*	**1.31**	78.05	*0.13*	**0.46**

Table 2: Benchmark results, showing mean, *standard error* and **slowdown factor** for all browsers and tests

set. This shows that with respect to its protection capabilities our approach is more reliable than currently deployed techniques, which do not offer protection against this type of attack.

Apart from reliable protection and a low false positive rate, one requirement for a browser-based XSS filter is its performance. Our performance measurements showed that our implementation incurs an overhead between 7 and 17%. Chrome's JavaScript engine V8 draws much of its superior performance from utilizing so-called *generated code*, i.e., ASM code generated directly from macros. To allow for a small margin for error, we opted to implement most of the logic – such as copying of taint information – in C++ runtime code. We realize that the performance impact of our current prototype might be too high to allow for productive deployment in Chrome. Nevertheless, we believe that an optimized implementation making more frequent use of said generated code would ensure better performance and possibly allow for deployment of our approach.

Our approach only aims at defeating DOM-based Cross-Site Scripting while the XSS Auditor's focus is on reflected XSS. We therefore believe that deployment besides the Auditor is a sound way of implementing a more robust client-side XSS filter, capable of handling both reflected and DOM-based XSS.

7 Outlook: HTML Injection

As we discussed in Section 5.4, our engine allows for precise tracking of tainted data throughout the execution of a program and hence, also to the HTML parser. Therefore, our approach also enables the browser to precisely block all attacker-injected HTML even it is not related to Cross-Site Scripting. Although this was out of scope for this work, we believe that it is relevant future work. Therefore, we give a short glimpse into the current state of the Web with respect to partially tainted HTML passed to the parser.

As we discussed in Section 6.1, we conducted a compatibility crawl of the Alexa Top 10,000 in which we analyzed a total of 9,304,036 documents, out of which 632,109 generated 2,393,739 tainted HTML reports. Typically, each of the HTML snippets contained the definition of more than one tag. In total, we found that parsing the snippets yielded in 3,650,506 tainted HTML elements whereas we consider an element tainted if either the tag name, any attribute name or any attribute value is tainted. Considering the severity of attacker-controllable HTML snippets, we distinguish between four types:

1. Tag injection (**TI**): the adversary can inject a tag with a name of his choosing.
2. Attribute injection (**AI**): injection of the complete attribute, namely both name and value
3. Full attribute value injection (**FAVI**): full control over the value, but not the name
4. Partial attribute value injection (**PAVI**): attacker only controls part of the attribute

We analyzed the data we gathered in our crawl to determine whether blocking of tainted HTML data is feasible and if so, with what policy. Our analysis showed that out of the Top 10,000 Alexa domains, just one made use of full tag injection, injecting a `p` tag originating from a postMessage. This leads us to believe that full tag injection with tainted data is very rare and not common practice.

The analysis also unveiled that the most frequently tainted elements – namely `a`, `script`, `iframe` and `img` – made up for 3,503,655 and thus over 95% of all elements containing any tainted data. Hence, we focused our analysis on these and examined which attributes were tainted. Analogous to our definition of a tainted element, we consider an attribute to be tainted if either its name or value contains any tainted characters. Considering this notion, we – for each of the four elements – ascertained which attribute is most frequently injected using tainted data. For `a` elements, the most frequent attribute containing tainted data was `href` whereas `script`, `iframe` and `img` tags mostly had tainted `src` attributes. Although we found no case where the name of an attribute was tainted, we found a larger number of elements with full attribute value injection. The results of our study are depicted in Table 3, which shows the absolute numbers of occurrences. We also gathered reports from documents

	FAVI		PAVI	
	Top 10k	all	Top 10k	all
iframe.src	349	2,222	384,946	438,415
script.src	4,215	8,667	1,078,015	1,292,046
a.href	124,812	133,838	1,162,093	1,191,598
img.src	5,128	6,791	275,579	312,033
Domains	799	1,014	4,446	6,772

Table 3: Amounts of full and partial value injection for domains in the Alexa Top 10,000 and beyond.

on domains not belonging to the Alexa Top 10,000 as content is often included from those. The first number in each column gives the amount for documents on the Alexa Top 10,000, whereas the second number shows the number for all documents we crawled.

Summarizing, we ascertain that taint tracking in the browser can also be used to stop HTML injection. Our study on tainted HTML content on the Alexa Top 10,000 domains has shown that blocking elements with tainted tag names is a viable way of providing additional security against attacks like information exfiltration [7] while causing just one incompatibly. We also discovered that the applications we crawled do not make use of tainted attribute names, hence we assume that blocking tainted attributes does also not cause incompatibilities with the current Web. In contrast, blocking HTML that either has fully or partially tainted attribute values does not appear to be feasible since our analysis showed that 8% of all domains make use of fully tainted attribute values whereas more than 44% used partially tainted values in their element's attributes. As there is an overlap between these two groups of domains, the total number of domains that would causes incompatibilities is 4,622, thus resulting in more than 46% incompatibilities. Thus, we established that although blocking HTML is technically possible with our implementation this would most likely break a large number of applications.

8 Related work

XSS Filter As already mentioned earlier, the conceptually closest work to this paper is Bates et al.'s [2] analysis of regular expression-based XSS filters and the subsequent proposal of the methodology that constitutes the basis for the XSS Auditor. Furthermore, Pelizzi and Sekar [26] proposed potential improvements for Bates et al.'s method in order to address the problem of partial injections. Similar to what Bates et al. discussed, they instrument the HTML parser and apply approximate string matching inside it. Due to the fact that DOM-based XSS allows an attacker to make use of insecure calls to `eval` as well as direct assignments to security-sensitive DOM APIs, it is still susceptible to some bypasses we discussed. Furthermore, the presented approach is not fully evaluated, especially with respect to the occurring false positive rate. Besides this, and the other two major browser-based XSS filters [21, 29], the majority of XSS protection approaches, such as [23, 14, 24, 35], reside on the server-side.

Filter evasion is an active topic especially in the offensive community. Academic approaches in this area include, for instance, the work by Heiderich et al. on SVG-based evasions [11] and filter evasion by misusing browser-based parser quirks and mutations [12] as well as approaches that rely on parser confusion and polyglots, such as Barth et al. [1] and Magazinius et al. [19].

Dynamic taint tracking Taint propagation is a well established tool to address injection attacks. After its initial introduction within the Perl interpreter [37], various server-side approaches have been presented that rely on this technique [25, 27, 33, 24, 3]. In 2007, Vogt et al. [36] pioneered browser-based dynamic taint tracking, employing the technique to prevent the leakage of sensitive data to a remote attacker rather than trying to prevent the attack itself. The first work to utilize taint tracking for the detection of DOM-based XSS was DOMinator [8], which was later followed by FLAX [31] and Lekies et al. [18]. For NDSS 2009, Sekar [32] proposed and implemented a scheme for taint inference, speeding up taint tracking approaches which had been presented up to this point.

9 Conclusion

In this paper we presented the design, implementation and thorough evaluation of a client-side countermeasure which is capable to precisely and robustly stop DOM-based XSS attacks. Our mechanism relies on the combination of a taint-enhanced JavaScript engine and taint-aware parsers which block the parsing of attacker-controlled syntactic content. Existing measures, such as the XSS Auditor, are still valuable to combat XSS in cases that are out of scope of our approach, namely XSS which is caused by vulnerable data flows that traverse the server.

In case of client-side vulnerabilities, our approach reliably and precisely detects injected syntactic content and, thus, is superior in blocking DOM-based XSS. Although our current implementation induces a runtime overhead between 7 and 17%, we believe that an efficient native integration of our approach is feasible. If adopted, our technique would effectively lead to an extinction of DOM-based XSS and, thus, significantly improve the security properties of the Web browser overall.

On the Effective Prevention of TLS Man-In-The-Middle Attacks in Web Applications

Nikolaos Karapanos and Srdjan Capkun
Department of Computer Science, ETH Zurich
{*firstname.lastname*}*@inf.ethz.ch*

Abstract

In this paper we consider TLS Man-In-The-Middle (MITM) attacks in the context of web applications, where the attacker is able to successfully impersonate the legitimate server to the user, with the goal of impersonating the user to the server and thus compromising the user's online account and data. We describe in detail why the recently proposed client authentication protocols based on TLS Channel IDs, as well as client web authentication in general, cannot fully prevent such attacks.

Nevertheless, we show that strong client authentication, such as Channel ID-based authentication, can be combined with the concept of server invariance, a weaker and easier to achieve property than server authentication, in order to protect against the considered attacks. We specifically leverage Channel ID-based authentication in combination with server invariance to create a novel mechanism that we call SISCA: Server Invariance with Strong Client Authentication. SISCA resists user impersonation via TLS MITM attacks, regardless of how the attacker is able to successfully achieve server impersonation. We analyze our proposal and show how it can be integrated in today's web infrastructure.

1 Introduction

Web applications increasingly employ the TLS protocol to secure HTTP communication (i.e., HTTP over TLS, or HTTPS) between a user's browser and the web server. TLS enables users to securely access and interact with their online accounts, and protects, among other things, common user authentication credentials, such as passwords and cookies. Such credentials are considered *weak*; they are transmitted over the network and are susceptible to theft and abuse, unless protected by TLS.

Nevertheless, during TLS connection establishment, it is essential that the server's authenticity is verified. If an attacker successfully impersonates the server to the user, she is then able to steal the user's credentials and subsequently use them to impersonate the user to the legitimate server. This way, the attacker gains access to the user's account and data which can be abused for a variety of purposes, such as spying on the user [18, 48]. This attack is known as TLS Man-In-The-Middle (MITM).

TLS server authentication is commonly achieved through the use of X.509 server certificates. A server certificate binds a public key to the identity of a server, designating that this server holds the corresponding private key. The browser accepts a certificate if it bears the signature of any trusted Certificate Authority (CA). Browsers are typically configured to trust hundreds of CAs.

An attacker can thus successfully impersonate a legitimate server to the browser by presenting a valid certificate for that server, as long as she holds the corresponding private key. In previous years, quite a few incidents involving mis-issued certificates [2, 9, 11, 48, 49] were made public. Even in the case where the attacker simply presents an invalid (e.g., self-signed) certificate not accepted by the browser, she will still succeed in her attack if the user defies the browser's security warning.

In order to thwart such attacks, various proposals have emerged. Some proposals focus on enhancing the certificate authentication model. Their objective is to prevent an attacker possessing a mis-issued, yet valid certificate, from impersonating the server (e.g., [20, 33, 36, 52]).

Other proposals focus on strengthening client authentication. *Strong* client authentication prevents user credential theft or renders it useless, even if the attacker can successfully impersonate the server to the user. One such prominent proposal is Channel ID-based client authentication, introduced in 2012. TLS Channel IDs [4] are experimentally supported in Google Chrome and are planned to be used in the second factor authentication standard U2F, proposed by the FIDO alliance [22].

In this paper we show that Channel ID-based approaches, as well as web authentication solutions that focus solely on client authentication are vulnerable to an attack that we call *Man-In-The-Middle-Script-In-The-Browser (MITM-SITB)*, and is similar to *dynamic pharming* [32] (see Section 4). This attack bypasses Channel ID-based defenses by shipping malicious JavaScript to the user's browser within a TLS connection with the attacker, and using this JavaScript in direct connections

with the legitimate server to attack the user's account.

Nevertheless, we show that TLS MITM attacks where the attacker's goal is user impersonation can still be prevented by strong client authentication, such as Channel ID-based authentication, provided that it is combined with the concept of *server invariance*, that is, the requirement that the client keeps communicating with the same entity (either the legitimate server, or the attacker) across multiple connections intended for the same server. Server invariance is a weaker requirement than server authentication, and thus, it is easier to achieve as no initial trust is necessary. Building on this observation, we propose a solution called *SISCA: Server Invariance with Strong Client Authentication*, that combines Channel ID-based client authentication and server invariance.

SISCA can resist TLS MITM attacks that are based on mis-issued valid certificates, as well as invalid certificates, requiring no user involvement in the detection of the attack (i.e., no by-passable security warnings when server invariance violation occurs). SISCA also thwarts attackers that hold the private key of the legitimate server.

Contributions. In this work we analyze TLS MITM attacks whose goal is user impersonation and make the following contributions. *(i)* We show, by launching a MITM-SITB attack, that Channel ID-based client authentication solutions do not fully prevent TLS MITM attacks; *(ii)* we further argue that effective prevention of MITM-based user impersonation attacks requires strong user authentication and (at least) server invariance; *(iii)* we propose a novel solution that prevents MITM-based user impersonation, based on the combination of strong client authentication and server invariance; *(iv)* we implement and evaluate a basic prototype of our solution.

2 Channel ID-based Authentication and MITM Attacks

2.1 Attacker Model and Goals

Attacker Goals. The attacker's goal in a MITM attack is typically to impersonate the user (victim) to the legitimate server (e.g., a social networking, webmail, or e-banking website) in order to compromise the user's online account and data. This is indeed the case where the attacker wishes for example to spy on the user [18, 48], or abuse his account for nefarious purposes, e.g., perform fraudulent financial transactions. Alternatively, the attacker could aim to only impersonate the server to the user (and not the user to the server), such that she serves the user with fake content (e.g., fake news). In this paper, we focus on the first, more impactful, scenario.

Attacker Model. We adopt the attacker model considered by Channel IDs [4]. The adversary is able to position herself suitably on the network and perform a TLS MITM attack between the user and the target web server. In other words, the attacker is able to successfully impersonate the server to the user. We distinguish between two types of MITM[1] attackers.

The *MITM+certificate* attacker holds *(i)* a *valid* certificate for the domain of the target web server, binding the identity of the server to the public key, of which she holds the corresponding private key. The attacker, however, has no access to the private key of the target web server. This, for example, can happen if the attacker compromises a CA or is able to force a CA issue such a certificate. Such attacks have been reported in the recent years [2, 9, 11, 48]. Moreover, in this category we also consider a weaker attacker that only holds *(ii)* an *invalid* (e.g., self-signed) certificate. In this case, the attacker will still succeed in impersonating the server to the user if the latter ignores the security warnings of the browser[2], which is a common phenomenon [51].

The *MITM+key* attacker holds the *private key of the legitimate server*. While we are not aware of publicized incidents involving server key compromise, such attacks are feasible, as the Heartbleed vulnerability in OpenSSL has shown [1], and can be very stealthy, remaining unnoticed. Thus, they are well worth addressing [28, 30, 35].

From the above it follows that the attacker is able to obtain the user's weak credentials, namely passwords and HTTP cookies. She is not, however, able to compromise the user's browser or his devices (e.g., mobile phones).

2.2 TLS Channel IDs

Channel IDs is a recent proposal for strengthening client authentication. It is a TLS extension, originally proposed in [15] as *Origin-Bound Certificates* (OBCs). A refined version has been submitted as an IETF Internet-Draft [4]. Currently, Channel IDs are experimentally supported by Google's Chrome browser and Google servers.

In brief, when the browser visits a TLS-enabled web server for the first time, it creates a new private/public key pair (on-the-fly and without any user interaction) and proves possession of the private key, during the TLS handshake. This TLS connection is subsequently identified by the corresponding public key, which is called the Channel ID. Upon subsequent TLS connections to the same web server, or more precisely, to the same web origin, the browser uses the same Channel ID. This enables the web server to identify the same browser across multiple TLS connections.

2.2.1 Channel ID-Based Authentication

By *Channel ID-based authentication* we refer to the use of Channel IDs *throughout* the user authentication process, designed to thwart both types of MITM attackers presented in Section 2.1 [4, §6], [13, §3].

[1] We use the terms "TLS MITM" and "MITM" interchangeably.

[2] We use the term "browser" to refer to any "user agent" in general.

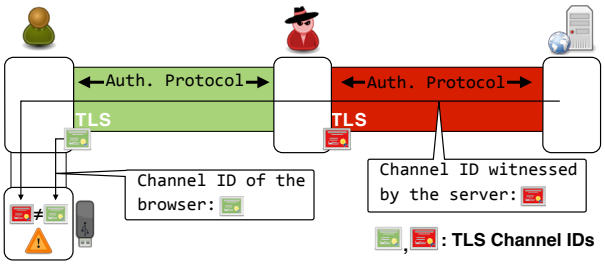

Figure 1: PhoneAuth and FIDO U2F; leveraging Channel IDs to secure the initial login against MITM attacks.

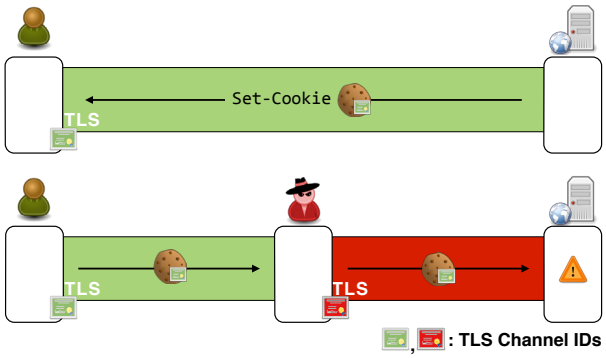

Figure 2: Binding authentication tokens (e.g., cookies) to the browser's Channel ID (green). A MITM attacker who steals such a cookie, cannot use it to impersonate the user, since the attacker has a different Channel ID (red).

Initial Login. When the user attempts to login to his online account for the first time from a particular browser, the web server requires that the user authenticates using a strong second factor authentication device, as in *PhoneAuth* [13] and *FIDO Universal 2nd Factor (U2F)* [22] protocols. These protocols leverage Channel IDs to secure the intial login process against MITM attacks. In brief, as part of the authentication protocol, the second factor device compares the Channel ID of the browser to the Channel ID of the TLS connection that the server witnesses. If they are equal, then the browser is directly connected to the web server through TLS (because they share the same view of the connection), and thus there is no MITM attack taking place. On the other hand, if the Channel IDs differ, then the server is not directly connected to the user's browser. Instead, as shown in Figure 1, there is an attacker in the middle, and the device aborts the authentication protocol, stopping the attack.

Subsequent Logins. Upon successful initial authentication the server sets a cookie to the user's browser, and binds it to the Channel ID of the browser. As proposed in [15], a server may create a *channel-bound cookie* as follows: $\langle v, \text{HMAC}(k, v|cid)\rangle$, where v is the original cookie value, cid is the browser Channel ID and k is a secret key only known to the server, used for computing a MAC over the concatenation of v and cid. The channel-bound cookie is considered valid only if it is presented over that particular Channel ID. Therefore, subsequent interaction with the server from that particular browser is protected by the channel-bound cookie. An attacker that manages to steal a channel-bound cookie, e.g., through a MITM attack, cannot use it to impersonate the user to the web server, since she does not know the private key of the correct Channel ID. Figure 2 illustrates this concept. Note that at this stage, the second factor device is not required for authenticating the user [12].

2.3 MITM Attack on Channel ID-Based Authentication

We show how Channel ID-based authentication still allows a MITM attacker to successfully impersonate the user. This is due to the way web applications are run and interact with the servers, which differs from other internet client-server protocols (e.g., IMAP over TLS).

In particular, web servers are allowed to send scripting code to the browser, which the latter executes within the security context of the web application (according to the rules defined by the *same-origin policy* [5]). In fact, client-side scripting and especially JavaScript, is the foundation of dynamic, rich web applications that vastly improve user experience, and its presence is ubiquitous.

Moreover, a browser can establish multiple TLS connections with the same server. In addition, a typical web application loads resources, such as images and scripts, from multiple domains (*cross-origin* network access [5]). Assuming that all communication is TLS-protected, this means that the browser needs to establish TLS connections with multiple servers while loading a web page.

Given the above, there is a conceptually simple attack that a MITM+certificate or MITM+key attacker can perform, which bypasses the security offered by Channel IDs. We assume that the user tries to access the target web server, say `www.example.com`. The attacker then proceeds as follows:

1. She intercepts a single TLS connection attempt made by the browser to `www.example.com`, and by presenting a valid certificate (or invalid with the user ignoring the browser's warning), she successfully impersonates the legitimate server to the browser.

2. Through the established connection, the browser makes an HTTP request to the server. The attacker replies with an HTTP response, which includes a malicious piece of JavaScript code. This script will execute within the origin of `www.example.com`.

3. The attacker closes the intercepted TLS connection. This forces the browser to initiate a new TLS con-

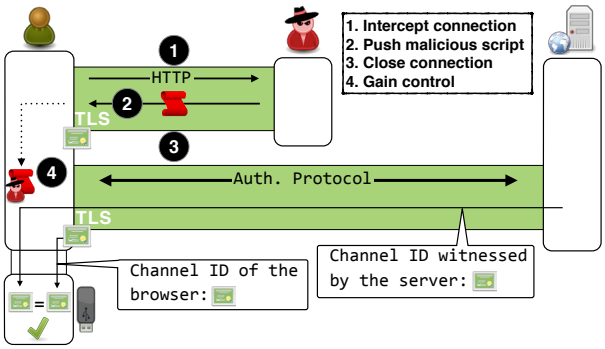

Figure 3: MITM-SITB attack on Channel ID-based PhoneAuth/U2F, used for the initial login. The attacker's JavaScript code is executed within the origin of the target server (shown by the dotted arrow).

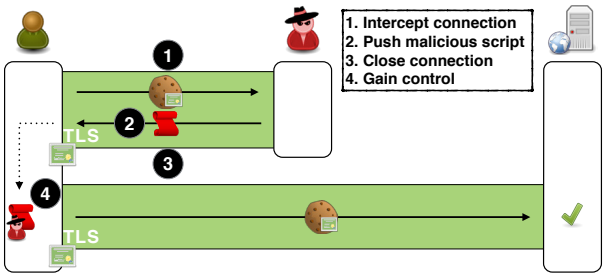

Figure 4: MITM-SITB attack on Channel ID-based authentication after the initial login, where requests are protected with a channel-bound cookie.

nection in order to transmit subsequent requests, or use another existing one, if any (this behavior conforms with the HTTP specification [23]). At the same time, the attacker allows subsequent TLS connection attempts to pass through, without interfering with them. As a result, once the attacker closes that single intercepted connection, all other connections, existing and new, are directly established between the browser and the legitimate server.

4. The attacker gains full control over the user's session in that particular web application. Her script has unrestricted access over the web documents belonging to `www.example.com` and can monitor all the client-side activity of the web application. Moreover, she can issue arbitrary malicious requests to the target server using the `XMLHttpRequest` object [3], in order to perform a desired action or extract sensitive user information. The malicious code can upload any extracted data to an attacker-controlled server. As another example, if the web application is Ajax-based, the attacker can perform *Prototype Hijacking* [46]. This allows her to eavesdrop and modify on-the-fly all the HTTP requests made through `XMLHttpRequest`.

In summary, the MITM attacker "transfers" herself (via the malicious script) within the user's browser, and continues her attack from there. We call this attack *Man-In-The-Middle-Script-In-The-Browser* (*MITM-SITB*).

Figure 3 illustrates the MITM-SITB attack in the case when the user is about to initially authenticate to `www.example.com` using PhoneAuth or U2F. The attacker intercepts a TLS connection, pushes her JavaScript code to the user's browser, and terminates the connection. The browser then establishes a new TLS connection for subsequent communication, only this time with the legitimate server; the attacker will not hijack it. This ensures that the user authentication is performed over a direct connection between the browser and the server, but with the attacker's code running in the browser. The view of the TLS channel will be the same for the browser and the server, and the Channel ID comparison made by the second factor device will pass.

Figure 4 shows how the attack works in the case when the user has already logged in on `www.example.com` in the past, and the server has set a channel-bound cookie in the user's browser. Like before, the attacker ships malicious JavaScript code to the browser by intercepting a TLS connection to `www.example.com`. She then terminates the intercepted connection. This forces the browser to establish a new TLS connection, which is not intercepted by the attacker. This ensures that any subsequent requests, either legitimate or malicious (issued by the attacker's script) are accepted by the legitimate server, since they will carry the channel-bound cookie, which authenticates the user, over the correct Channel ID.

From the above attack description there are various details that remain unclear. For example, which TLS connection the attacker should intercept, whether to "hit and run" or persist as much as possible, etc. Depending on the scenario, there are various alternatives, which are mostly implementation decisions. The attacker can for example choose the following strategy. She intercepts the *very first* TLS connection, i.e., the one that the browser initiates once it is directed to `www.example.com`. Depending on the situation, the attacker's HTTP response could contain the expected HTML document of the website's starting page, together with the appropriately injected malicious script, or it could only contain the malicious script, which will take care of loading the starting page in the browser. Then, as described before, the attacker closes this first connection and subsequent communication (malicious or not) takes place through a direct connection to the legitimate server.

The Cross-Origin Communication Case. Visiting a single web page typically involves cross-origin communication with different domains in the background. For exam-

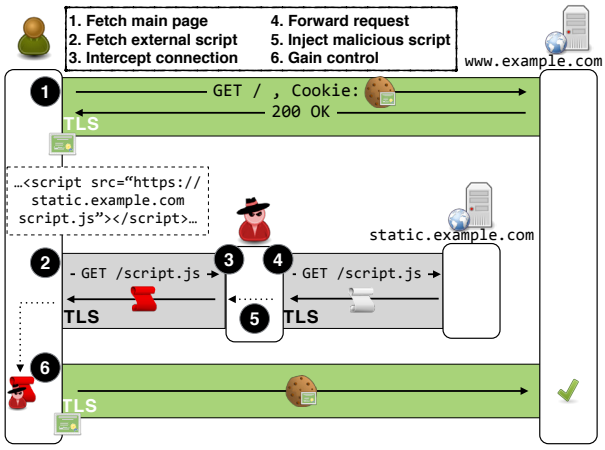

Figure 5: MITM-SITB attack on Channel ID-based authentication leveraging cross-origin communication. Channel IDs for `static.example.com` are of no use.

ple a typical network optimization technique is to have the browser load the static resources of the website, such as images, style sheets and scripts, from so-called *cookieless domains* (e.g., Google websites usually load static resources from `gstatic.com` [24]). These domains, as their name suggests, do not set any cookies, so as to minimize network latency. As a matter of fact, on such domains, client authentication does not apply at all, as they are just used to serve static resources, which anyone, including the attacker, can access. Hence in those cases, the attacker can perform a conventional MITM attack against a cookieless domain, and inject her malicious code at the moment when the target web server requests a legitimate JavaScript file from that domain (Figure 5).

2.4 Proof of Concept Attack

We validate our attack against Channel IDs through a proof of concept implementation. We use two Apache TLS-enabled servers (one for the attacker, one for the legitimate server) and an interception proxy that can selectively forward TLS connections to either server. The legitimate server uses a patched OpenSSL version that supports Channel IDs and leverages them for creating channel-bound cookies. We use Google Chrome as the user's browser, since it supports Channel IDs, and ensure that it accepts the certificates of both servers. We are then able to inject JavaScript code to the user's browser from the attacker's server and issue HTTP requests that are accepted and processed by the legitimate server.

2.5 Scope and Implications of the Attack

The MITM-SITB attack presented in Section 2.3 is not specific to Channel ID-based client authentication protocols. In fact, it applies to *any* web client authentication method. This attack demonstrates that, in the context of web applications, it does not seem possible to prevent TLS MITM attacks via client authentication alone.

We provide the following informal reasoning for the above claim. Client authentication does not prevent an attacker from impersonating the legitimate server. This allows her to intercept a server-authenticated (i.e., TLS) connection and ship her JavaScript code to the user's browser. The browser, treating the attacker's code as trusted (as it came through a server-authenticated connection), executes it within the target server's origin. The attacker accesses the user's account through requests initiated by her code and transmitted over another, direct connection between the browser and the legitimate server.

As a result, schemes such as traditional TLS client authentication [14] and TLS Session Aware User Authentication [42, 43] are still susceptible to TLS MITM attacks, via MITM-SITB. The attacker succeeds in impersonating the user to the web server and compromising his account.

3 Addressing TLS MITM Attacks

As shown in Section 2, strong client authentication alone is not sufficient to prevent MITM attacks that lead to user impersonation in web applications. So, how can we effectively prevent such attacks? In this section we show that there are two *orthogonal* solutions; *(i)* the known solution of preventing the attacker from impersonating the legitimate server at all, i.e., ensuring correct server authentication; *(ii)* our novel approach of combining strong client authentication with server invariance.

3.1 Prevent Server Impersonation

The known and straightforward solution to the problem at hand is to prevent the attacker from impersonating the server in the first place. This way, the attacker can neither steal weak user credentials in order to mount a conventional MITM attack, nor ship malicious Javascript in order to mount a MITM-SITB attack. Note that in this case, strong client authentication (e.g., Channel ID-based) is not necessary for preventing MITM attacks (it is, however, still useful for preventing other attacks, such as phishing and server password database compromise).

The solutions that try to prevent server impersonation essentially address the issue of forged server certificates (and thus defeating MITM+certificate attacks), by performing *enhanced certificate verification*. Such solutions are mainly based on *pinning* [20, 38], *multi-path probing* [33, 36, 37, 52] and hybrid approaches [19, 29] (a thorough survey can be found in [10]).

3.2 Our Proposal: SISCA

3.2.1 Main Concept

The fact that strong client authentication alone cannot effectively prevent MITM attacks in web applications,

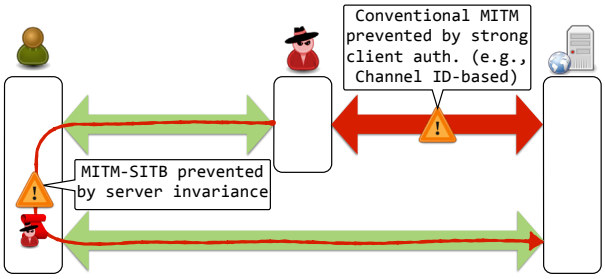

Figure 6: TLS MITM attacks in web applications can be thwarted by combining strong client authentication with server invariance.

raises the following question. Is there a way to somehow still benefit from strong client authentication with respect to addressing MITM attacks?

To answer, we make the following observation. In the context of web applications, a MITM attacker can perform user impersonation via two approaches:

1. The *conventional MITM* attack, in which the attacker compromises the user's credentials and uses them for impersonation. This attack can be effectively prevented by strong client authentication e.g., using Channel ID-based protocols (Figures 1, 2).

2. The *MITM-SITB* attack, presented in Section 2.3 (Figures 3, 4, 5). As discussed in Section 2.5, client authentication alone cannot prevent this attack.

For the MITM-SITB attack to be successful, the user's browser needs to communicate with two different entities, namely the attacker and the target web server. Communicating with the attacker is, of course, necessary for injecting the attacker's script to the browser through the intercepted TLS connection. In addition, communication with the target server is essential, so that the attacker accesses the user's account and data, through her script.

As a result, we can prevent MITM-SITB by making sure that the browser communicates only with *one entity*, either the legitimate server, or the attacker, but *not* with both, during a *browsing session* (a browsing session is terminated when the user closes the browser). In other words, we need to enforce server invariance. When combined with strong client authentication (e.g., Channel ID-based), which stops the conventional MITM approach, this technique manages to effectively thwart MITM attacks. Figure 6 illustrates the concept.

In the remaining section we present a novel solution, called *Server Invariance with Strong Client Authentication (SISCA)*, which stems from the above result. SISCA is able to resist MITM+certificate attacks, offering advantages compared to existing solutions that focus at preventing server impersonation (see Section 3.2.9), as well as MITM+key attacks under the assumption that the attacker does not persistently compromise the server (see Section 3.2.2). The details of our solution follow below.

3.2.2 Design Goals and Assumptions

In SISCA we seek to satisfy the following requirements: *(i)* incremental deployment, *(ii)* scalability, *(iii)* minimal overhead, *(iv)* account for cross-origin communication, assuming that the involved origins belong to, and are administered by the *same entity*, *(v)* mitigation of MITM+key attacks (besides MITM+certificate attacks).

We make the following assumptions. First, strong client authentication, which prevents the conventional way of implementing MITM attacks (Figures 1, 2) is in place. Specifically, we assume that SISCA-enabled servers implement *Channel ID-based client authentication*. As mentioned before, Channel IDs are already experimentally supported in Google Chrome. Moreover, FIDO U2F leverages Channel IDs, as metiononed in Section 2.2.1, so it is likely that Channel ID-based authentication will become available in the foreseeable future.

Second, we assume that SISCA-enabled servers support *TLS with forward secrecy* by default [28, 30, 35]. As we discuss below, this is only required for preventing MITM+key attacks (not relevant for MITM+certificate attacks). Moreover, we assume that TLS is secure and cannot be broken by cryptographic attacks, such as those surveyed in [10].

We finally assume that the MITM+key attacker does not persistently compromise the target web server. As we discuss later, this enables SISCA to resist server key compromise (i.e., MITM+key attackers) through frequent rotation of the server secrets that are used in SISCA (see Section 3.2.8). We also note that if an attacker gained persistent control over the target server, she would probably not need to resort to MITM attacks to compromise the users' accounts, but at the same time she would increase the probability of being detected.

3.2.3 Server Invariance Versus Authentication

As stated above, our goal is to combine strong client authentication with server invariance. Invariance is a *weaker* property than authentication, and thus, *easier* to achieve, as *no a priori trust* is necessary. In contrast, authentication requires some form of initial trust so that the client can correctly authenticate the server [17].

Consequently, we stress the following very important difference. Server authentication (and solutions that try to enforce it, like those mentioned in Section 3.1) implies that every single TLS connection should be established with the legitimate server. If the attacker attempts to intercept such a connection, she should be detected by the browser, i.e., no server impersonation should be possible.

In contrast, server invariance, embraces the fact that

the attacker can successfully impersonate the server. As such, we distinguish two scenarios concerning the browser's *first connection* to a particular server: *(i)* The first connection is *not intercepted* by the attacker. Then, server invariance implies that the attacker is allowed to *intercept none* of the subsequent connections to that server. *(ii)* The first connection is *intercepted* by the attacker. Then, server invariance implies that the attacker has to *intercept all* subsequent connections to that server. In either scenario, if the attacker violates server invariance, she will be detected.

We consider server invariance as a *transient* property whose scope is one browsing session. Server invariance is *reset* whenever the browser restarts, i.e., the attacker is allowed again to choose whether to intercept or not the first connection to the server.

3.2.4 Towards Implementing Server Invariance

In order to implement server invariance, it is important to understand the implications of the fact that the attacker is allowed to impersonate the server. Namely, the attacker can intercept the first connection and influence the entire HTTP response, which clearly cannot be blindly trusted. Therefore, techniques that assume the attacker is able to influence only a part of the HTTP response, such as *Content Security Policy* (CSP) [50] for mitigating *Cross-Site-Scripting* (XSS) [44], as well as techniques that assume the first connection is trusted (i.e., not intercepted by the attacker), such as pinning, cannot be directly applied for implementing server invariance.

Instead, a server invariance protocol should consist of *two phases*, namely *invariance initialization* and *invariance verification* – initialization and verification for brevity. In the initialization phase, which is executed in the first connection to the server during a browsing session (and could be intercepted by the attacker), the browser establishes a *point of reference*. Then, in subsequent connections to the same server, the verification phase is executed, where the browser verifies that the point of reference remains unchanged, i.e., the browser keeps connecting to the same entity.

Server Public Keys. Assuming that we only consider MITM+certificate attackers, we can leverage the servers' public keys as the point of reference. Even if the attacker intercepts the first connection, she will not be able to let any subsequent connections reach the legitimate server, because the server's public key will be different from the attacker's. Nevertheless, servers of the same domain may use different public keys and also, cross-origin interacting domains will have different keys. To solve this issue, we need to "tie" all the involved public keys together, to reflect the fact that they belong to the same entity and thus server invariance should hold across all these domains and keys. We sketch the following technique for implementing server invariance.

During initialization (first connection), the server sends a list of all the involved domains and all their public keys to the browser, and the latter uses the witnessed key as well as the list as the point of reference. Then, in subsequent connections, the browser verifies *(i)* that the public key which the server presents is contained in the list which was received during initialization, and *(ii)* that the server agrees on the legitimacy of the public key that was originally witnessed by the browser during initialization. Notice how this differs from pinning, which operates under the assumption that the initial connection is trusted, and thus does not seek to verify the legitimacy of the initial connection, and consequently of the received pins, upon subsequent connections.

The above technique is indeed useful when considering MITM+certificate attacks and can be used to implement the server invariance protocol in SISCA. Nevertheless, in the following sections we present an alternative approach that does not leverage server public keys, and aims to mitigate MITM+key attacks, as well. We note that the security analysis as well as most of the design patterns that are discussed in the approach that follows (e.g., how to prevent downgrade attacks and allow for partial support and exceptions – Section 3.2.6, how to secure resource caching – Section 3.2.7, etc) would similarly apply to the previously sketched technique, too.

Our High-Level Approach. In SISCA we choose to implement server invariance as a simple challenge/response protocol. In the initialization phase (first connection) the browser sets up a fresh challenge/response pair (which acts as the point of reference) with the server. Then, in the verification phase (subsequent connections) the browser challenges the server to verify server invariance, i.e., that it is the same entity with which the browser executed the initialization.

SISCA has to be executed before any HTTP traffic influenced by the attacker is processed by the browser or the server. We choose to implement the protocol at the application layer, over established TLS sessions via an HTTP header, named `X-Server-Inv`, and transmitted together with the *first* HTTP request/response pair over a particular TLS connection. For the protocol to be secure, on the client side this header is controlled solely by the browser. It cannot be created or accessed programmatically via scripts (similar to cookie-related headers [3]).

Alternatively, we could implement the server invariance protocol in SISCA as a TLS extension, i.e., at the transport layer. We deem the application layer more appropriate, since server invariance encompasses semantics that are naturally offered by the application layer, such as cross-origin interaction and content inclusion.

Figure 7 depicts a simple example of how a protocol based on our approach can look like. In this example

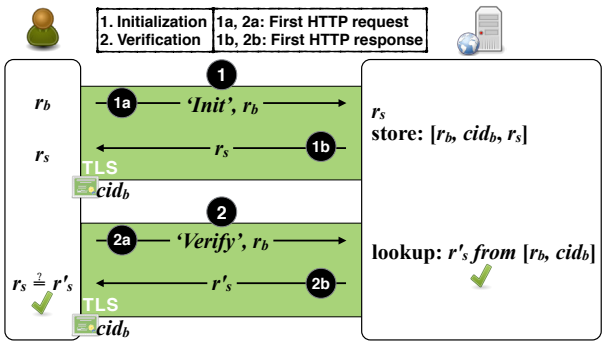

Figure 7: An example challenge/response-based server invariance protocol requiring per-client server state.

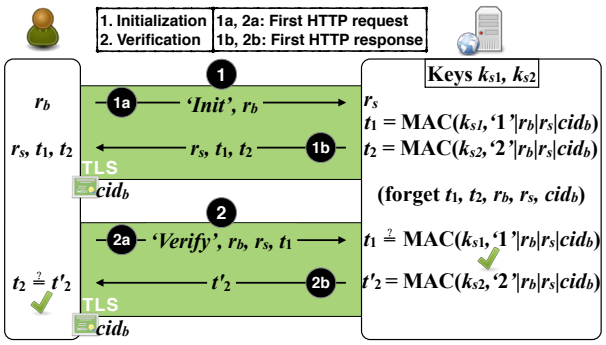

Figure 8: Basic SISCA protocol.

protocol, during the initialization phase the browser and server generate random numbers r_b and r_s, which they both store (the server also stores the browser's Channel ID cid_b). The browser subsequently uses r_b as a challenge during the verification phase, expecting the response r_s by the server. The latter looks up r_s by using r_b and cid_b. For the shake of brevity, we do not analyze this example, but we make the following important remarks.

First, this example requires the server to store per-client state. This may be undesirable and it also makes it harder for multiple servers belonging to the same entity to share the common state which is needed in order to be able to correctly execute the protocol. For this reason, SISCA uses symmetric cryptography (MAC), in order to securely offload the state to the clients.

Second, during the verification phase, the server should process the incoming HTTP request, only if the lookup succeeds. If it fails, it means that the attacker intercepted the first connection (initialization phase) and that the incoming request may be malicious. We explain this concept further in the analysis of the SISCA protocol. We note that due to this fact, SISCA uses a second MAC tag in order to enable the server perform this check.

3.2.5 Basic Protocol

We now describe the server invariance protocol of SISCA in detail. We follow a structural approach, meaning that we start with a basic version of our protocol, described in this section. Then, in subsequent sections, we incrementally add features.

Figure 8 illustrates the protocol, assuming no attack. Prior to the protocol execution, the server, `www.example.com`, generates two keys k_{s1} and k_{s2}, called *SISCA keys*. The same SISCA keys are used for all protocol executions (i.e., not for a specific client) and are never disclosed to other parties. Moreover, recall that the server and client deploy Channel ID-based authentication. Each TLS connection will therefore have a Channel ID cid_b, that is created by the user's browser. As already mentioned, the protocol consists of two phases.

Initialization. The initilization phase occurs once the browser establishes a TLS connection to `www.example.com`, for the *first time* in a browsing session (upper connection in Figure 8). The browser picks a random number r_b. It then sends $\langle$'*Init*',$r_b\rangle$ to the server ('*Init*' is a string constant), within the *first* HTTP request[3] over that connection. Upon receiving this message, the server chooses a random number r_s and computes the following message authentication tags:

$$t_1 = \text{MAC}(k_{s1}, \text{'1'}|r_b|r_s|cid_b) \quad (1)$$

$$t_2 = \text{MAC}(k_{s2}, \text{'2'}|r_b|r_s|cid_b) \quad (2)$$

where '1' and '2' are strings constants. Notice that the server binds the computed tags to the browser's Channel ID cid_b. r_b, r_s and the MAC tags will be used in subsequent TLS connections to verify server invariance.

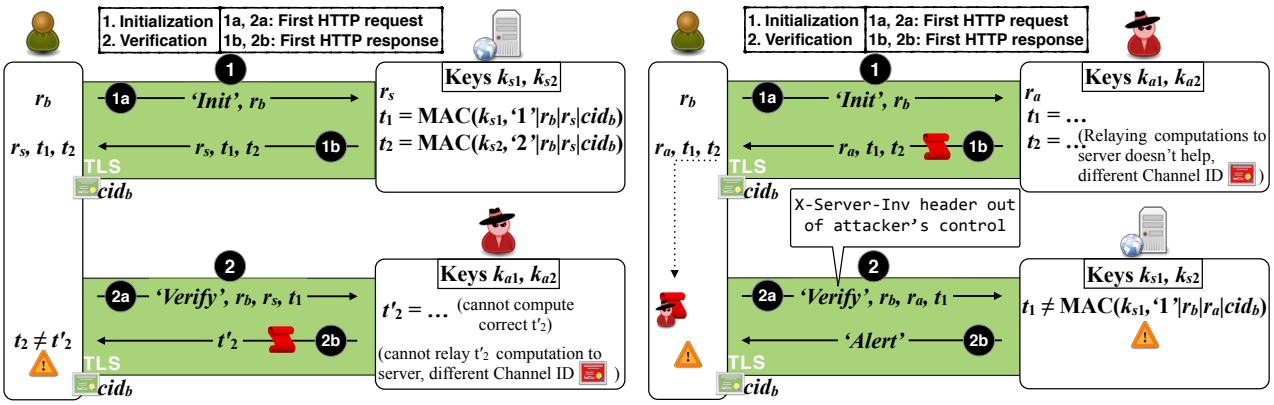
Finally, the server sends $\langle r_s,t_1,t_2\rangle$ to the browser within its first HTTP response. The browser stores $\langle r_b,r_s,t_1,t_2\rangle$, while the server does not store any client-specific information. At this point, the initialization phase is complete. Subsequent HTTP requests and responses over that particular TLS connection do *not* include an `X-Server-Inv` header.

Verification. The verification phase takes place upon every subsequent TLS connection to `www.example.com`, which occurs within the same browsing session (lower connection in Figure 8). Like in the first phase, the protocol messages are exchanged within the *first* HTTP request/response pair. The browser sends $\langle$'*Verify*',$r_b,r_s,t_1\rangle$ to the server, as part of the first request. After receiving the request, and *before* processing it, the server first checks if

$$t_1 \stackrel{?}{=} \text{MAC}(k_{s1}, \text{'1'}|r_b|r_s|cid_b). \quad (3)$$

Here, cid_b corresponds to the Channel ID of the TLS session within which the protocol is currently being exe-

[3]Note that this is a request that browser would anyway submit, i.e., required for loading the web page. It is not an extra request.



(a) Attacker intercepts the verification phase.

(b) Attacker intercepts the initialization phase.

Figure 9: Resilience of SISCA to MITM-SITB (conventional MITM is prevented by Channel-ID based authentication).

cuted, which, if under attack, might differ from the Channel ID that was used in the initialization phase. If the check passes, the server computes

$$t'_2 = \text{MAC}(k_{s2}, \text{'2'}|r_b|r_s|cid_b), \quad (4)$$

processes the received request, and passes $\langle t'_2 \rangle$ within the HTTP response to the browser. Finally, the browser checks if $t'_2 \stackrel{?}{=} t_2$ and if it succeeds, it means that server invariance holds for this TLS connection.

Analysis When Under Attack. Figure 9 illustrates how the protocol prevents MITM attacks. Recall that, due to the usage of Channel ID-based authentication, the attacker cannot perform the conventional attack (Figures 1, 2) – the attacker's TLS sessions will have a different Channel ID than the client's and will thus be rejected. Instead, she has to execute a MITM-SITB attack.

In Figure 9 we illustrate two possible attack scenarios (based on the discussion of Section 3.2.3) and we show why the attacker fails in both. In Figure 9a the attacker intercepts the verification phase of SISCA. Since the attacker didn't participate in the initialization phase of the protocol, she does not know the correct MAC response t_2 to the client's challenge. Moreover, since she does not have access to k_{s2}, she cannot calculate the correct t_2 either (Eq. (4)). As a result, the user's browser rejects the attacker's response and terminates the session, notifying the user (no user decision is required). Even if the attacker pushes a malicious script in her response, it will not get a chance of being executed.

In the second scenario, depicted in Figure 9b, the attacker intercepts the first TLS connection to `www.example.com`. She thus executes the initialization phase with the browser and injects her script, which is executed within the web origin of `www.example.com`. To successfully complete her attack, the attacker needs to let a subsequent TLS connection reach the legitimate server, and access the user's account via that connection.

After the browser establishes a connection with the legitimate server, the two of them execute the verification phase, as part of the first HTTP request/response pair. The server, before processing the HTTP request (which might as well be malicious), checks whether Condition (3) is true. Since the attacker does not have access to key k_{s1}, she could not have computed the correct t_1 (Eq. (1)). Thus, during the initialization phase, she sends a t_1 value to the browser that is not the correct one. Consequently, Condition (3) will not be satisfied. In this case the server does not process the request, and instead notifies the browser by sending an empty HTTP response containing $\langle$'*Alert*'$\rangle$ in the `X-Server-Inv` header. This indicates violation of the server invariance and the browser aborts the session.

We remark that in the second scenario, it is the legitimate server that checks server invariance, detects the ongoing MITM attack and notifies the browser. This is important in order to prevent even a single malicious request from being accepted and processed by the server.

We conclude our analysis, with a few remarks that are relevant for both of the scenarios described above. First, note that the attacker cannot relay any of the necessary MAC computations to the legitimate server. In other words, she cannot manipulate the server to compute for her the values needed for cheating in the protocol. This is because the server binds all its computations to the channel ID of the client with whom it communicates (the attacker's channel ID will be different from the user's).

Second, note that the protocol is secure so long as the attacker cannot "open" already established TLS connections between the browser and the legitimate server (i.e., connections that she chose not to intercept). If she could do that, she would be able to extract the correct values of both t_1 and t_2 and successfully cheat. Recall that, the MITM+key attacker holds the private key of the legitimate server. Therefore, in order to prevent such an at-

tacker from eavesdropping on already established TLS connections, it is essential that these connections have TLS forward secrecy enabled.

Third, when considering MITM+key attacks it is reasonable to assume that the attacker can also extract the SISCA keys, similar to the private key of the server. As stated in the assumptions (Section 3.2.2) and explained in Section 3.2.8, SISCA keys, unlike the private key, can be frequently rotated. SISCA can thus resist MITM+key attacks, assuming no persistent server compromise.

Finally, the attacker can choose not to reply at all, when executing SISCA with the user. This essentially leads to a Denial of Service (DoS) attack. However, such attacks can already be achieved even by attackers less powerful that those considered here. That is, attackers that cannot perform TLS MITM attacks, but can block network traffic between the browser and the server.

Different Origins. The SISCA protocol execution is guided by the same-origin policy [5]. In particular, SISCA is executed independently, i.e., different *protocol instances*, when loading web pages and documents that belong to different origins. For example, assume that the browser navigates to `www.example.com` for the first time in the current browsing session. Then, a new instance of SISCA will be created for this origin and its initialization phase will be executed on the first TLS connection. If the browser further navigates to pages belonging to `www.example.com`, and this triggers the creation of new TLS connections by the browser, then for those connections the browser will execute the verification phase of the previously created SISCA instance corresponding to `www.example.com` (same origin). When the browser navigates to another website (different origin), say `www.another.com`, then a new instance of SISCA will be created and used for the loading of documents from that origin (assuming that this is the first visit to `www.another.com` in that browsing session). Also any HTTP redirections during navigation that lead to different origins will cause the corresponding SISCA instances for those origins to be created and used.

3.2.6 Cross-Origin Communication

In the previous section we assumed that accessing the web pages of `www.example.com` involves communication only with that domain, i.e., web origin. However, this is not a realistic scenario in today's web applications. Many websites perform cross-origin requests, e.g., to load resources. SISCA can accommodate for such scenarios so long as all the involved domains belong to, and are administered by the *same entity*, such that the required SISCA keys, k_{s1} and k_{s2}, can be shared across all relevant servers.

Therefore, for cross-origin communication the browser uses the SISCA instance corresponding to the initiating origin. For example, assume that a page loaded from `www.example.com` performs a cross-origin request to `static.example.com`. The browser will create a TLS connection to `static.example.com` and will execute the verification phase of the SISCA instance that corresponds to `www.example.com`. Any potential HTTP redirections will also use the SISCA instance of the initiating origin, `www.example.com`.

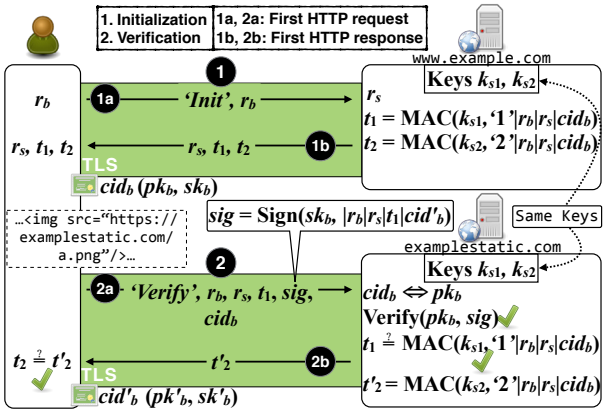


Figure 10: SISCA adapted for cross-origin communication (the origins share the same SISCA keys), when the browser uses a different Channel ID for each origin. Here, `www.example.com` performs a cross-origin request to `examplestatic.com`.

Different Channel IDs. The basic protocol we described in Section 3.2.5 also works in the cross-origin communication scenario, provided that the Channel ID used by the browser is the *same*. The Channel ID specification draft already recommends using the same Channel ID for a domain and its subdomains [4, 15] (to account for cookies that have the `Domain` attribute set). For example, the browser should use the same Channel ID for `www.example.com` and `static.example.com`. Nevertheless, for privacy reasons, the specification recommends using different Channel IDs for unrelated domains. In such cases, SISCA has to account for using different Channel IDs across domains, when cross-origin communication takes place.

Figure 10 depicts how the protocol works in such a scenario. The browser navigates to `www.example.com`, and starts a new SISCA instance for that origin. The browser uses Channel ID cid_b (with public key pk_b, and private key sk_b). At some later point in time, the page loaded from `www.example.com` performs a cross-origin request to `examplestatic.com`, which is controlled by the same entity. Nevertheless, since it corresponds to a different domain (i.e., not a subdomain), the browser uses a different Channel ID, say cid'_b (with pk'_b, sk'_b being the corresponding public/private key pair). In this case, although the initialization phase of SISCA was ex-

ecuted using cid_b, the verification phase will have to be executed over a TLS connection with Channel ID cid'_b.

As Figure 10 shows, the browser needs to tell the server (`examplestatic.com`) to use cid_b instead of cid'_b, but do so in a secure way. To achieve this, the browser endorses cid'_b, by signing it with sk_b, and thus proving to the server that it owns the private keys of both Channel IDs cid_b and cid'_b. The browser extends the '$Verify$' message by appending cid_b and a signature over cid'_b (i.e., the Channel ID of that TLS connection) and the rest of the message parameters using sk_b. The server, before processing the request, verifies the signature on cid'_b using the supplied cid_b (i.e., pk_b). If it passes, then the server uses cid_b for the subsequent steps of the verification phase, which remain unchanged.

Overlapping Cross-Origin Access. Browsers typically send multiple HTTP requests over the same network connection (persistent connections [23]). Due to the existence of cross-origin communication, a TLS connection to a particular domain, say `static.example.com`, can be used by the browser to transmit cross-origin requests to `static.example.com` made by different initiating origins. For example, the browser uses the same TLS connection to `static.example.com`, to transmit, first, a request originating from a document belonging to `www.example.com` and then, a request originating from a document belonging to `shop.example.com` (we still assume that all three domains belong to the same entity). In this case, the TLS connection to `static.example.com` has to be verified using SISCA for both initiating domains, independently.

In the above scenario, the browser executes the verification phase with the SISCA instance of `www.example.com`, upon establishing the TLS connection to `static.example.com` and sending the first HTTP request, originating from `www.example.com`. Subsequently, when the browser wants to reuse the same connection to send a cross-origin request from `shop.example.com` to `static.example.com`, it once again executes the verification phase, only this time with the SISCA instance of `shop.example.com`. This takes place upon transmitting the first HTTP request, which originates from `shop.example.com`.

Origin Change. A web page is allowed to change its own origin (effective origin) to a suffix of its domain, by programmatically setting the value of `document.domain` [40]. This allows two pages belonging to different subdomains, but presumably to the same entity, to set their origin to a common value and enable interaction between them[4]. For example, a page from `www.example.com` and a page from `shop.example.com` can both set their origin to `example.com`. In such a case, the attacker can attack the user account at `shop.example.com`, by intercepting the first connection to `www.example.com` (or any other `example.com` subdomain), or vice versa.

To prevent such an attack, the browser has to verify that server invariance holds across each pair of origins that change their effective origin to a common value, before allowing any interaction between them. Each origin has its own SISCA instance established, and we must ensure that both SISCA instances were initialized with the same remote entity. This can be achieved by running the verification phase of both instances over the same TLS connection (established to either origin). The browser can reuse an already established and verified connection with one origin, and just verify the connection with the SISCA instance of the other origin. If no such connection exists at that time, then the browser can create a new one to either origin and execute the verification phase of both SISCA instances. If there is no actual HTTP request to be sent at that time, the browser can make use of an HTTP `OPTIONS` request.

Partial Support and Downgrade Attacks. SISCA must be incrementally deployable, which means that it must maintain compatibility with legacy web servers, without compromising the security of the SISCA-enabled servers. Moreover, websites must be able to opt for partial support. As an example, a domain implements SISCA but still needs to perform cross-origin requests to another domain, called *incompatible*, that either does not support SISCA, or supports it but belongs to a 3rd party, i.e., it has different SISCA keys (we discuss on the security of such design choices at the end of this section).

The above can be achieved by allowing *exceptions*. If a particular domain does not support SISCA (including legacy servers that are not aware of SISCA at all), then it can simply ignore the `X-Server-Inv` header, sent during the initialization phase, and reply without including any SISCA-related information. This will be received by the browser as an *exception claim*. Moreover, if a domain supports SISCA but performs cross-origin communication with one or more incompatible domains, then it can append an *exception list* in its response, during the initialization phase, designating the incompatible domains.

However, we note that if the attacker intercepts the initialization phase of the protocol, then she could perform a *protocol downgrade attack*, by providing false exception claims or exception lists in her response.

To prevent downgrade attacks, the browser should verify any exception that was received during the initialization phase, upon every subsequent connection. If the attacker intercepted the initialization phase and replied with fake exception claims, then if any of the subsequent connections reaches the legitimate server, the browser, with the help of the legitimate server, would detect the

[4] Both pages have to explicitly set `document.domain`.

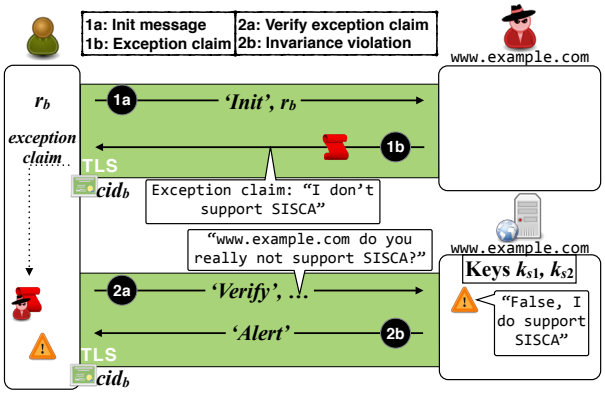

Figure 11: Preventing downgrade attacks (same-origin case).

attack. This scenario is illustrated in Figure 11.

Regarding cross-origin communication, in order to help SISCA-enabled legitimate servers detect fake exception lists previously received by the browser, SISCA protocol messages should include (in the `X-Server-Inv` header) the origin associated with the SISCA instance. Suppose for example, that the browser executes the initialization phase with `www.example.com` which supports SISCA (executes the protocol normally), but also includes an exception list stating that it performs cross-origin requests to `shop.example.com` which does not support SISCA. Whenever the browser connects to `shop.example.com` to perform a cross-origin request from `www.example.com`, the browser includes the origin of the SISCA instance (`www.example.com`) and asks `shop.example.com` whether it indeed does not support SISCA with respect to that origin. Assuming that the connection was not intercepted, `shop.example.com` can leverage the supplied origin information to decide whether the exception reported by the browser is valid. If not, then it should abort processing the request and notify the browser of the detected attack. Note that the above assumes that each SISCA-enabled server is aware of all the domains that is compatible to execute SISCA with (i.e., domains with which it shares the same SISCA keys), which is not difficult to implement.

3rd Party Content Inclusion. As mentioned above, a domain, say `www.example.com`, implementing SISCA can still perform cross-origin requests to incompatible 3rd party domains as long as it designates those domains as exceptions for the protocol. This of course means that TLS connections to those domains will not be protected by SISCA, and could be MITM-ed by the attacker to perform a user impersonation attack on `www.example.com`. This can be indeed the case if `www.example.com` includes active content [39] (in particular, JavaScript and CSS) from those domains. Embedding JavaScript from 3rd party sites is generally not recommended, and usually there are ways of avoiding it [41]. Furthermore, depending on the use case, it may be possible to use *iframes* to isolate active 3rd party content, instead of directly embedding it within the target origin, in order to mitigate the risk (the `sandbox` attribute can help even further).

The embedding of passive content only, such as images, does not give the attacker the ability to execute her code within the target origin. Hence, with respect to preventing user impersonation, such embeddings are safe and do not undermine the security offered by SISCA.

3.2.7 Resource Caching

Caching of static resources, such as scripts and images, helps reduce web page loading times as well as server resource consumption. However, the way caching is currently implemented [23, 25] can give a MITM attacker the opportunity to subvert SISCA.

In brief, during one browsing session, the attacker intercepts all TLS connections and ensures that a legitimate, yet maliciously modified script that is required by the target web server is cached by the browser. Then, during a second browsing session, the attacker lets all connections pass through. When the legitimate web page asks for the inclusion of the aforementioned script, the browser will load it from cache, essentially enabling the execution of the attacker's malicious code. The attacker will thus be able to access the target web server.

To prevent the above attack, we need to change the way caching is performed for active content that would enable this attack (JavaScript and CSS files). We need to make sure that the browser always communicates with the server in order to verify that the cached version is the most recent and also the correct one (i.e., not maliciously modified). Thus, caching of such files should be performed only using Entity Tags (ETags) [23], but in a more rigorous way than specified in the current HTTP specification. In particular, if a web server wishes to instruct a browser to cache a JavaScript or CSS file, the server should use an `ETag` header which always contains a cryptographic hash of the file. The browser, before using, and caching the file should *verify* that the supplied hash is correct. Subsequently, before the browser uses the cached version of the file, it first verifies that the local version matches the version of the server (using the `If-None-Match` header, as currently done).

3.2.8 Key Rotation

In SISCA, the server has a pair of secret keys, k_{s1} and k_{s2}. To resist key compromise (i.e., MITM+key attackers), these keys, unlike the server's private key, can be easily rotated. This is because the SISCA keys need not undergo any certification process, and can thus be rotated frequently, e.g., weekly, daily, or even hourly. The more frequent the rotation the smaller the attacker's window of

opportunity to successfully mount MITM attacks.

The key transition, of course, has to be performed such that it does not break the execution of active browser SISCA instances that rely on the previous keys. At a high level, one way of achieving this, is to have the server keep previous keys for a certain period of time (i.e., allow partial overlap of keys). This can enable browsers with active SISCA instances that rely on the previous keys to securely transition to new protocol parameters, i.e., t_1 and t_2, computed using the new server SISCA keys.

For domains served by a single machine, this is only a matter of implementing the corresponding functionality in the web server software (e.g., Apache). For multiple domains controlled by the same entity and served by multiple machines, located in the same data center or even in different data centers across the world, arguably more effort is required in order to distribute the ever-changing keys and keep the machines in sync. Nevertheless, a similar mechanism is needed for enabling TLS forward secrecy while supporting TLS session tickets [34]. According to Twitter's official blog [30], Twitter engineers have implemented such a key distribution mechanism.

3.2.9 SISCA Benefits and Drawbacks

SISCA offers the following advantages regarding MITM+certificate attack prevention. Compared to multi-path probing solutions, SISCA does not rely on any third party infrastructure, trusted or not. Since SISCA is built on top of Channel ID-based authentication, it has to assume that no MITM attack takes place during user enrollment. Nevertheless, after this step, no "blind" trust is required when the user uses a new or clean browser, contrary to pinning solutions (except preloaded pins), as discussed in Section 3.2.4. Moreover, in SISCA no user decision is necessary whenever server invariance violation is detected. This can occur either due to an attack, or due to an internal server fault, thus the browser can abort (possibly after retrying) the session. SISCA is scalable since it can be deployed incrementally by web providers (assuming browser support). Finally, SISCA resists MITM+key attacks, assuming that the attacker does not persistently compromise the server.

The main disadvantage of SISCA is that it only protects against MITM attackers whose goal is to impersonate the user to the server. This is arguably the most common and impactful attacker goal. SISCA does not protect against attackers whose objective is to provide fake content to the user. In such cases the attacker can simply intercept *all* connections and interact with the user by serving her own, fake content. In contrast, the techniques that focus on ensuring the correctness of server authentication (Section 3.1) can protect against such attacks (MITM+certificate attackers). As a result, a recommended strategy would be to use SISCA in conjunction with any of these techniques. Finally, SISCA requires coordination between an entity's different domains, in the sense they must have access to the same SISCA keys. This is needed for securing cross-origin communication and, depending on the scale of the entity, can be challenging from an engineering perspective to set up.

3.2.10 Interaction With Other Web Technologies

SPDY. SPDY [6] multiplexes concurrent HTTP requests over the same TLS connection to improve network performance. In order for SISCA to be compatible with the general SPDY functionality, the browser must ensure that before the SISCA protocol is completed successfully (i.e., the first request/response pair is exchanged), no further requests are sent through the SPDY connection.

Furthermore, SPDY IP Pooling allows, under certain circumstances, HTTP sessions from the same browser to different domains (web origins) to be multiplexed over the same connection. Version 3 of SPDY is compatible with Channel IDs (recall that different Channel IDs may need to be used for different origins, but now there is only one TLS connection). SISCA is compatible with IP Pooling, as long as the browser manages the multiplexed HTTP sessions independently, with respect to the execution of the SISCA protocol.

WebSocket. SISCA is compatible with the WebSocket protocol [21], when the latter is executed over TLS. This, of course assumes that *(i)* Channel IDs are used for the WebSocket TLS connections, *(ii)* the SISCA protocol is executed during the WebSocket handshake (i.e., first request/response pair), and *(iii)* JavaScript is not be able to manipulate the `X-Server-Inv` header.

Web Storage. Web Storage [27] is an HTML5 feature that allows a web application to store data locally in the browser. SISCA can protect `code.sessionStorage` (temporary storage), but does not prevent a MITM attacker from accessing information stored in `window.localStorage` (permanent storage), so no sensitive information should be stored there.

Offline Web Applications. HTML5 offers Offline Web Applications [26] which allow a website to create an offline version, stored locally in the browser. As with regular file caching (see Section 3.2.7), this feature can be leveraged by the attacker to bypass SISCA. Making this feature secure requires the introduction of design concepts similar to what we proposed for regular caching.

Other Client-Side Technologies. The attacker might attempt to leverage various active client-side technologies besides JavaScript, such as Flash, Java and Silverlight. Such technologies allow the attacker to create direct TLS connections to the legitimate server. Some of the APIs offered by those technologies also allow the attacker to forge and arbitrarily manipulate HTTP headers, including cookie-related headers or the `X-Server-Inv` header.

However, provided that Channel IDs and SISCA are not integrated with these technologies[5], the attacker will not be able to impersonate the user and compromise his account on the legitimate server.

3.3 Prototype SISCA Implementation

We created a proof of concept implementation of the basic SISCA protocol, with additional support for cross-origin communication, provided that the same Channel ID is used. On the server side we use Apache 2.4.7 with OpenSSL 1.0.1f, patched for Channel ID support. SISCA is implemented as an Apache module and consists of 313 lines of C code. On the client side we implement SISCA by modifying the source code of Chromium 35.0.1849.0 (252194) and the WebKit (Blink) engine. We make a total of 319 line modifications (insertions/deletions) in existing files and we add 6 new files consisting of 418 lines of C++ code.

We use Base64 encoding for binary data transmission. When using 128-bit random values (r_b and r_s) and HMAC-SHA256 (i.e., 256-bit tags, t_1 and t_2), the client's lengthiest message is 114 bytes long, plus the origin of the SISCA instance that has to be sent as well. The server's lengthiest message is 132 bytes long.

We finally verified that our implementation successfully blocks our proof of concept MITM-SITB attack.

Performance Evaluation. To assess the performance overhead imposed by SISCA (the server invariance part, not the overhead due to Channel IDs), we measured the latency of HTTP request/response roundtrips, with SISCA enabled and disabled. For the measurements we used a 4KB HTML page, as well as an 84KB jQuery compressed file, retrieved over a domain that we set up as being "cookieless". Chromium ran on a Macbook Pro laptop (2.3GHz CPU, 8GB RAM) and Apache ran on a typical server machine (six core Intel Xeon 2.53GHz, 12GB RAM), connected through the campus network.

We found that the overhead of the basic SISCA protocol is negligible, as no increase in latency was measured (averaged over 300 repetitions). Moreover, the HTTP request to the cookieless domain was able to fit in a single outgoing packet (a typically desired objective).

Regarding cross-origin communication over different Channel IDs (see Section 3.2.6), approximately 180 bytes are further added to the request (one ECDSA public key and signature in Base64 encoding), which can still fit in a single packet (for cookieless domain requests). Furthermore, the server has to perform one ECDSA signature verification. This overhead could be minimized, if the browser used the same Channel ID, not only for subdomains of the same domain, but also for domains belonging to the same entity. Although we do not elaborate on this idea here, this could be heuristically determined by the browser, based on which domains are involved in the execution of the same SISCA instance.

Finally, recall that a SISCA instance is executed only once per TLS connection and not on every HTTP request/response.

[5]This, for example, means that a TLS connection created by such an API will have to create and use its own Channel IDs, and that the browser will not execute SISCA over those connections.

4 Related Work

A significant amount of research in the past years surrounds the security of the TLS protocol, in the context of web applications (i.e., HTTPS), as well as web server and client authentication. A comprehensive overview is provided in [10], which, among others, surveys existing primitives that try to enhance the CA trust model in order to more effectively address MITM attacks.

The use of server impersonation for the compromise of the user's account by serving the attacker's script to the victim's browser was first introduced in [32]. In this attack, called *dynamic pharming*, the attacker exploits DNS rebinding vulnerabilities in browsers, by dynamically manipulating DNS records for the target server, in order to force the user's browser to connect either to the attacker (to inject her script) or to the legitimate server.

MITM-SITB is therefore very similar to dynamic pharming in that it leverages server impersonation to serve the script to the victim's browser. Dynamic pharming focuses on the attacker's ability to control the client's network traffic via DNS attacks, while in this paper we do not make such assumptions. Instead, MITM-SITB can leverage any form of MITM where the attacker controls the communication to the client (e.g., an attacker sitting on a backbone) and relies only on the behavior of the browser to re-establish a connection (with the legitimate server) once the attacker closes the connection within which she injected her script to the browser. Dynamic pharming can equally be used to successfully attack Channel ID-based solutions. Recently, the act of leveraging script injection via server impersonation against TLS client authentication was also discussed in [47].

We note that MITM-SITB (as well as dynamic pharming) differs from *Man-In-the-Browser* (MITB) [45]. The latter implies that the attacker is able to take full control of the browser by exploiting some vulnerability, or installing a malicious browser plugin. In MITM-SITB, the attacker runs normal JavaScript code within the target web origin and only within the boundaries established by the JavaScript execution environment. Therefore, no browser exploitation is required. Similarly, MITM-SITB is different from XSS [44]. In XSS the attacker is able to influence only parts of the served document (by exploiting a script injection vulnerability), while in MITM-SITB she is able to impersonate the server and thus influence the entire HTTP response sent to the browser.

SISCA does not prevent MITB or XSS and addressing these attacks is orthogonal to our work.

To prevent dynamic pharming, the locked same-origin policy (SOP) was proposed [32]. Weak locked SOP considers attackers with invalid certificates, while strong locked SOP also defends against attackers with valid, mis-issued certificates. Strong locked SOP refines the concept of origin by including the public key of the server and can also accommodate for multiple server keys. Strong locked SOP isolates web objects coming from connections with not endorsed server public keys in a separate security context (i.e., different origin). Strong locked SOP per se does not prevent a MITM attacker from mounting a conventional MITM attack in order to impersonate the user. A strong client authentication solution should be used in conjunction, as with SISCA.

Locked SOP does not resist MITM+key attacks, as SISCA does. Moreover, locked SOP is not able to secure cross-origin active content inclusion. The risks involved when a web page imports active content, such as JavaScript, that can be intercepted and modified by an attacker are discussed in [31]. SISCA can secure cross-origin inclusions as long as the involved domains belong to the same entity and thus share the same SISCA keys.

The current Channel ID specification [4] was recently found to be vulnerable to *triple handshake attacks* [7], which affect TLS client authentication in general. The mitigation proposed in [7] has already been implemented in the version of Chromium that we used in this work. SISCA assumes that Channel IDs work as expected, so eliminating triple handshake attacks is essential for its security. However, we note that addressing triple handshake attacks does not prevent MITM-SITB attacks.

Recent work has proposed leveraging Channel ID-based authentication to strengthen federated login [16] and Cloud authorization credentials [8], against MITM attacks and credential theft in general. However, such proposals fail to address MITM attacks, as they are susceptible to MITM-SITB, unless augmented with server invariance, as we propose in this paper with SISCA.

Server invariance is based on *sender invariance* which was formally defined in [17]. SISCA is inspired by this notion, assuming that the server's authenticity cannot be established via server certificate verification and instead trying to enforce the weaker property of invariance.

5 Conclusion

In this paper we discussed the requirements to effectively preventing TLS MITM attacks in the context of web applications, when the attacker's goal is to impersonate the user to the legitimate server and gain access to the user's account and data. Striving to defeat this type of attack is essential, especially given the recent revelations about government agencies (e.g., the NSA) mounting such attacks in order to perform mass surveillance against users of major internet services [18, 48].

We showed that strong client authentication alone, such as the recently proposed Channel ID-based authentication, cannot prevent such attacks. Instead, strong client authentication needs to be complemented with the concept of server invariance, which is a weaker and easier to enforce property than server authentication. Our solution, SISCA, shows that server invariance can be implemented with minimal additional cost on top of the proposed Channel ID-based approaches, and can be deployed incrementally, thus making it a scalable solution. Given its security benefits, we believe that SISCA can act as an additional, strong protection layer in conjunction with existing proposals that focus on amending today's server authentication issues, towards the effective prevention of TLS MITM attacks.

Scheduler-based Defenses against Cross-VM Side-channels

University of Wisconsin

Abstract

Public infrastructure-as-a-service clouds, such as Amazon EC2 and Microsoft Azure allow arbitrary clients to run virtual machines (VMs) on shared physical infrastructure. This practice of multi-tenancy brings economies of scale, but also introduces the threat of malicious VMs abusing the scheduling of shared resources. Recent works have shown how to mount cross-VM side-channel attacks to steal cryptographic secrets. The straightforward solution is *hard isolation* that dedicates hardware to each VM. However, this comes at the cost of reduced efficiency.

We investigate the principle of *soft isolation*: reduce the risk of sharing through better scheduling. With experimental measurements, we show that a *minimum run time (MRT) guarantee* for VM virtual CPUs that limits the frequency of preemptions can effectively prevent existing Prime+Probe cache-based side-channel attacks. Through experimental measurements, we find that the performance impact of MRT guarantees can be very low, particularly in multi-core settings. Finally, we integrate a simple per-core CPU state cleansing mechanism, a form of hard isolation, into Xen. It provides further protection against side-channel attacks at little cost when used in conjunction with an MRT guarantee.

1 Introduction

Public infrastructure-as-a-service (IaaS) clouds enable the increasingly realistic threat of malicious customers mounting side-channel attacks [35, 46]. An attacker obtains tenancy on the same physical server as a target, and then uses careful timing of shared hardware components to steal confidential data. Damaging attacks enable theft of cryptographic secrets by way of shared per-core CPU state such as L1 data and instruction caches [46], despite customers running within distinct virtual machines (VMs).

A general solution to prevent side-channel attacks is *hard isolation*: completely prevent sharing of particular sensitive resources. Such isolation can be obtained by avoiding multi-tenancy, new hardware that enforces cache isolation [42, 44], cache coloring [34, 36], or software systems such as StealthMem [22]. However, hard isolation reduces efficiency and raises costs because of stranded resources that are allocated to a virtual machine yet left unused.

Another approach has been to prevent attacks by adding noise to the cache. For example, in the Düppel system the guest operating system protects against CPU cache side-channels by making spurious memory requests to obfuscate cache usage [47]. This incurs overheads, and also requires users to identify the particular processes that should be protected.

A final approach has been to interfere with the ability to obtain accurate measurements of shared hardware by removing or obscuring time sources. This can be done by removing hardware timing sources [28], reducing the granularity of clocks exposed to guest VMs [41], allowing only deterministic computations [6], or using replication of VMs to normalize timing [26]. These solutions either have significant overheads, as in the last solution, or severely limit functionality for workloads that need accurate timing.

Taking a step back, we note that in addition to sharing resources and having access to fine-grained clocks, shared-core side-channel attacks also require the ability to measure the state of the cache *frequently*. For example, Zhang et al.'s cross-VM attack on ElGamal preempted the victim every 16 µs on average [46]. With less frequent interruptions, the attacker's view of how hardware state changes in response to a victim becomes obscured. Perhaps surprisingly, then, is the lack of any investigation of the relationship between CPU scheduling policies and side-channel efficacy. In particular, scheduling may enable what we call *soft isolation*: limiting the frequency of potentially dangerous cross-VM interactions. (We use

the adjective soft to indicate allowance of occasional failures, analogous to soft real-time scheduling.)

Contributions. We evaluate the ability of system software to mitigate cache-based side-channel attacks through scheduling. In particular, we focus on the type of mechanism that has schedulers ensure that CPU-bound workloads cannot be preempted before a minimum time quantum, even in the presence of higher priority or interactive workloads. We say that such a scheduler offers a *minimum run time (MRT) guarantee*. Xen version 4.2 features an MRT guarantee mechanism for the stated purpose of improving the performance of batch workloads in the presence of interactive workloads that thrash their cache footprint [11]. A similar mechanism also exists in the Linux CFS scheduler [29].

Cache-based side-channel attacks are an example of such highly interactive workloads that thrash the cache. One might therefore hypothesize that by reducing the frequency of preemptions via an MRT guarantee, one achieves a level of soft isolation suitable for mitigating, or even preventing, a broad class of shared-core side-channel attacks. We investigate this hypothesis, providing the first analysis of MRT guarantees as a defense against cache-based side-channel attacks. With detailed measurements of cache timing, we show that even an MRT below 1 ms can defend against existing attacks.

But an MRT guarantee can have negative affects as well: latency-sensitive workloads may be delayed for the minimum time quantum. To evaluate the performance impact of MRT guarantees, we provide extensive measurements with a corpus of latency-sensitive and batch workloads. We conclude that while worst-case latency can be hindered by large MRTs in some cases, in practice Xen's existing core load-balancing mechanisms mitigate the cost by separating CPU-hungry batch workloads from latency-sensitive interactive workloads. As just one example, memcached, when running alongside batch workloads, suffers only a 7% overhead on 95^{th}-percentile latency for a 5 ms MRT compared to no MRT. Median latency is not affected at all.

The existing MRT mechanism only protects CPU-hungry programs that do not yield the CPU or go idle. While we are aware of no side-channel attacks that exploit such victim workloads, we nevertheless investigate a simple and lightweight use of CPU *state cleansing* to protect programs that quickly yield the CPU by obfuscating predictive state. By implementing this in the hypervisor scheduler, we can exploit knowledge of when a cross-VM preemption occurs and the MRT has not been exceeded. This greatly mitigates the overheads of cleansing, attesting to a further value to soft-isolation style mechanisms. In our performance evaluation of this mechanism, we see only a 10–50 µs worse-case overhead on median latency due to cleansing while providing protection for all guest processes within a VM (and not just select ones, as was the case in Düppel). In contrast, other proposed defenses have similar (or worse) overhead but require new hardware, new guest operating systems, or restrict system functionality.

Outline. In the next section, we provide background on cache-based side-channel attacks and existing defense mechanisms. In Section 3 we describe the Xen hypervisor scheduling system, its MRT mechanism, and the principle of soft isolation. In Section 4 we measure the effectiveness of MRT as a defense. Section 5 shows the performance of Xen's MRT mechanism, and Section 6 describes combining MRT with cache cleansing.

2 Background and Motivation

Our work is motivated by the increasing importance of threats posed by side-channel attacks in multi-tenant clouds, in which VMs from multiple customers run on the same physical hardware. We focus on cache-based side-channels, which are dangerous because they can leak secret information such as encryption keys and have been demonstrated between virtual machines in a cloud environment [46].

Side-channel attacks. We can delineate side-channel attacks into three classes: time-, trace-, and access-driven. Time-driven attacks arise when an attacker can glean useful information via repeated observations of the (total) duration of a victim operation, such as the time to compute an encryption (e.g., [5, 7, 10, 16, 24]). Trace-driven attacks work by having an attacker continuously monitor a cryptographic operation, for example via electromagnetic emanations or power usage leaked to the attacker (e.g., [14, 23, 33].

We focus on access-driven side-channel attacks, in which the attacker is able to run a program on the same physical server as the victim. These abuse stateful components of the system shared between attacker and victim program, and have proved damaging in a wide variety of settings, including [3, 15, 31, 32, 35, 45]. In the cross-process setting, the attacker and victim are two separate processes running within the same operating system. In the cross-VM setting, the attacker and victim are two separate VMs running co-resident (or co-tenant) on the same server. The cross-VM setting is of particular concern for public IaaS clouds, where it has been shown that an attacker can obtain co-residence of a malicious VM on the same server as a target [35]

Zhang, Juels, Reiter, and Ristenpart (ZJRR) [46] demonstrated the first cross-VM attack with sufficient

granularity to extract ElGamal secret keys from the victim. They use a version of the classic Prime+Probe technique [31]: the attacker first *primes* the cache (instruction or data) by accessing a fixed set of addresses that fill the entire cache. He then yields the CPU, causing the hypervisor to run the victim, which begins to evict the attacker's data or instructions from various cache. As quickly as possible, the attacker preempts the victim, and then *probes* the cache by again accessing a set of addresses that cover the entire cache. By measuring the speed of each cache access, the attacker can determine which cache lines were displaced by the victim, and hence learn some information about which addresses the victim accessed.

The ZJRR attack builds off a long line of cross-process attacks (c.f., [3, 4, 15, 31, 32]) all of which target per-core microarchitectural state. When simultaneous multi-threading (SMT) is disabled (as is typical in cloud settings), such per-core attacks require that the attacker time-shares a CPU core with the victim. In order to obtain frequent observations of shared state, attacks abuse scheduler mechanisms that prioritize interactive workloads in order to preempt the victim. For example, ZJRR use inter-processor interrupts to preempt every 16 µs on average. In their cross-process attack, Bangerter et al. abuse the Linux process scheduler [15].

Fewer attacks thus far have abused (what we call) off-core state, such as last-level caches used by multiple cores. Some off-core attacks are coarse-grained, allowing attackers to learn only a few bits of information (e.g., whether the victim is using the cache or not [35]). An example of a fine-grained off-core attack is the recent Flush+Reload attack of Yarom and Falkner [45]. Their attack extends the Bangerter et al. attack to instead target last-level caches on some modern Intel processors and has been shown to enable very efficient theft of cryptographic keys in both cross-process and cross-VM settings. However, like the Bangerter et al. attack, it relies on the attacker and victim having shared memory pages. This is a common situation for cross-process settings, but also arises in cross-VM settings should the hypervisor perform memory page deduplication. While several hypervisors implement deduplication, thus far no IaaS clouds are known to use the feature and so are not vulnerable.

Threat model and goals. Our goal is to mitigate or completely prevent cross-VM attacks relevant to modern public IaaS cloud computing settings. We assume the attacker and victim are separate VMs co-resident on the same server running a Type I hypervisor. The attacker controls the entire VM, including the guest operating system and applications, but the hypervisor is run by the cloud provider and is trusted. SMT and memory deduplication are disabled. In this context, the best known attacks rely on:

(1) *Shared per-core state* that is accessible to the attacker and that has visibly different behavior based on its state, such as caches and branch predictors.

(2) *The ability to preempt the victim VM* at short intervals to allow only a few changes to that hardware state.

(3) *Access to a system clock* with enough resolution to distinguish micro-architectural events (e.g., cache hits and misses).

These conditions are all true in contemporary multi-tenant cloud settings, such as Amazon's EC2. Defenses can target any of these dependencies, and we discuss some existing approaches next.

Prior defenses. Past work on defenses against such side-channel attacks identified the above requirements for successful side-channels and tried to obviate one or more of the above necessary conditions for attacks. We classify and summarize these techniques below.

An obvious solution is to prevent an attacker and victim from sharing hardware, which we call *hard isolation*. Partitioning the cache in hardware or software prevents its contents from being shared [22, 34, 36, 42]. This requires special-purpose hardware or loss of various useful features (e.g., large pages) and thus limits the adoption in a public cloud environment. Assigning VMs to run on different cores avoids sharing of per-core hardware [21, 27, 38], and assigning them to different servers avoids sharing of any system hardware [35]. A key challenge here is identifying an attacker and victim in order to separate them; otherwise this approach reduces to using dedicated hardware for each customer, reducing utilization and thus raising the price of computing.

Another form of hard isolation is to reset hardware state when switching from one VM to another. For example, flushing the caches on every context switch prevents the cache state from being shared between VMs [47]. However, this can decrease performance of cache-sensitive workloads both because of the time taken to do the flush and the loss in cache efficiency.

Beyond hard isolation are approaches that modify hardware to add noise, either in the timing or by obfuscating the specific side-channel information. The former can be accomplished by removing or modifying timers [26, 28, 41] to prevent attackers from accurately distinguishing between microarchitectural events, such as a cache hit and a miss. For example, StopWatch [26] removes all timing side-channels and incurs a worse-case overhead of 2.8x for network intensive workloads. Specialized hardware-support could also be used to obfuscate and randomize processor cache usage [25, 44]. All

of these defenses either result in loss of high-precision timer or require hardware changes.

Similarly, one can allocate exclusive memory resources for a sensitive process [22] or add noise to obfuscate its hardware usage [47]. Similarly, programs can be changed to obfuscate access patterns [8, 9]. These approaches are not general-purpose, as they rely on identifying and fixing all security-relevant programs. Worst-case overheads for these mechanisms vary from 6–7%.

Several past efforts attempt to minimize performance interference between workloads (e.g., Q-clouds [30] and Bubble-Up [27], but do not consider adversarial workloads such as side-channel attacks.

3 MRT Guarantees and Soft Isolation

We investigate a different strategy for mitigating per-core side-channels: adjusting hypervisor core scheduling to limit the rate of preemptions. This targets the second requirement of attacks such as ZJRR. Such a scheduler would realize a security design principle that we call *soft isolation*[1]: limiting the frequency of potentially dangerous interactions between mutually untrustworthy programs. Unlike hard isolation mechanisms, we will allow shared state but attempt to use scheduling to limit the damage. Ideally, the flexibility of soft isolation will ease the road to deployment, while still significantly mitigating or even preventing side-channel attacks. We expect that soft isolation can be incorporated as a design goal in a variety of resource management contexts. That said, we focus in the rest of this work on CPU core scheduling.

Xen scheduling. Hypervisors schedule virtual machines much like an operating system schedules processes or threads. Just as a process may contain multiple threads that can be scheduled on different processors, a virtual machine may consist of multiple virtual CPUs (VCPUs) that can be scheduled on different physical CPUs (PCPUs). The primary difference between hypervisor and OS scheduling is that the set of VCPUs across all VMs is relatively static, as VM and VCPU creation/deletion is a rare event. In contrast, processes and threads are frequently created and deleted.

Hypervisor schedulers provide low-latency response times to interactive tasks by prioritizing VCPUs that need to respond to an outstanding event. The events are typically physical device or virtual interrupts from packet arrivals or completed storage requests. Xen's credit scheduler normally lets a VCPU run for 30ms before preempting it so another VCPU can run. However,

[1]The term "soft" is inherited from soft real-time systems, where one similarly relaxes requirements (in that case, time deadlines, in our case, isolation).

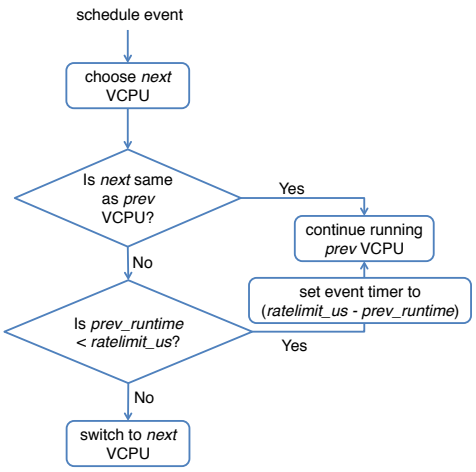

Figure 1: **Logic underlying the Xen MRT mechanism.**

when a VCPU receives an event, it may receive *boost* priority, which allows it to preempt non-boosted VCPUs and run immediately.

VCPUs are characterized by Xen as either *interactive* (or *latency-sensitive*) if they are mostly idle until an interrupt comes in, at which point they execute for a short period and return to idle. Typical interactive workloads are network servers that execute in response to an incoming packet. We refer to VCPUs that are running longer computations as *batch* or *CPU-hungry*, as they typically execute for longer than the scheduler's time slice (30ms for Xen) without idling.

Schedulers can be *work conserving*, meaning that they will never let a PCPU idle if a VCPU is ready to run, or *non-work conserving*, meaning that they enforce strict limits on how much time a VCPU can run. While work-conserving schedulers can provide higher utilization, they also provide worse performance isolation: if one VCPU goes from idle to CPU-hungry, another VCPU on the same PCPU can see its share of the PCPU drop in half. As a result, many cloud environments use non-work conserving schedulers. For example, Amazon EC2's *m1.small* instances are configured to be non-work conserving, allocating roughly 40% of a PCPU (called cap in Xen) to each VCPU of a VM.

Since version 4.2, Xen has included a mechanism for rate limiting preemptions of a VCPU; we call this mechanism a minimum run-time (MRT) guarantee. The logic underlying this mechanism is shown as a flowchart in Figure 1. Xen exposes a hypervisor parameter, `ratelimit_us` (the MRT value) that determines the minimum time any VCPU is guaranteed to run on a PCPU before being available to be context-switched out of the PCPU by another VCPU. One could also rate limit preemptions in other ways, but an MRT guarantee is sim-

ple to implement. Note that the MRT is not applicable to VMs that voluntarily give up the CPU, which happens when the VM goes idle or waits for an event to occur.

As noted previously, the original intent of Xen's MRT was to improve performance for CPU-hungry workloads run in the presence of latency-sensitive workloads: each preemption pollutes the cache and other microarchitectural state, slowing the CPU-intensive workload

Case study. We experimentally evaluate the Xen MRT mechanism as a defense against side-channel leakage by way of soft isolation. Intuitively, the MRT guarantee rate-limits preemptions and provides an attacker less granularity in his observations of the victim's use of per-CPU-core resources. Thus one expects that increased rate-limits decreases vulnerability. To be deployable, however, we must also evaluate the impact of MRT guarantees on benign workloads. In the next two sections we investigate the following questions:

(1) How do per-core side-channel attacks perform under various MRT values? (Section 4)

(2) How does performance vary with different MRT values? (Section 5)

4 Side-channels under MRT Guarantees

We experimentally evaluate the MRT mechanism as a defense against side-channel leakage for per-core state. We focus on cache-based leakage.

Experimental setup. Running on the hardware setup shown in Figure 2, we configure Xen to use two VMs, a victim and attacker. Each has two VCPUs, and we pin one attacker VCPU and one victim VCPU to each of two PCPUs (or cores). We use a non-work-conserving scheduler whose configuration is shown in Figure 9. This is a conservative version of the ZJRR attack setting, where instead the VCPUs were allowed to float — pinning the victims to the same core only makes it easier for the attacker. The hardware and Xen configurations are similar to the configuration used in EC2 m1.small instances [12]. (Although Amazon does not make their precise hardware configurations public, we can still gain some insight into the hardware on which an instance is running by looking at `sysfs` and the `CPUID` instruction.)

Cache-set timing profile. We start by fixing a simple victim to measure the effects of increasing MRT guarantees. We have two functions that each access a (distinct) quarter of the instruction cache (I-cache)[2]. The victim

[2]Our test machine has a 32 KB, 4-way set associative cache with 64-byte lines. There are 128 sets.

Machine Configuration	Intel Xeon E5645, 2.40GHz clock, 6 cores in one package
Memory Hierarchy	Private 32 KB L1 (I- and D-cache), 256 KB unified L2, 12 MB shared L3 and 16 GB main memory.
Xen Version	4.2.1
Xen Scheduler	Credit Scheduler 1
Dom0 OS	Fedora 18, 3.8.8-202.fc18.x86_64
Guest OS	Ubuntu 12.04.3, Linux 3.7.5

Figure 2: **Hardware configuration in local test bed.**

alternates between these two functions, accessing each quarter 500 times. This experiment models a simple I-cache side-channel where switching from one quarter to another leaks some secret information (we call any such leaky function a *sensitive* operation). Executing the 500 access to a quarter of the I-cache requires approximately 100 µs when run in isolation.

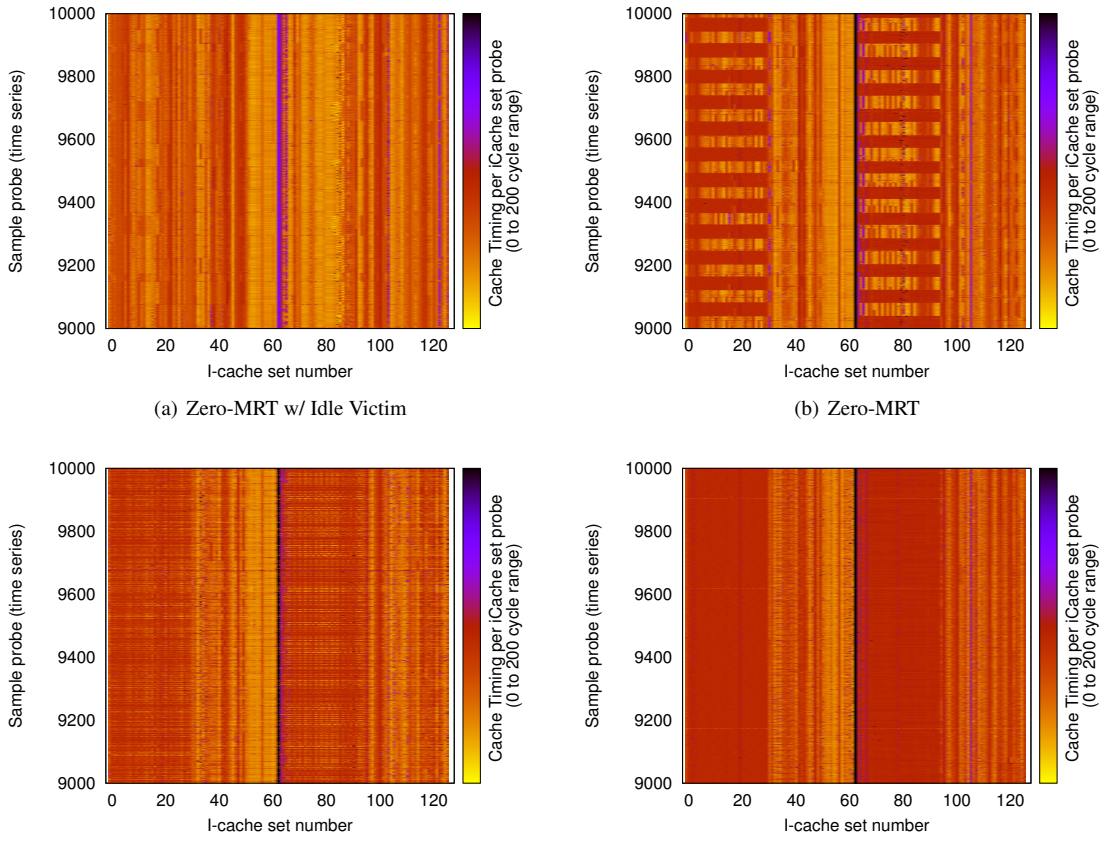
We run this victim workload pinned to a victim VCPU that is pinned to the same PCPU as the attacker VCPU. The attacker uses the IPI-based Prime+Probe technique[3] and measures the time taken to access each I-cache set, similar to ZJRR [46].

Figure 3 shows heat maps of the timings of the various I-cache sets as taken by the Prime+Probe attacker, for various MRT values between 0 (no MRT) and 5 ms. Darker colors are longer access times, indicating conflicting access to the cache set by the victim. One can easily see the simple alternating pattern of the victim as we move up the y-axis of time in Figure 3(b). Also note that this is different from an idle victim under zero-MRT shown in Figure 3(a). With no MRT, the attacker makes approximately 40 observations of each cache set, allowing a relatively detailed view of victim behavior.

As the MRT value increases we see the loss of resolution by the attacker as its observations become less frequent than the alternations of the victim. At an MRT of 100 µs the pattern is still visible, but noisier. Although the victim functions run for 100 µs, the prime+probe attacker slows downs the victim by approximately a factor of two, allowing the pattern to be visible with a 100 µs MRT. When the MRT value is set to 1 ms the attacker obtains no discernible information on when the switching between each I-cache set happens.

In general, an attacker can observe victim behavior that occurs at a lower frequency than the attacker's preemptions. We modify the victim program to be 10x

[3]Note that the attacker requires two VCPUs, one measuring the I-cache set timing whenever interrupted and the other issuing the IPIs to wake up the other VCPU. The VCPU issuing IPIs is pinned to a different PCPU.



(a) Zero-MRT w/ Idle Victim

(b) Zero-MRT

(c) 100 µs-MRT

(d) 1 ms-MRT

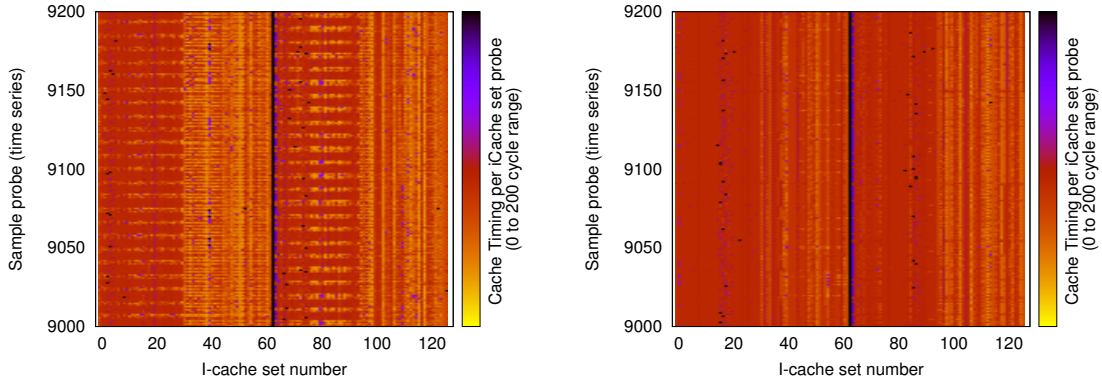
Figure 3: **Heatmaps of I-cache set timing as observed by a prime-probe attacker.** Displayed values are from a larger trace of 10,000 timings. (a) Timings for idle victim and no MRT. (b)–(d) Timings for varying MRT values with the victim running.

slower (where each function takes approximately 1 ms standalone). Figure 4 shows the result for this experiment. With a 1 ms MRT, we observe the alternating pattern. When the MRT is raised to 5 ms, which is longer than the victim's computation ($\approx$ 2 ms), no pattern is apparent. Thus, when the MRT is longer than the execution time of a security-critical function this side-channel fails.

While none of this proves lack of side-channels, it serves to illustrate the dynamics between side-channels, duration of sensitive victim operations, and the MRT: as the MRT increases, the frequency with which an attacker can observe the victim's behavior decreases, and the signal and hence leaked information decreases. All this exposes the relationship between the speed of a sensitive operation, the MRT, and side-channel availability for an attacker. In particular, very long operations (e.g., longer than the MRT) may still be spied upon by side-channel attackers. Also, infrequently accessed but sensitive memory accesses may leak to the attacker. We hypothesis that at least for cryptographic victims, even moderate MRT values on the order of a handful of milliseconds are sufficient to prevent per-core side-channel attacks. We next look, therefore, at how this relationship plays out for cryptographic victims.

ElGamal victim. We fix a victim similar to that targeted by ZJRR. The victim executes the modular exponentiation implementation from libgcrypt 1.5.0 using a 2048-bit exponent, base and modulus, in a loop. Pseudocode of the exponentiation algorithm appears in Figure 5. One can see that learning the sequence of operations leaks the secret key values: if the code in lines 7 and 8 is executed, the bit is a 1; otherwise it is a zero. We instrument libgcrypt to write the current bit being operated upon to a memory page shared with the attacker, allowing us to determine when preemptions occur relative to operations within the modular exponentiation.

For no MRT guarantee, we observe that the attacker can preempt the victim many times per individual square, multiply, or reduce operation (as was also reported by ZJRR). With MRT guarantees, the rate of preemptions drops so much that the attacker only can interrupt once



(a) 1 ms-MRT (b) 5 ms-MRT

Figure 4: **Heatmaps of I-cache set timings as observed by a prime-probe attacker for 10x slower victim computations.** Displayed values are from a larger trace of 9,200 timings.

```
SQUAREMULT(x, e, N):

 2: y ← 1
 3: for i = n down to 1 do
 4:     y ← SQUARE(y)
 5:     y ← MODREDUCE(y, N)
 6:     if e_i = 1 then
 7:         y ← MULT(y, x)
 8:         y ← MODREDUCE(y, N)
 9:     end if
10: end for
11: return y
```

Figure 5: **Modular exponentiation algorithm used in libgcrypt version 1.5.0.** Note that the control flow followed when $e_i = 1$ is lines $4 \to 5 \to 6 \to 7 \to 8$ and when $e_i = 0$ is lines $4 \to 5$; denoted by the symbols `1` and `0`, respectively.

Xen MRT (ms)	Avg. ops/run	Min. ops/run
0	0.096	0
0.1	14.1	4
0.5	49.0	32
1.0	92.6	68
2.0	180.7	155
5.0	441.2	386
10.0	873.1	728

Figure 6: **The average and minimal number of ElGamal secret key bits operated upon between two attacker preemptions for a range of MRT values.** Over runs with 40K preemptions.

Xen MRT (ms)	Preemptions per function call		
	Min	Median	Max
0	3247	19940	20606
0.1	74	155	166
0.5	22	42	47
1.0	16	22	25
2.0	10	11	13
5.0	0	4	6
10.0	1	2	3

Figure 7: **Rate of preemption with various MRT.** Here the function called is the Modular-Exponentiation implementation in libgcrypt with a 2048 bit exponent. Note that for zero MRT the rate of preemption is very high that victim computation involving a single bit was preempted multiple times.

every several iterations of the inner loop. Figure 6 gives the number of bits operated on between attacker preemptions for various MRT values. Figure 7 gives the number of preemptions per entire modular exponentiation computation. We see that for higher MRT values, the rate of preemption per call to the full modular exponentiation reduces to just a handful. The ZJRR attack depends on multiple observations *per operation* to filter out noise, so even at the lowest MRT value of 100 µs, with 4–14 operations per observation, the ZJRR attack fails. In the full version [40], we discuss how one might model this leakage scenario formally and evidence a lack of any of a large class of side-channel attacks.

AES victim. We evaluate another commonly exploited access-driven side-channel victim, AES, which leaks secret information via key-dependent indexing into tables stored in the L1 data cache [15, 31]. The previous attacks, all in the cross-process setting, depend on observing a very small number of cache accesses to obtain a clear signal of what portion of the table was accessed by the victim. Although there has been no known AES attack in the cross-VM setting (at least when deduplication is turned off, otherwise see [19]), we evaluate effectiveness of MRT against the best known IPI Prime+Probe

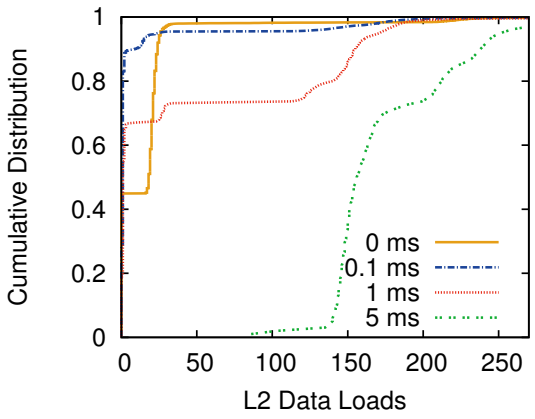

Figure 8: **CDF of L2 data-loads per time slice experienced by OpenSSL-AES victim.** L2 data loads are performance counter events that happen when a program requests for a memory word that is not in both L1 and L2 private caches (effectively a miss). When running along-side a Prime+Probe attacker, these data-cache accesses can be observed by the attacker.

spy process due to ZJRR. In particular, we measured the number of private data-cache misses possibly observable by this Prime+Probe attacker when the victim is running AES encryption in a loop.

To do so, we modified the Xen scheduler to log the count of private-cache misses (in our local testbed both L1 and L2 caches are private) experienced by any VCPU during a scheduled time slice. This corresponds to the number of data-cache misses an attacker could ideally observe. Figure 8 shows the cumulative distribution of the number of L2-data cache misses (equivalently, private data-cache loads) during a time slice of the victim running OpenSSL-AES. We can see that under no or lower MRTs the bulk of time slices suffer only a few tens of D-cache misses that happen between two back-to-back preemptions of the attacker. (We note that this is already insufficient to perform prior attacks.) The number of misses increases to close to 200 for an MRT value of 5 ms. This means that the AES process is evicting its own data, further obscuring information from a would-be attacker. Underlying this is the fact that the number of AES encryptions completed between two back-to-back preemptions increases drastically with the MRT: found that thousands to ten thousands AES block-encryptions were completed between two preemptions when MRT was varied from 100 µs to 5 ms, respectively.

Summary. While side channels pose a significant threat to the security of cloud computing, our measurements in this section show that, fortunately, the hypervisor scheduler can help. Current attacks depend on frequent preemptions to make detailed measurements of cache contents. Our measurements show that even delaying preemption for a fraction of millisecond prevents known attacks. While this is not proof that future attacks won't be found that circumvent the MRT guarantee, it does strongly suggest that deploying such a soft-isolation mechanism will raise the bar for attackers. This leaves the question of whether this mechanism is cheap to deploy, which we answer in the next section.

Note that we have focused on using the MRT mechanism for CPU and, indirectly, per-core hardware resources that are shared between multiple VMs. But rate-limiting-type mechanisms may be useful for other shared devices like memory, disk/SSD, network, and any system-level shared devices which suffer from a similar access-driven side-channels. For instance, a timed disk read could reveal user's disk usage statistics like relative disk head positions [20]. Fine-grained sharing of the disk across multiple users could leak sensitive information via such a timing side-channel. Reducing the granularity of sharing by using MRT-like guarantees in the disk scheduler (e.g., servicing requests from user for at least T_{min}, minimum service time, before serving requests from another user) would result in a system with similar security guarantees as above, eventually making such side-channels harder to exploit. Further research is required to analyze the end-to-end performance impact of such a mechanism for various shared devices and schedulers that manage them.

5 Performance of MRT Mechanism

The analysis in the preceding section demonstrates that MRT guarantees can meaningfully mitigate a large class of cache-based side-channel attacks. The mitigation becomes better as MRT increases. We therefore turn to determining the maximal MRT guarantee one can fix while not hindering performance.

5.1 Methodology

We designed experiments to quantify the negative and positive effects of MRT guarantees as compared to a baseline configuration with no MRT (or zero MRT). Our testbed configuration uses the same hardware as in the last section and the Xen configurations are summarized in Figure 9. We run two DomU VMs each with a single VCPU. The two VCPUs are pinned to the same PCPU. Pinning to the same PCPU serves to isolate the effect of the MRT mechanism. The management VM, Dom0, has 6 VCPUs, one for each PCPU (a standard configuration option). The remaining PCPUs in the system are otherwise left idle.

Work-conserving configuration

Dom0	6 VCPU / no cap / weight 256
DomU	1 VCPU / 2 GB memory / no cap / weight 256

Non-work-conserving configuration

Dom0	6 VCPU / no cap / weight 512
DomU	1 VCPU / 2 GB memory / 40% cap / weight 256

Figure 9: **Xen configurations used for performance experiments.**

CPU-hungry Workloads

Workload	Description
SPECjbb	Java-based application server [37]
graph500	Graph analytics workload [1] with scale of 18 and edge factor of 20.
mcf, *sphinx*, *bzip2*	SpecCPU2006 cache sensitive benchmarks [17]
Nqueens	Microbenchmark solving n-queens problem
CProbe	Microbenchmark that continuously trashes L2 private cache.

Latency-sensitive Workloads

Workload	Description
Data-Caching	Memcached from Cloud Suite-2 with twitter data set scaled by factor of 5 run for 3 minutes with rate of 500 requests per second [13].
Data-Serving	Cassandra KV-store from Cloud Suite-2 with total of 100K records[4] [13]
Apache	Apache webserver, HTTPing client [18], single 4 KB file at 1 ms interval.
Ping	Ping command at 1 ms interval.
Chatty-CProbe	One iteration of *CProbe* every 10 µs.

Figure 10: **Workloads used in performance experiments.**

We use a mix of real-world applications and microbenchmarks in our experiments (shown in Figure 10). The microbenchmark *CProbe* simulates a perfectly cache-sensitive workload that continuously overwrites data to the (unified) L2 private cache, and *Chatty-CProbe* is its interactive counterpart that overwrites the cache every 10 µs and then sleeps. We also run the benchmarks with an idle VCPU (labeled *Idle* below).

5.2 Latency Sensitivity

The most obvious potential performance downside of a MRT guarantee is increased latency: interactive workloads may have to wait before gaining access to a PCPU. We measure the negative effects of MRT guarantees by running latency-sensitive workloads against *Nqueens* (a CPU-bound program with little memory access). Figure 11 shows the 95^{th} percentile latency for the interactive workloads. The baseline results are shown as a MRT of 0 on the X-axis. As expected, the latency is approximately equal to the MRT for almost all workloads (*Apache* has higher latency because it requires multiple packets to respond, so it must run multiple times to complete a request). Thus, in the presence of a CPU-intensive workload and when pinned to the same PCPU, the MRT can have a large negative impact on interactive latency.

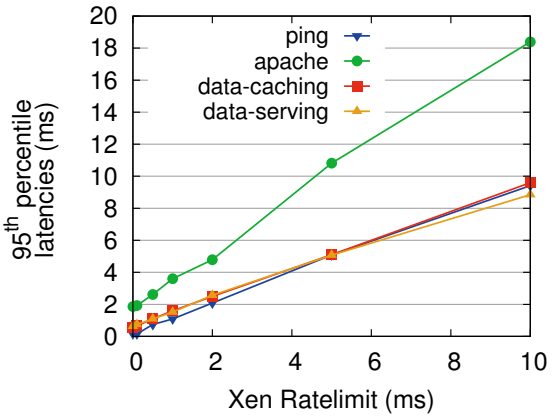

Figure 11: **95^{th} Percentile Latency of Various Latency Sensitive Workloads.** Under non-work-conserving scheduling.

As the workloads behave essentially similarly, we now focus on just the *Data-Caching* workload. Figure 12 shows the response latency when run against other workloads. For the two CPU-intensive workloads, *CProbe* and *Nqueens*, latency increases linearly with the MRT. However, when run against either an idle VCPU or *Chatty-CProbe*, which runs for only a short period, latency is identical across all MRT values. Thus, the MRT has little impact when an interactive workload runs alone or it shares the PCPU with another interactive workload.

We next evaluate the extent of latency increase. Figure 13 shows the 25^{th}, 50^{th}, 75^{th}, 90^{th}, 95^{th} and 99^{th} percentile latency for *Data-Caching*. At the 50^{th} percentile and below, latency is the same as with an idle VCPU. However, at the 75^{th} latency rises to half the MRT, indicating that a substantial fraction of requests are delayed.

We repeated the above experiments for the work-conserving setting, and the results were essentially the same. We omit them for brevity. Overall, we find that enforcing an MRT guarantee can severely increase latency when interactive VCPUs share a PCPU with CPU-intensive workloads. However, they have limited impact when multiple interactive VCPUs share a PCPU.

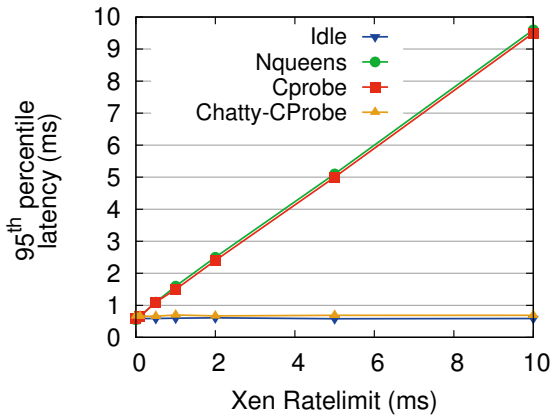

Figure 12: **95th Percentile Request Latency of *Data-Caching* Workload with Various Competing Micro-benchmarks.** Under non-work-conserving scheduling.

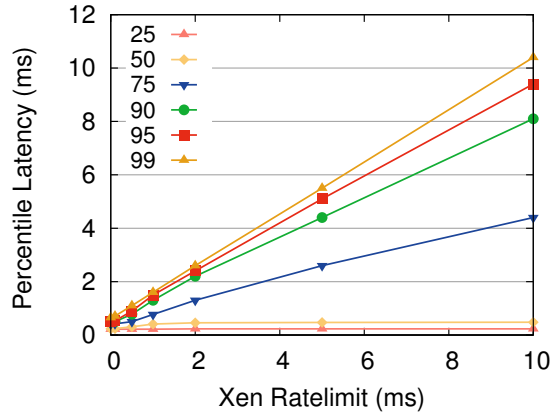

Figure 13: **25th, 50th, 75th, 90th, 95th and 99th Percentile Latency of *Data-Caching* Workload when run alongside *Nqueens*.** Under non-work-conserving scheduling.

5.3 Batch Efficiency

In addition to measuring the impact on latency-sensitive workloads, we also measure the impact of MRT guarantees on CPU-hungry workloads. The original goal of the MRT mechanism was to reduce frequent VCPU context-switches and improve performance of batch workloads. We pin a CPU-hungry workload to a PCPU against competing microbenchmarks.

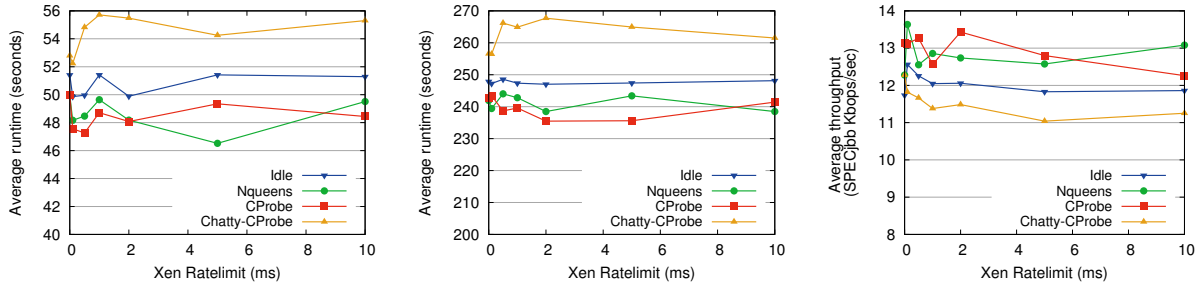
Figure 14 shows the effect of MRT values on the *graph500* workload when run alongside various competing workloads. Because this is work-conserving scheduling, the runtime of *graph500* workload increases by roughly a factor of two when run alongside *Nqueens* and *CProbe* as compared to *Idle*, because the share of the PCPU given to the VCPU running *graph500* drops by one half. The affect of MRT is more pronounced when looking running alongside *Chatty-CProbe*, the workload which tries to frequently interrupt *graph500* and trash its cache. With no MRT guarantee, this can double the runtime of a program. But with a limit of only 0.5 ms, performance is virtually the same as with an idle VCPU, both because *Chatty-CProbe* uses much less CPU and because it trashes the cache less often.

With a non-work-conserving scheduler, the picture is significantly different. Figure 15 shows the performance of three batch workloads when run alongside a variety of other workloads, for various MRT values. First, we observe that competing CPU-bound workloads such as *Nqueens* and *CProbe* do not significantly affect the performance of CPU-bound applications, even in the case of *CProbe* that trashes the cache. This occurs because the workloads share the PCPU at coarse intervals (30 ms), so the cache is only trashed once per 30 ms period. In contrast, when run with the interactive workload *Chatty-CProbe*, applications suffer up to 4% performance loss, which *increases* with longer MRT guarantees. Investigating the scheduler traces showed that under zero MRT the batch workload enjoyed longer scheduler time slices of 30 ms compared to the non-zero MRT cases. This was because under zero MRT highly interactive *Chatty-CProbe* quickly exhausted Xen's boost priority. After this, *Chatty-CProbe* could not preempt and waited until the running VCPU's 30 ms time slice expires. With longer MRT values, though, *Chatty-CProbe* continues to preempt and degrade performance more consistently.

Another interesting observation in Figure 15 is that when the batch workloads share a PCPU with an idle VCPU, they perform worse than when paired with *Nqueens* or *CProbe*. Further investigation revealed that an idle VCPU is not completely idle but wakes up at regular intervals for guest timekeeping reasons. Overall, under non-work-conserving settings, running a batch VCPU with any interactive VCPU (even an idle one) is worse than running with another batch VCPU (even one like *CProbe* that trashes the cache).

5.4 System Performance

The preceding sections showed the impact of MRT guarantees when both applications are pinned to a single core. We next analyze the impact of the Xen scheduler's VCPU placement policies, which choose the PCPU on which to schedule a runnable VCPU. We configure the system with 4 VMs each with 2 VCPUs to run on 4 PCPUs under a non-work conserving scheduler. We run three different sets of workload mixes, which together capture a broad spectrum of competing workload combinations. Together with a target workload running on both VCPUs of a single VM, we run: (1) *All-Batch* — consisting of worst-case competing CPU-hungry work-



(a) *mcf* (b) *graph500* (c) *SPECjbb*

Figure 15: **Average runtime of various batch workloads under non-work conserving setting.** Note that for *SPECjbb* higher is better (since the graph plots the throughput instead of runtime). All data points are averaged across 5 runs.

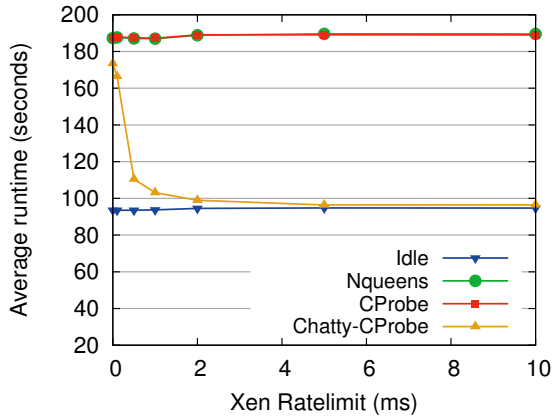


Figure 14: **Average runtime of *graph500* workload when run alongside various competing workloads and under work-conserving scheduling.** Averaged over 5 runs.

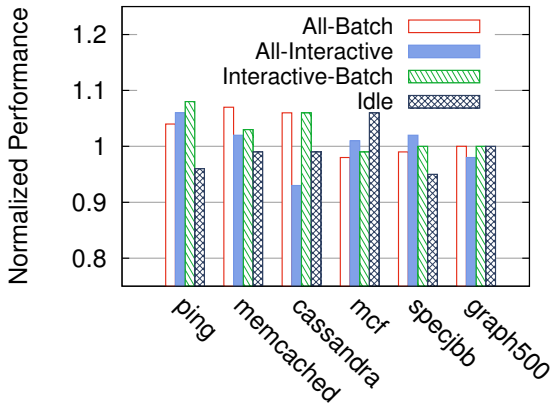

Figure 16: **Normalized Performance in a non-work-conserving configuration with 5 ms MRT.** Normalized to performance under zero-MRT case. The left three workloads report 95^{th} percentile latency and the right three report runtime, averaged across 5 runs. In both cases lower is better.

load (*CProbe*); (2) *All-Interactive* — consisting of worst-case competing interactive workload (*Chatty-CProbe*); and (3) *Batch & Interactive* — where half of other VCPUs run *Chatty-CProbe* and half *CProbe*. We compare the performance of Xen without MRT to running with the default 5ms limit. The result of the experiment is shown in Figure 16. For interactive workloads, the figure shows the relative 95^{th} percentile latency, while for CPU-hungry workloads it shows relative execution time.

On average across the three programs and three competing workloads, latency-sensitive workloads suffered on average of only 4% increase in latency with the MRT guarantee enabled. This contrasts sharply with the 5-fold latency increase in the pinned experiment discussed earlier. CPU-hungry workloads saw their performance improve by 0.3%. This makes sense given the results in the preceding section, which showed that an MRT guarantee offers little value to batch jobs in a non-work-conserving setting.

To understand why the latency performance is so much better than our earlier results would suggest, we analyzed a trace of the scheduler's decisions. With the non-work-conserving setting, Xen naturally segregates batch and interactive workloads. When an interactive VCPU receives a request, it will migrate to an idle PCPU rather than preempt a PCPU running a batch VCPU. As the PCPU running interactive VCPUs is often idle, this leads to coalescing the interactive VCPUs on one or more PCPUs while the batch VCPUs share the remaining PCPUs.

5.5 Summary

Overall, our performance evaluation shows that the strong security benefits described the in Section 4 can be achieved at low cost in virtualized settings. Prior research suggests more complex defense mechanisms [22, 26, 28, 43, 47] that achieve similar low performance overheads but at a higher cost of adoption, such as sub-

stantial hardware changes or modifications to security-critical programs. In comparison, the MRT guarantee mechanism is simple and monotonically improves the security against many existing side-channel attacks with zero cost of adoption and low overhead.

We note that differences between hypervisor scheduling and OS scheduling mean that the MRT mechanism cannot be as easily applied by an operating system to defend against malicious processes. As mentioned above, a hypervisor schedules a small and relatively static number of VCPUS onto PCPUs. Thus, it is feasible to coalesce VCPUs with interactive behavior onto PCPUs separate from those running batch VCPUs. Furthermore, virtualized settings generally run with *share-based* scheduling, where each VM or VCPU is assigned a fixed share of CPU resources. In contrast, the OS scheduler must schedule an unbounded number of threads, often without assigned shares. Thus, there may be more oversubscription of PCPUs, which removes the idle time that allows interactive VCPUs to coalesce separately from batch VCPUs. As a result, other proposed defenses may still be applicable for non-virtualized systems, such as PaaS platforms that multiplex code from several customers within a single VM [2].

6 Integrating Core-State Cleansing

While the MRT mechanism was shown to be a cheap mitigation for protecting CPU-hungry workloads, it may not be effective at protecting interactive ones. If a (victim) VCPU yields the PCPU quickly, the MRT guarantee does not apply and an attacker may observe its residual state in the cache, branch predictor, or other hardware structures. We are unaware of any attacks targeting such interactive workloads, but that is no guarantee future attacks won't.

We investigate incorporating per-core state-cleansing into hypervisor scheduling. Here we are inspired in large part by the Düppel system [47], which was proposed as a method for guest operating systems to protect themselves by periodically cleansing a fraction of the L1 caches. We will see that by integrating a selective state-cleansing (SC) mechanism for I-cache, D-cache and branch predictor states into a scheduler that already enforces an MRT guarantee incurs much less overhead than one might expect. When used, our cleansing approach provides protection for all processes within a guest VM (unlike Düppel, which targeted particular processes).

6.1 Design and Implementation

We first discuss the cleansing process, and below discuss when to apply it. The cleanser works by executing a specially crafted sequence of instructions that together overwrite the I-cache, D-cache, and branch predictor states of a CPU core. A sample of these instructions is shown in Figure 17; these instructions are 27 bytes long and fit in a single I-cache line.

In order to overwrite the branch predictor or the Branch Target Buffer (BTB) state, a branch instruction conditioned over a random predicate in memory is used. There are memory move instructions that add noise to the D-cache state as well. The last instruction in the set jumps to an address that corresponds to the next way in the same I-cache set. This jump sequence is repeated until the last way in the I-cache set is accessed, at which point it is terminated with a `ret` instruction. These instructions and the random predicates are laid out in memory buffers that are equal to the size of the I-cache and D-cache, respectively. Each invocation of the cleansing mechanism randomly walks through these instructions to touch all I-cache sets, D-cache sets, and flush the BTB.

We now turn to how we have the scheduler decide when to schedule cleansing. There are several possibilities. The simplest strategy would be to check, when a VCPU wakes up, if the prior running VCPU was from another VM and did not use up its MRT. If so, then run the cleansing procedure before the incoming VCPU. We refer to this strategy as *Delayed-SC* because we defer cleansing until a VCPU wants to execute. This strategy guarantees to cleanse only when needed, but has the downside of potentially hurting latency-sensitive applications (since the cleanse has to run between receiving an interrupt and executing the VCPU). Another strategy is to check, when a VCPU relinquishes the PCPU before its MRT guarantee expires, whether the next VCPU to run is from another domain or if the PCPU will go idle. In either case, a cleansing occurs before the next VCPU or idle task runs. Note that we may do unnecessary cleansing here, because the VCPU that runs after idle may be from the same domain. We therefore refer to this strategy as *Optimistic-SC*, given its optimism that a cross-VM switch will occur after idle. This optimism may pay off because idle time can be used for cleansing.

Note that the CPU time spent in cleansing in Delayed-SC is accounted to the incoming VCPU but it is often free with Optimistic-SC as it uses idle time for cleansing when possible.

6.2 Evaluation

We focus our evaluation on latency-sensitive tasks: because we only cleanse when an MRT guarantee is not hit, CPU-hungry workloads will only be affected minimally by cleansing. Quantitatively the impact is similar to the results of Section 5 that show only slight degradation due to *Chatty-CProbe* on CPU-hungry workloads.

We use the hardware configuration shown in Figure 2.

```
000 <L13-0xd>:
  0: 8b 08           mov    (%rax),%ecx
  2: 85 c9           test   %ecx,%ecx
  4: 74 07           je     d <L13>
  6: 8b 08           mov    (%rax),%ecx
  8: 88 4d ff        mov    %cl,-0x1(%rbp)
  b: eb 05           jmp    12 <L14>

00d <L13>:
  d: 8b 08           mov    (%rax),%ecx
  f: 88 4d ff        mov    %cl,-0x1(%rbp)

012 <L14>:
 12: 48 8b 40 08     mov    0x8(%rax),%rax
 17: e9 e5 1f 00 00  jmpq   <next way in set>
```

Figure 17: **Instructions used to add noise.** The assembly code is shown using X86 GAS Syntax. `%rax` holds the address of the random predicate used in the `test` instruction at the relative address `0x2`. The moves in the basic blocks `<L13>` and `<L14>` reads the data in the buffer, which uses up the corresponding D-cache set.

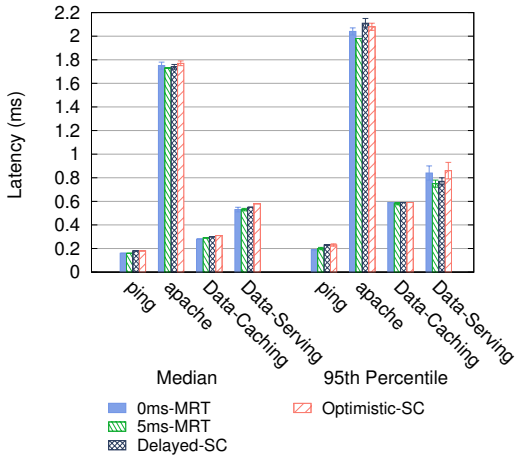

Figure 18: **Median and 95^{th} percentile latency impact of the cleansing scheduler under *worst-case* scenario.** Here all the measured workloads are feed by a client at 500 requests per second. The error bars show the standard deviation across 3 runs.

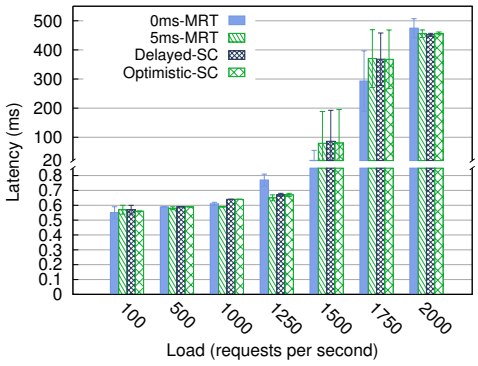
We measured the standalone, steady state execution time of the cleansing routine as 8.4 µs; all overhead beyond that is either due to additional cache misses that the workload experiences or slow down of the execution of the cleansing routine which might itself experience additional cache misses. To measure the overhead of the cleansing scheduler, we pinned two VCPUs of two different VMs to a single PCPU. We measured the performance of one of several latency-sensitive workloads running within one of these VMs, while the other VM ran a competing workload similar to *Chatty-CProbe* (but it did not access memory buffers when awoken). This ensured frequent cross-VM VCPU-switches simulating a worst case scenario for the cleansing scheduler.

We ran this experiment in four settings: no MRT guarantee (0ms-MRT), a 5 ms MRT guarantee (5ms-MRT), a 5 ms MRT with Delayed-SC, and finally a 5 ms MRT with Optimistic-SC. Figure 18 shows the median and 95^{th} percentile latencies under this experiment. The median latency increases between 10–50 µs compared to the 5ms-MRT baseline, while the 95^{th} percentile results are more variable, and show at worst a 100 µs increase in tail latency. For very fast workloads, like *Ping*, this results in a 17% latency increase despite the absolute overhead being small. Most of the overhead comes from reloading data into the cache, as only 1/3rd of the overhead is from executing the cleansing code.

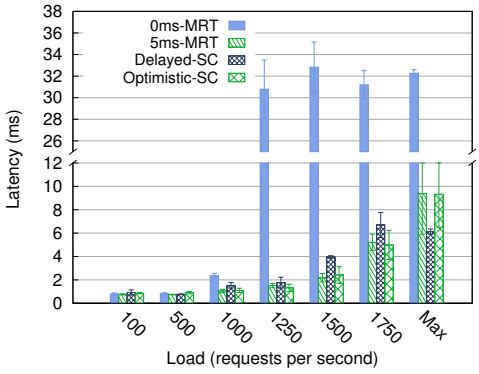
To measure overhead for non-adversarial workloads, we replaced the synthetic worst-case interactive workload with a moderately loaded Apache webserver (at 500 requests per second). The result of this experiment is not shown here as it looks almost identical to Figure 18, suggesting the choice of competing workload has relatively little impact on overheads. In this average-case scenario, we observed an overhead of 20–30 µs across all workloads for the *Delayed-SC* and 10–20 µs for *Optimistic-SC*, which is 10 µs faster. Note that in all the above cases, the cleansing mechanism perform better than the baseline of no MRT guarantee with no cleansing.

To further understand the trade-off between the two variations of state-cleansing, we repeated the first (worst-case) experiment above with varying load on the two latency-sensitive workloads, *Data-Caching* and *Data-Serving*. The 95^{th} percentile and median latencies of these workloads under varying loads are shown in Figure 19 and Figure 20, respectively. The offered load shown on the x-axis is equivalent to the load perceived at the server in all cases except for *Data-Serving* workload whose server throughput saturates at 1870rps (this is denoted as *Max* in the graph).

The results show that the two strategies perform similarly in most situations, with optimization benefiting in a few cases. In particular, we see that the 95% latency for heavier loads on *Data-Serving* (1250, 1500, and 1750) is significantly reduced for Optimistic-SC over Delayed-SC. It turned out that the use of idle-time for cleansing in Optimistic-SC was crucial for *Data-Serving* workload as the tens to hundreds of microsecond overhead of cleansing mechanism under the Delayed-SC scheme was enough to exhaust boost priority at higher loads. From scheduler traces of the runs with *Data-Serving* at 1500rps, we found that the VM running the *Data-Serving* workload spent 1.9s without boost priority under Delayed-SC compared to 0.8s and 1.1s spent under

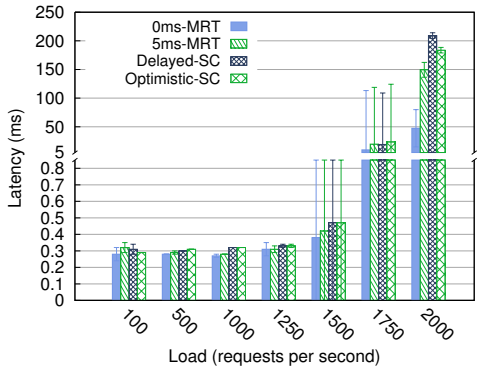


(a) *Data-Caching*

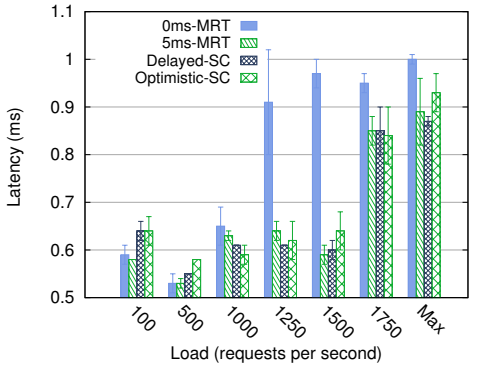


(b) *Data-Serving*

Figure 19: 95^{th} **percentile latency impact of the cleansing scheduler with varying load on the server.** (a) *Data-Caching* and (b) *Data-Serving*. The error bars show the standard deviation across 3 runs.



(a) *Data-Caching*



(b) *Data-Serving*

Figure 20: **Median latency impact of the cleansing scheduler with varying load on the servers.** (a) *Data-Caching* and (b) *Data-Serving*. The error bars show the standard deviation across 3 runs.

5ms-MRT and Optimistic-SC, respectively (over a 120 long second run). The *Data-Serving* VM also experienced 37% fewer wakeups under Delayed-SC relative to 5ms-MRT baseline, implying less interactivity.

We conclude that both strategies provide a high-performance mechanism for selectively cleansing, but that Optimistic-SC handles certain cases slightly better due to taking advantage of idle time.

7 Conclusions

Cloud computing promises improved efficiency, but opens up new threats due to the sharing of hardware across mutually distrustful customers. While virtual machine managers effectively prevent *direct access* to the data of other customers, current hardware platforms inherently leak information when that data is accessed through predictive structures such as caches and branch predictors.

We propose that the first line of defense against these attacks should be the software responsible for determining access: the hypervisor scheduler. For cache-based side channels, we showed that the simple mechanism of MRT guarantees can prevent useful information from being obtained via side-channel attacks that abuse per-core state. This suggests a high performance way of achieving soft isolation, which limits the frequency of potentially dangerous cross-VM interactions.

We also investigate how the classic defense technique of CPU state cleansing can interoperate productively with MRT guarantees. This provides added protection for interactive workloads at low cost, and takes advantage of the fact that the use of MRT makes rescheduling (each of which may require cleansing) rarer.

Finally we note that while the focus of our work was on side-channel attacks, the soft-isolation approach, and the mechanisms we consider in this paper in particular, should also be effective at mitigating other classes of shared-resource attacks. For example, resource-freeing [39] and on-system degradation-of-service attacks.

Acknowledgments

We thank Yinqian Zhang for sharing his thoughts on defenses against side-channel attacks and the code for the IPI-attacker that was used in the ZJRR attack. Preventing Cryptographic Key Leakage in Cloud Virtual Machines

Abstract

In a typical infrastructure-as-a-service cloud setting, different clients harness the cloud provider's services by executing virtual machines (VM). However, recent studies have shown that the cryptographic keys, the most crucial component in many of our daily used cryptographic protocols (e.g., SSL/TLS), can be extracted using cross-VM side-channel attacks. To defeat such a threat, this paper introduces HERMES, a new system that aims to protect the cryptographic keys in the cloud against any kind of cross-VM side-channel attacks by simply partitioning the cryptographic keys into random shares, and storing each share in a different VM. Moreover, it also periodically re-shares the cryptographic keys, thereby invalidating the potentially extracted partial ones. We have implemented HERMES as a library extension that is transparent to the application software, and performed deep case studies with a web and a mail server on Amazon EC2 cloud. Our experimental results show that the runtime overhead of the proposed system can be as low as 1%.

1 Introduction

Recent advances in cloud computing enable customers to outsource their computing tasks to the cloud service providers (CSPs). Typically, CSPs manage extensive amount of computational resources, and provide services, such as *Infrastructure-as-a-service* (IaaS) [40], *Platform-as-a-service* (PaaS) [31], *Software-as-a-service* (SaaS) [44]. By *outsourcing* core computing to the cloud, customers can mitigate the burden of resource management, and concentrate more on the core business tasks. A recent study on the cloud usage [3] reported that nearly 30% of enterprise IT organizations use public IaaS, such as Microsoft's Azure Service [12], Amazon's Elastic Compute Cloud (EC2) [4], or Google's Compute Engine [9].

Despite its numerous advantages, cloud computing also introduces new challenges and concerns, primarily the security and privacy risks [48]. The concerns simply stem from outsourcing critical data (e.g., health records, social security numbers, or even cryptographic keys) and/or computing capabilities to a distant computing environment, where the resources are shared with other potentially untrusted customers.

In particular, to increase efficiency and reduce costs, a CSP may place multiple *virtual machines* (VMs), belonging to different customers, to the same physical machine. In such an execution platform, VMs should be logically isolated from each other to protect the privacy of each client. The CSPs use *virtual machine monitors* (VMM) to realize logical isolation among VMs running on the same physical machine. However, recent studies show that a clever adversary can perform *cross-VM side-channel attacks* (for brevity, cross-VM attack) to learn private information that resides in another VM, even under carefully enforced logical isolation in public cloud infrastructures. More specifically, Ristenpart et al. [41] showed heuristics to improve an adversary's capabilities to place its VMs alongside the *victim* VMs, and learn crude information (e.g., aggregate cache usage). Most recently, Zhang et al. [51] managed to extract ElGamal decryption keys by cross-VM attacks. These studies have clearly demonstrated that logical isolation and trustworthy cloud provider are not necessarily enough to guarantee the security of sensitive information.

It would be too optimistic to assume that an adversary is only limited to the two aforementioned attacks. Unfortunately, there exists a wide variety of side-channel attacks, each with its own setup and methodology (e.g., [13–15, 19, 26, 28, 34, 43]). Simply, the absence of such attacks on public cloud infrastructures does not necessarily mean that they are inapplicable. In fact, there are side-channel attacks that target virtualized environments, and leverage timings of cryptographic operations or monitoring of common resource usage [39, 47]. Those attacks may be just one step behind being directly applicable to the public cloud setting; which is why proposing prevention mechanisms is extremely vital for the security and

privacy of the sensitive data in the VMs including the cryptographic keys.

To this end, we present HERMES, a system that remedies the cryptographic key disclosure vulnerabilities of VMs in the public cloud by using well-established cryptographic tools such as *Secret Sharing* and *Threshold Cryptography*. Specifically, the key technique in our system is to partition a cryptographic key into several pieces, which are computed using threshold cryptosystems, and to store each *share* on a different VM. This makes it harder for an adversary to capture the complete cryptographic key itself, since it now has to extract shares from multiple VMs (note that there is no single key or a centralized key anymore in HERMES). To further improve the resilience, the *same* cryptographic key is *re-shared* periodically, such that a share is *meaningful* in only one time period. Consequently, we introduce two significant challenges against a successful attack: (i) multiple VMs should be attacked, and (ii) each attack should succeed within a certain time period. As a proof-of-concept, we apply HERMES to protect the cryptographic keys of *Secure Sockets Layer* (SSL) and *Transport Layer Security* (TLS) protocols.

Contributions. In short, this paper makes the following four contributions:

1. We present HERMES, a novel system to prevent the leakage of cryptographic keys in cloud VMs via mathematically proven techniques – *Secret Sharing* and *Threshold Cryptography*.

2. As a proof-of-concept, we build a prototype of HERMES and apply it to protect the SSL/TLS cryptographic keys, which is significantly more resilient to any cross-VM attack.

3. We empirically evaluate HERMES with micro benchmarks, and case studies for a web server and a mail server, and show that with optimal setup, HERMES can operate with overheads as low as 1%.

4. We formalize the problem of finding *good* HERMES configurations, which minimizes the security risk for given monetary and performance constraints.

Organization. The rest of the paper is structured as follows: We start by providing some background information in §2 about the protocols and techniques used in HERMES. It is followed by the threat model in §3, and the full technical details of HERMES in §4. Then, we evaluate HERMES regarding its efficiency in §5, and discuss its security in §6. Finally, we review the related work in §7, and conclude in §8.

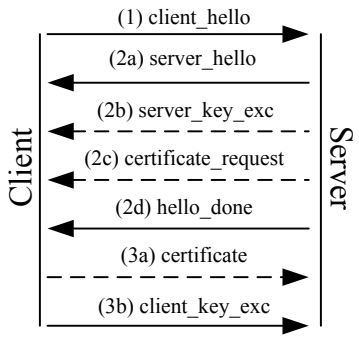

Figure 1: Overview of SSL Protocol Handshake.

2 Background

2.1 SSL/TLS Protocols

SSL and TLS are widely accepted communication protocols to establish a secure channel between two mutually-distrusting parties, where two protocols contain only a few minor differences [16, 25, 29, 37]. For brevity, we will refer the protocols as SSL; and any statement for SSL is also applicable to TLS.

The SSL protocol consists of a *handshake* and a *record* process, where the parties in the protocol are called the *client* and the *server*. In the handshake process, they use *public key cryptography* (PKC) to authenticate each other and agree on the session keys. The session keys are bound for only one session, and used for confidentiality and integrity. To calculate session keys, parties need to share a *master secret*, which is derived from random data exchanged, and *pre-master secret*.

Fig. 1 shows an overview of the handshake process. First, the client starts by sending *client_hello* message (**Step 1**), which contains a set of supported cryptographic algorithms (*cipher suites* in SSL terms), and some random data to be used in key generation. Then, the server sends its certificate, some random data, and the accepted cipher suite (**Step 2a**); and key exchange parameters if necessary (**Step 2b**). Moreover, if the server wants to authenticate the client, it requests the client's certificate (**Step 2c**). The server finishes by sending *hello_done* message (**Step 2d**). If requested, the client sends its certificate to the server, along with some random data signed by its private key (**Step 3a**). Next, it creates a random pre-master secret, encrypts it with the server's public key, and sends to the server (**Step 3b**). Now, both parties can calculate the master secret from the pre-master secret and random data using protocol specific combinations of pseudo-random functions.

Based on the chosen cipher suite, the number and the content of the messages may vary. For instance, when Diffie-Helman (DH) [22] is used for pre-master agree-

ment, the parties sign their DH parameters with their private keys, and send them in **Step 2b** and **Step 3b**. On the other hand, they may use RSA to agree on the pre-master secret, where the client encrypts the pre-master secret with the server's RSA public key, and the server decrypts it using its private key.

2.2 RSA Variants

The following variants of the RSA algorithm alter the way that a message is exponentiated with the private key. In both versions, the dealer holds a public-private RSA key pair, and wants to partition the private key over l non-colluding parties.

Distributed RSA (D-RSA). Given a private key d, D-RSA uses *additive secret sharing*, and partitions d into l random shares $d_1, \ldots, d_l$, where $d \equiv d_1 + \ldots + d_l \bmod \phi(n)$, n is the modulus, and ϕ is Euler's totient function. Given the public key (n, e) and a share, none of the parties can learn anything about d. Furthermore, an adversary should capture all l shares to learn d.

To exponentiate a message $M \in \mathbb{Z}_n$ with d, one of the parties acts as the *combiner*, whose job is to combine partial results from all parties. Each party p_i for $1 \leq i \leq l$ calculates M^{d_i}, and sends it to the combiner. Then, the combiner simply multiplies each message and finalizes the operation. At the end of the process, the combiner does not learn anything about the private key, but only the final result M^d. For a detailed security analysis, we refer to the original paper [24].

Threshold RSA (T-RSA). In this variant, the given private key is partitioned using *shamir secret sharing*, in which only $1 < k \leq l$ shares are needed to complete an exponentiation with d. The key technique in T-RSA is to embed the private key into a degree $(k-1)$ polynomial, evaluate the polynomial on l different points, and share the results over the set of parties. Once again, a party cannot learn the partitioned private key simply from the public key and its share.

To exponentiate a message, k parties are chosen uniformly at random, where the combiner once again does not learn anything other than M^d. On the other hand, an adversary should capture k shares to learn the private key. In App. B, we present more details on private key partitioning and usage, while an intensive security analysis is performed in the original paper [42].

3 Threat Model

Entities. The entities in our threat model are the *Cloud Service Provider* (CSP), the *Defender*, and the *Adversary*, where the last two are simply the clients of the first. The *CSP* offers IaaS and PaaS, which the clients can benefit by initiating VMs. The defender and the adversary use the same CSP, where the latter attacks the former to retrieve private information. Although the CSP has a potential to violate its clients' privacy and integrity, we assume that the CSP is trusted. This is a valid assumption, since (i) *Service Level Agreements* (SLA) provide a clear-cut distinction between what a CSP can and cannot perform on a client's data/VM, and (ii) disobeying a SLA may impose prohibiting punishment for the CSP.

Logical isolation. To improve utilization, the cloud provider may perform multiplexing. Hence, multiple VMs may run on the same physical machine, which means a VM of the adversary may run on the same physical machine with a VM of the defender; and they may share the same physical resources (e.g., CPU, memory, hard-drives, cache). On the other hand, we have no distinction on the VMM that the CSP uses, as long as it provides logical isolation between the VMs on the same physical machine. We assume that the adversary knows the software running on the defender VMs, but cannot leverage the memory vulnerabilities of those software to compromise (i.e., to take full control of) the VMs.

Adversary's goal. The defender has multiple VMs in the cloud, and each one may contain a set of private cryptographic information. This set of information includes temporary symmetric keys (e.g., AES key), or a share of a distributed private key (e.g., share of an RSA key) that is created by HERMES. An adversary's aim is to capture PKC keys, since capturing a session key is useful for only one session, while acquiring PKC keys grants full access. To fulfill its desire, the adversary is allowed to execute any cross-VM attack in its disposal to extract private information from each VM, where the attack itself is applicable to the cloud setup. For instance, in access-driven attacks, the adversary may need to co-reside its VMs with the defender VMs. In such a case, the adversary should achieve co-residency, and make the attack applicable in a typical cloud setup. Moreover, the attacks on the defender VMs are not necessarily executed in serial manner. Each separate adversary VM can employ the cross-VM attack in parallel, if the nature of the attack enables such setup.

Finally, since the adversary uses the same cloud as the defender, we assume that all channels may be eavesdropped by the adversary, starting from right after the bootstrapping of HERMES. Giving this capability to the adversary may seem like an overprovision. However, we take precautions to handle even the worst case scenario, in which the adversary, somehow by-passing CSP's security mechanisms, listens to the conversations between the defender VMs.

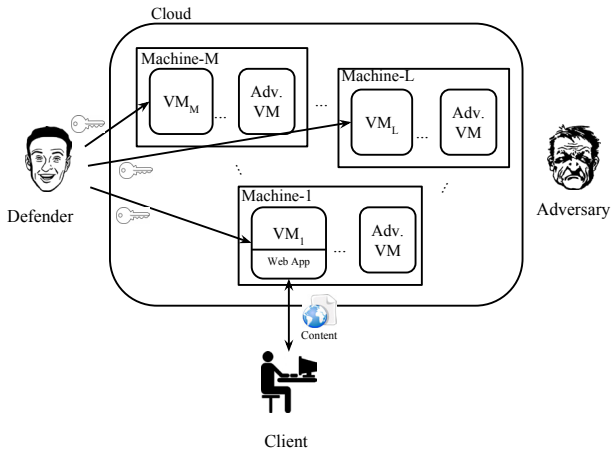

Figure 2: Overview of HERMES Layout.

Misc. We do not consider the placement of the defender VMs, and its effects on the security of HERMES. For instance, one platform (e.g., a region, a physical machine, etc.) may, somehow, be more susceptible to a certain range of cross-VM attacks; or one can claim that the more distributed the defender VMs, the better the security. Zhang et al. aim to physically isolate a defender VM as much as possible [50], thus preventing only access-driven side-channel attacks. Such precautions will tighten the defense against access-driven attacks; however, it will fail to stop the adversary from executing different attacks. On the other hand, HERMES aims to protect the cryptographic keys from all cross-VM attacks, no matter how the VMs are placed.

4 The Proposed System – HERMES

In SSL, a certificate may contain public parameters of different PKCs (e.g., RSA, DSA, ECC), which are employed to encrypt secret information, or to sign and show that certain temporary data is authentic. In HERMES, we assume that the parties use RSA as the PKC; however, extension to other PKCs is trivial as long as a threshold cryptosystem for that new PKC is provided.

Setup. Figure 2 shows an overview of the entities in HERMES: the defender, the adversary, l number of VMs that belong to the defender, and the clients who want to establish secure connection to the defender's VMs using SSL and benefit from the defender's web application. The defender holds a set of private RSA keys, and partitions them over the set of defender's VMs. Each VM holds one share for each partitioned private key, and they act together to exponentiate with it. The VM that directly talks with the client is called the *combiner*, while the remaining VMs are called *auxiliary VMs*. The adversary aims to learn at least one of the partitioned RSA private keys by (i) performing cross-VM attacks on each VM to capture its shares, and by (ii) listening each message flowing between the VMs. To achieve secure communication, each channel is established using our enhanced SSL protocol. More specifically, inter-VM channels are established with mutual verification (i.e., both end of the parties authenticate each other), while only the combiner VM is authenticated in a channel between that VM and a client/defender. The defender re-shares the same private keys every τ seconds. The time window between two consecutive re-sharing moments will be referred to as an *epoch*, while the shares of a private key in any two sessions are independent.

Modes. HERMES has two modes of operation, namely D-RSA and T-RSA modes, using the corresponding RSA variant (cf. §2.2). When the system runs in D-RSA mode, the adversary has to capture all shares of a private key to learn the key itself; whereas in T-RSA mode, it has to capture at least k shares. The benefits of the second mode are two-fold: (i) The system is more fault-tolerant to server failures, and (ii) the system can achieve better utilization by distributing work among different subsets of VMs, especially when $k \leq (l/2)$.

Stages. The execution of HERMES is composed of several stages: (i) Partitioning a private key (§4.2); (ii) Bootstrapping the system by handing in the initial set of shares, and establishing initial inter-VM SSL channels (§4.3); (iii) Establishing connection between a defender VM and a client (§4.4); (iv) Renegotiating an inter-VM SSL channel (§4.5); and (v) Distributing new shares of the same private keys (§4.6).

4.1 Enhancing the SSL Protocol

In SSL, the communicating parties may execute *mutual verification* or *server-only* verification. In any case, the server uses its private key at two possible steps (cf. Fig. 1): (i) After **Step 2a** to sign temporary parameters; (ii) after **Step 3b** to decrypt the pre-master secret. On the other hand, the client uses its private key before **Step 3a** only in the mutual verification. With respect to a regular SSL execution, we change the way that the server or client computes the modular exponentiation of a message with its RSA private key at those steps.

Fig. 3 shows the outline of our modifications in a server-only verified SSL execution. The client performs SSL handshake with the combiner, while the VMs communicate over already established secure channels. After **Step 2a**, the combiner may create temporary key parameters and sign them in collaboration with the auxiliary VMs. It sends a `help_sign` message to all auxiliary VMs in D-RSA mode (or up to k in T-RSA mode), where the

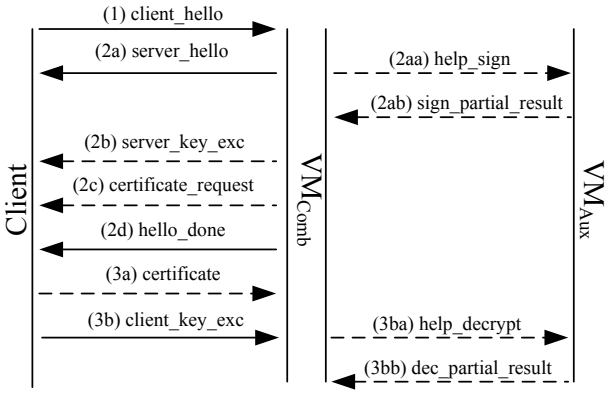

Figure 3: Security Enhanced SSL Outline for Server-only Verification.

message content is simply the parameters to be signed (**Step 2aa**). Each auxiliary VM in the computation calculates its partial result using its share of the private key and gives it to the combiner in the `sign_partial_result` message (**Step 2ab**). On the other hand, if the combiner has to decrypt an incoming message from the client, it sends a `help_decrypt` message to all auxiliary VMs in D-RSA mode (or up to k in T-RSA), containing the *masked* or plain version of the client's message (**Step 3ba**). Then, each auxiliary VM sends the computed partial result with the `dec_partial_result` message to the combiner (**Step 3bb**).

Whether or not the content of the `help_decrypt` message should be masked with a random number depends on the mode of operation. Even in the worst case, where the adversary knows each message exchanged between VMs, the combiner does not have to mask the message in D-RSA. The reason comes from the security of D-RSA. Assume the client sends $M^e \mod n$ to the combiner, where M is the pre-master secret, and (n,e) is the public key. In order to learn M, the adversary needs each VM's partial result, just like the combiner does. However, even if the adversary cracks down all secure channels and captures all messages, it can only learn $l-1$ parties' partial results, since the combiner does not send its partial result to anyone. Thus, the adversary cannot learn any useful information, and cannot compute M. If T-RSA is employed, then the combiner selects k VMs, $S = \{i_1, \ldots, i_k\}$, uniformly at random from the set of VMs and sends the message to them. There are two cases to consider: (i) If the combiner is included in S, then the message does not need masking similar to D-RSA case. The adversary needs k partial results, but can only capture $k-1$. (ii) Otherwise, the combiner masks the message with a random number; since the adversary may have captured k partial results sent from k different auxiliary VMs, and the other parameters in the calculation are public (e.g., $\Delta = l!$, a and b can be calculated from $gcd(e, 4\Delta^2)$), the adversary can now calculate M.

In addition to server-only verified SSL channels, HERMES necessitates mutual verification, since any two defender VMs, VM_i and VM_j, may perform key renegotiation to refresh session keys. Without loss of generality, assume that VM_i is the client in SSL protocol, while VM_j acts as the server. Now, both parties should communicate with the auxiliary VMs to perform operation with their own private keys. The server may need co-operation after steps **2a** and **3b**, while the client may need to sign random data with its private key before **Step 3a**. The server acts as mentioned in server-only authenticated Enhanced SSL. On the other hand, the client sends `help_sign` message to auxiliary VMs before **Step 3a**, and combines the partial results. By following those steps, two defender VMs can execute a successful handshaking process, using already established secure and authenticated SSL channels with the auxiliary VMs.

4.2 Partitioning Keys

Given an RSA key pair (n,e,d) and the number of VMs l, the defender performs partitioning and calculates the shares of each defender's VM. In case HERMES is running in T-RSA mode, the defender uses the third parameter k, minimum number of VMs needed to operate.

In D-RSA, the share of the i^{th} VM, denoted by sh_i, is simply a uniformly randomly chosen value from the domain $\mathbb{Z}_{\phi(n)}$, where $sh_1 + \ldots + sh_l$ is equal to d. Hence, the defender chooses $l-1$ random values, and calculates the final share as $sh_l = d - (sh_1 + \ldots + sh_{l-1}) \mod \phi(n)$.

On the contrary, key partitioning process is a bit more complicated in T-RSA. Algo. 1 shows an outline of preparations of each VM's share. For each subset $S_\alpha \subseteq \{1, \ldots, l\}$, where $|S_\alpha| = k$, the defender calculates the interpolation constants $\lambda_{0,j}^{S_\alpha}$, and exponents for each $VM_j \in S_\alpha$ (line 10-16). Moreover, the defender stores the modulus values for a, b in V_i's share for d, since i (the function input) states that the given private key belongs to VM_i (line 18-19).

4.3 Bootstrapping the System

The defender creates l VM instances on the CSP, and an RSA key pair (n_i, e_i, d_i) for each VM_i, $1 \le i \le l$. Next, she partitions each private key into shares and gives each VM a unique ID $i \in [1,l]$, the shares that correspond to that ID, and the certificate for the i^{th} RSA key pair.

At this stage, the VMs need to establish initial authenticated and secure SSL channels using our Enhanced SSL. However, as mentioned in §4.1, Enhanced SSL necessitates already established secure SSL channels to transfer messages between VMs. We have to make an assumption here, which will allow us to bypass this requirement, and

Algorithm 1 Preparing shares for T-RSA

Input: RSA Parameters n, $p = 2p' + 1$, $q = 2q' + 1$, e, d

    $sh_j \leftarrow \emptyset$
end for
$\Delta \leftarrow l!$
Calculate $S = \{S_1, \ldots, S_z\}$, where $z = \binom{l}{k}$, $\forall S_j \in S, |S_j| = k$, $S_j \subseteq \{1, \ldots, l\}$, and each S_j is distinct
$m = \phi(n)/4$
Create $f(X) = d + \sum_{j=1}^{k-1} a_j X^j$, where $\forall a_j \xleftarrow{R} \mathbb{Z}$
for all $S_\alpha \in S$ **do**
    for all $j \in S_\alpha$ **do**
        Calculate $\lambda_{0,j}^{S_\alpha}$
        $exp \leftarrow 4 \cdot \Delta \cdot f(j) \cdot \lambda_{0,j}^{S_\alpha} \bmod m$
        $sh_j \leftarrow sh_j \cup (i, S_\alpha, exp)$
    end for
end for
$(a, b) \leftarrow ecgd(e, 4\Delta^2)$, where $a4\Delta^2 + be = 1$
$sh_i \leftarrow sh_i \cup (a \bmod m, b \bmod m)$
return $sh_1, \ldots, sh_l$

to establish initial inter-VM SSL channels. We assume that the VMs, and the initial set of SSL channels are provisioned securely, i.e., no adversarial attack occurs until the initial set of SSL channels are established for inter-VM communications. This is a reasonable assumption, since (i) locating defender VMs on the cloud takes time [41], and (ii) the whole process of bootstrapping takes short time, especially if key-partitioning is performed beforehand. Once the initial inter-VM SSL channels are established, HERMES gets ready to serve the clients. Note that a defender VM uses the same RSA key pair for inter-VM and client connections.

Finally, in HERMES, we assume that the number of VMs is fixed throughout the entire life-time of execution. However, to augment HERMES capabilities with dynamic expansion of the system, one should care about the bootstrapping of those new VMs in terms of planting the initial secrets and initiating secure channels. As will be clear in §4.6, during the key re-sharing process, the defender may hand in secret shares to the newly added VMs. Still, introducing dynamic expansion via new VMs may lead to security vulnerabilities that should be investigated thoroughly.

4.4 Connecting to a Client

Once the bootstrapping stage is over, a client or the defender may request connection to a defender VM (i) to consume the services offered by the defender, or (ii) to distribute new shares for the private keys. In any case, the connection is established using server-only verified Enhanced SSL, where the connected VM takes the role of the combiner VM.

Assume the client wishes to connect to VM_i using Enhanced SSL. Throughout the handshaking process, VM_i interacts with the auxiliary VMs (i.e., all VMs other than VM_i), and performs distributed signing or decryption procedures as described in §4.1. The whole distributed operations are transparent to the client, while the combiner or any auxiliary VM learns nothing, but the result.

4.5 Inter-VM Key Renegotiation

Over time, any two defender VMs may decide to end one SSL session, and renegotiate keys for the next one. In such a case, those two VMs use their RSA key pairs, and perform a new handshaking process using our Enhanced SSL with mutual verification. Assume VM_i and VM_j decides to perform renegotiation, where VM_i and VM_j act as the client and server, respectively. Both VMs execute our Enhanced SSL handshaking process using already established SSL channels with the auxiliary VMs. When VM_i or VM_j needs to perform exponentiation with its private key, it collaborates with the auxiliary VMs, and calculates the result.

HERMES allows only one simultaneous key renegotiation at a given time, since an on-going process necessitates already established SSL channels. When two defender VMs start the process, it issues a warning to all VMs, blocking any other attempt for key renegotiation. Once the on-going procedure halts, HERMES removes the warning and allows the first renegotiation attempt.

4.6 Key Re-sharing

At the end of each epoch, the defender creates new shares for the same private RSA keys that were partitioned and distributed in the bootstrapping stage. In essence, it uses the key-partitioning algorithm discussed in §4.2 and generates shares that are independent from the previous ones. Then, it simply connects to each defender VM with our Enhanced SSL, as in §4.4, and hands in the new shares for all partitioned private keys.

The reason to adhere such a process is to mitigate the risk of private key disclosure, since the adversary may have already captured a set of shares for a partitioned private key. It is obvious that partitioning the same key for the second time will result in a different set of shares, which are totally independent from the previous. Hence, if the adversary did not capture enough shares to identify the exact key in one epoch, it will have to start from scratch, since those captured shares mean nothing in the next

epoch. The defender VMs do not immediately start using the new keys, since each defender should get the new shares, otherwise HERMES would have synchronization problems. Instead, a defender VM broadcasts a message to announce that it has the new shares. When all defender VMs have the new shares, they pass on to the next epoch, start using the new shares, and zeroise the old shares to leave no trace. Till then, the VMs continue using the *old* epoch shares.

5 Evaluation

We have implemented a prototype of HERMES atop the most commonly used open source SSL library, OpenSSL [10] v1.0.1e, the latest version as of this writing. Our implementation is a separate *shared library* compatible with the OpenSSL's *Engine API*. Without changing the OpenSSL source, programmers can plug-in our implementation and vary the way that RSA computations are performed with the private key. Meanwhile, we have also created multi-threaded applications (i) for the auxiliary VMs to establish SSL connections with the combiner VM, and to perform mathematical operations (e.g., exponentiation with the private key share); (ii) for the defender to partition the RSA private keys and hand in the shares to each defender VM. In this section, we present our evaluation result.

5.1 Experiment Setup

Case Studies. As it is challenging to exhaustively test HERMES with all the network benchmarks, we evaluated our system using a micro benchmark to profile the performance, and two representative case studies, in which SSL connection is necessary. The micro benchmark experiments evaluate the performance under varying system setups to target possible bottlenecks. Once the system dynamics are profiled, we execute two real-life case studies and check any efficiency deficits. The first case study is a web server, for which we used Apache HTTP Server [7] v2.4.4. A client connects to the server via HTTPS, and retrieves the default web page that comes with the application, which is a static HTML page of size $2KB$. The second case study is a mail server using Postfix v2.10 [11]. On top of that, we installed Dovecot [8] v2.2.4 as the IMAP(s)/POP3(s) server. A client connects to the Dovecot instance via IMAPS and checks the status of a mailbox, which contains a single mail of size $1KB$. Both server applications are executed with the *keep alive* property off (i.e., the server does not store SSL sessions, and performs a new handshake for every connection attempt by the clients).

One may argue that testing the web and mail servers with such low-sized content is applicable to real-world case. It is true that almost all web sites serve contents that may have much larger sizes. However, the purpose of the experiments is to put as much pressure as possible to HERMES in the given web and mail server case studies. As will be clear in the results, as the number of connections performed per unit time increases, HERMES acts more efficiently due to decreased network overhead. Hence, increasing the content sizes would increase the amount of time the server spends on processing a query, and decrease the number of requests per unit time. Instead, we used 1 and 2KB contents, and tried pushing HERMES as much as possible.

Benchmarks. To extract micro benchmark results, we developed applications that connect to the given defender VM, using given number of concurrent clients. For the web server application, we used two different benchmarking tools: Apache HTTP server benchmarking tool [5] (AB) v2.4.4, which allows us to send HTTPS queries with a variety of execution options; and Apache JMeter [6] (AJ) v2.9, where we used the default HTTPS request sampler that comes with the standard AJ binaries. For the mail server application, we used AJ again, with the default mail reader sampler. Similar to the server-side, we

did not use the keep alive functionality in the benchmarking tools, which forces the clients to perform a new SSL handshaking for each request.

Hardware. For our experiments, we created 10 VM instances on Amazon EC2. The VM that serves that is augmented with the web and mail server applications is of the type *m1.xlarge* with 4 virtual CPU and 15GB of RAM. The remaining VMs are of the type *m1.small* with 1 virtual CPU, 1 virtual core, 1.7GB of RAM, and 64-bit Red Hat Enterprise Linux 6.4. The reason that we don't perform experiments with more number of VMs is that our results for 10 VMs are enough to extrapolate relations between HERMES modes, parameters (e.g., l, k, τ), and the performance metrics (e.g., average latency, throughput). All instances are created in the same EC2 region, US-West at Oregon. The instances communicate with each other over Amazon's private network, while a client or the defender interacts with the VMs over the public network. On the other hand, we used a single machine to send connection, web page, or mail check queries, where the machine is an IBM x3500m3 server with 16GB of RAM, and 4 quad-core CPUs at 2.4 GHz. Our client machine is located in our university campus, and is connected to the defender VMs over the Internet.

Parameters. We vary the number of concurrent clients from 1 to 1000 exponentially to observe the effects of increasing load on HERMES. We believe that the number 1000 is enough, since the number of web page views for most popular web sites goes up to 37 billion per year, which is approximately 1100 per second [1,2]. Each experiment ran for 5 minutes, and the average value of 5 runs is shown as the final result. As will be shown in the following subsection, we observe that a key re-sharing process takes approximately 50 *msec*. Combined with the observation that the average time to process a query may go up to 2 *sec*, we vary τ (i.e., the key re-sharing period) from 5 to 125 seconds.

We perform experiments using 10 VMs, and represent the setup as (l,k), where l is the number of active VMs, and k is the number of shares needed to calculate the RSA result. When l is equal to k, the system runs with D-RSA mode of operation using l VMs. Furthermore, $(1,1)$ represents the **single VM setup**, where the *default SSL (i.e., the one without our modification and there is only one key)* is used. Also, as l must be greater than or equal to k, it is important to note that we do not have any experiment set up of (l,k) where $l < k$.

5.2 Results

Micro Benchmarking. In this set of experiments, we aimed to observe the sole effects of HERMES on the performance, where the client simply connects to the combiner VM, and immediately closes the SSL channel, without sending any additional query. Naturally, we expected to observe a massive load on the combiner VM, since all it does is to establish SSL channel with the client using our enhanced SSL, and nothing else. Thus, the number of requests per unit time will be high, which will introduce an increased network overhead.

Table 1 shows the micro benchmark results for D-RSA with up to 10 VMs (e.g., $l = 10$). We vary the number of concurrent clients from 1 to 1000, and measure the average connection time, average time spent for inter-VM communication, and average time spent for combining partial results in milliseconds. It is observed that combining partial results from the auxiliary VMs do not incur more than 3 *msec* overhead; thus, does not affect a successful enhanced SSL connection in terms of efficiency. The reason is the simplicity of combining partial results (i.e., l modular multiplication). On the other hand, inter-VM communication dominates the overhead introduced by the enhanced SSL in D-RSA mode. Especially when the number of concurrent clients is 1000, average time required to execute an SSL connection exceeds 1 *sec* if $l > 7$. Thus, the network communication becomes the bot-

Table 3: Average Connection, Network, and Combining Time Spent for Fixed $k = 2$ in milliseconds.

tleneck for D-RSA in high load, in case the combiner VM closes the connection right after a successful connection. In the results for our case studies, we observe that if the combiner has to process a request (e.g., prepare a web page, or check a mailbox) after a successful SSL connection, the network overhead decreases, which results in less average latency.

As previously mentioned, we introduce T-RSA mode to reduce the overhead by simply distributing work amongst different sets of VMs. Given the performance of 10 VMs in D-RSA mode, we check if the performance can be improved in T-RSA mode by reducing k (i.e., the number of needed VMs). Table 2 shows the results for a fixed $l = 10$ and varying number of k values. Furthermore, we perform experiments to observe the effect of increasing number of VMs for a fixed $k = 2$, and show the results in Table 3. The performance metrics and the client parameters are the same as in Table 1. It is observed that for a fixed l value, the average latency to complete an enhanced SSL connection drops down as k gets smaller, especially when $k \leq (l/2)$. The reason is that different sets of auxiliary VMs are consulted to complete a single SSL connection each time, which results in less network connection overhead. Hence, per each inter-VM connection, we observe less load, resulting up to 3 times better performance than D-RSA mode with same l value (e.g., between $(10,10)$ and $(10,2)$). On the other hand, it is still reasonable to pass to T-RSA, even if $k > (l/2)$, since decreasing k has, definitely, positive effects on the performance. For a fixed k value, increasing l by introducing new defender VMs has positive effects on the average time to complete an enhanced SSL connection, by simply reducing the inter-VM communication overhead. The value of k, indeed, affects the number of VMs that should be introduced to reduce the average completion time. We extrapolate that introducing nearly $2k$ new VMs into HERMES helps decreasing the overhead by nearly 50%. To solidify our derivations, we performed the same T-RSA experiments for different fixed values of k and l. For brevity, we moved the results of those experiments to App. A, from which the same observations can be easily made.

Key re-sharing time (*msec*)					
l	*Avg.Lat.*	l	*Avg.Lat.*	l	*Avg.Lat.*
2	17.59	5	37.89	8	54.64
3	23.60	6	43.65	9	57.34
4	29.51	7	49.82	10	61.28

Table 4: Average Completion Time for Key Re-sharing in milliseconds.

We, further, measured the average time of completion for a single key re-sharing process for varying number of defender VMs. Since, the number of connections that the defender has to do in the re-sharing process depends on l, but not on k, we performed the experiments in D-RSA mode with l number of VMs. Table 4 shows the results, where the defender re-shares the same partitioned keys every 5 seconds, and no other client attempts to connect to the VMs. The experiments ran for 5 minutes, and the average time to complete a single key re-sharing is calculated. We observe that the average time increases with the number of VMs, since the defender has to connect each VM separately, incurring additional inter-VM communication overhead. We see that the values in Table 4 coincides with the values in Table 1. When l is equal to 10, the defender has to make 10 simultaneous connections to HERMES, resulting a similar result as 10 clients D-RSA for the setup $(10,10)$. In case of high load (e.g., 1000 clients), the key re-sharing process would, definitely, take longer time. Thus, the optimal τ value for the key re-sharing epoch should be chosen while considering the server load, and the number of defender VMs.

Web Server. In our first case study, our aim is to show that the performance improves as the combiner executes a CPU intensive operation (e.g., prepare a web page) once connected to the client. The experimental setup is the same as the micro benchmarking setup, except now the combiner VM is a web server. When a client employs

SSL to connect to the combiner VM and retrieve a web page, the combiner VM collaborates with the auxiliary VMs, and executes our enhanced SSL.

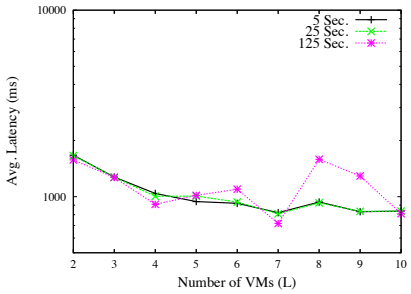
Fig. 4a and 4d show the results for HERMES in D-RSA mode, where the number of VMs changes from 1 to 10, and the number of concurrent clients changes between 1 to 1000 for τ of 125 *sec*. We use AB and AJ benchmarking tools, run the experiments for 5 minutes, and report the average time needed to execute a web page retrieval request, and the number of requests per second. We observe similar performance patterns for both of our metrics (e.g., performance decrease when l is increased) in compare to the micro benchmarks. However, the performance difference between the two end points (i.e., between $(1,1)$ and $(10,10)$) is narrower, due to more CPU-intensive processing done by the combiner. For 1000 concurrent clients, average latency and throughput in $(1,1)$ is 740 *msec* and 255 req/sec, respectively. On the other hand, the $(10,10)$ setup results in nearly 2 *sec* average latency, and 120 req/sec throughput. Compared to nearly 10 times increase in the micro benchmarking results, we see that the more CPU-intensive job the server does, the closer the gap between the $(1,1)$ and $(10,10)$ setups is.

Once again, we check if the performance can be boosted by passing to T-RSA mode, with decreased number of needed VMs. Fig. 4b and 4e show the results for fixed $l = 10$ and $\tau = 125$ *sec*. We observe that especially when $k \leq (l/2)$, the overhead reduces down to nearly 10% with respect to $(1,1)$ setup. For instance, in the $(10,5)$ setup, the average latency is 1088 ms, while the throughput is 220 req/sec. Even better, the throughput increases to 248 in $(10,3)$ setup, and to 250 in $(10,2)$ setup, which is just 2% less than $(1,1)$. The reason stems from distributing workload to more VMs by keeping seperate parts of the network busy at the same time, which reduces the inter-VM communication overhead.

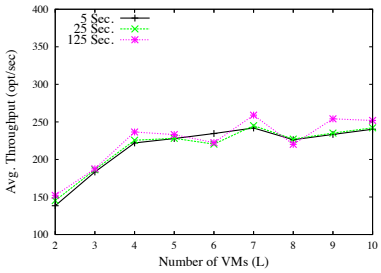
We remark that the results are gathered using the second *slowest* VM instances in Amazon EC2. The defender can instantiate stronger VM instances, with faster network, which will definitely improve the performance, since the network latency turns out to be the bottleneck. Furthermore, the defender can distribute the combiner role to multiple VMs to achieve further workload distribution.

The next results for the web server case study are given in Fig. 4c and 4f, where we measure the performance for varying l parameter and a fixed $k = 2$. We observe that having $l > 2k$ boosts the performance. Even in the $(4,2)$ setup, we measure that the average latency and throughput is 909 *msec* and 236 req/sec, respectively, which means less than 10% overhead for the second metric. When the number of VMs is more than $3k$, HERMES performs nearly the same as the $(1,1)$ setup.

To show that our choice of $\tau = 125$ *sec* does not have major effects on the overall performance, we vary the length of an epoch exponentially from 5 to 125 *sec* for different number of VMs, and fixed number of concurrent clients of 1000. We chose to execute epoch experiments for the fastest HERMES setup, namely fixed k with high l values, and to check if performance degradation occurs for decreased key re-sharing period. Fig. 5 shows the results for fixed $k = 2$ and 1000 concurrent clients, and varying τ values. We observe that even when $\tau = 5$ *sec*, the performance metrics behave similar to $\tau = 125$ *sec* case. This stems from the server being already loaded with enough concurrent clients, so that the seldom requests to re-share keys are only minor issues that does not take too much time to process.



(a) Avg. Latency for Epoch Times



(b) Avg. Throughput for Epoch Times

Figure 5: Web Server results for $k = 2$ with varying τ

Mail Server. Mail Server is our second case study, where the clients establish connection using SSL via IMAPS protocol, and check a mailbox that contains a single mail. The default setting with regular SSL (i.e., $(1,1)$ setup) already results in an average 5758 *ms* latency, and 49.5 req/sec for 1000 concurrent clients. Hence, the combiner has to do more CPU-intensive operation for each client request. We claim that the margin between $(1,1)$ and $(10,10)$ setups will be less, since the network will be less occupied at a given time; thus, it will result in less inter-VM communication overhead.

Fig. 6 shows the results for the mail server case study, where the clients vary from 1 to 1000, and re-sharing period is 125 *sec*. First of all, we observe that the performance of each setup looks very similar, with nearly at most 8% overhead with respect to $(1,1)$. The reason to

(d) Avg. Throughput for D-RSA (e) Avg. Throughput for $l = 10$ (f) Avg. Throughput for $k = 2$

Figure 4: Web Server results

observe such a pattern is, as hypothesized, the fact that an average mail inquiry takes too much time to process. It causes low throughput values, resulting less number of SSL handshakes being made per unit time, which in turn causes less inter-VM communication overhead.

Once more, we observe that increasing the number of VMs for D-RSA mode has negative effects on the performance metrics, as shown in Fig. 6a and 6d. On the contrary, increasing l for fixed k value in T-RSA mode enhances the overall performance, due to better distribution of the defender VMs, as seen in Fig. 6c and 6f.

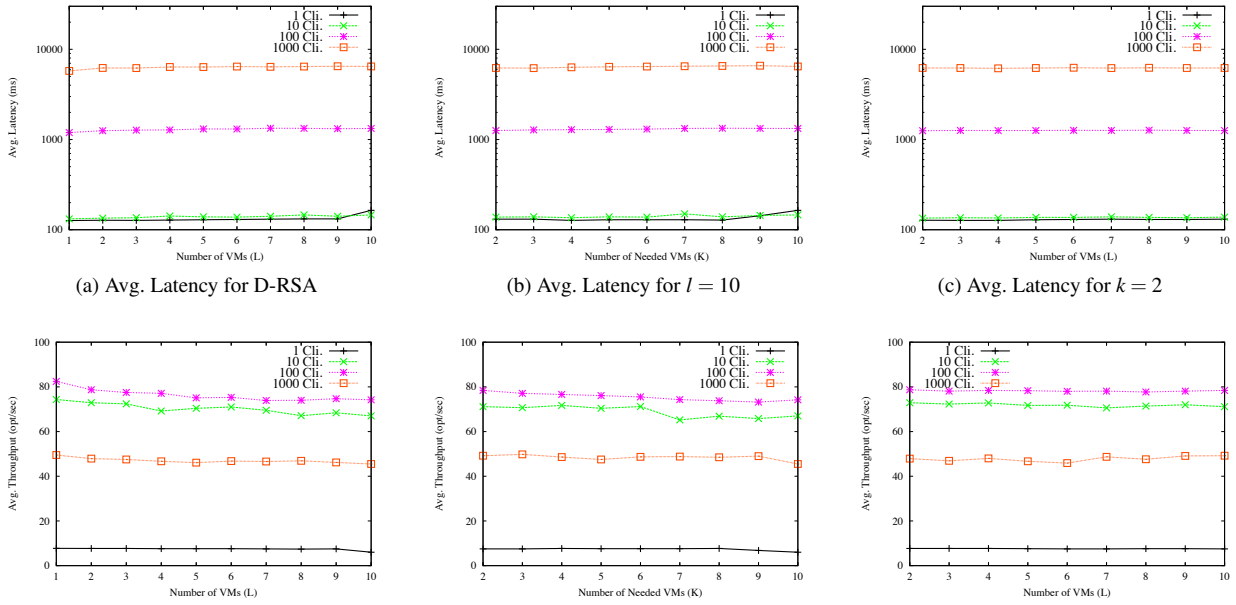
6 Security Analysis

The theoretical security of HERMES is based on the formally proven security of D-RSA and T-RSA, as discussed in §2.2. Combined with key re-sharing, the adversary should successfully capture at least l shares in D-RSA or k in T-RSA to calculate the shared cryptographic key. On the other hand, in practice, HERMES should give guarantees on the probability of a successful attack based on some assumptions on the nature of the attack and the system parameters (e.g., τ, l, k). The defender may have limited budget, or have certain performance requirements. In any case, HERMES must minimize any security risk by choosing l, k, and τ *optimally*. In this section, we first formalize the problem of finding such *optimal* values for those parameters, and then apply the optimization technique to a sample configuration: the micro benchmarking scenario discussed in §5. Our choice to apply optimization to only one configuration is due to space constraints; however, our approach is modular, and is easily applicable to any other cases.

6.1 Problem Formalization

In our formalization, we consider three main aspects: security, cost, and performance. Security aspect allows us to provide an upper bound on the possibility of a successful key extraction attack on HERMES for the given k, l, and τ values. Theoretically, increasing k and l, or decreasing τ will make it harder for the adversary to achieve its goal. However, increasing l implies more defender VMs running on the cloud, which increases the total cost. Moreover, our experiments showed that the performance degrades as l and k increase together. Hence, the optimal values should be assigned to k, l, τ for the given constraints (e.g., budget, performance limit).

Security Aspect. To quantify the probability of a successful attack in an epoch, we assume that the adversary has to start from scratch in each epoch, which implies that it loses all its previously acquired information. This is a valid assumption, since shares for each epoch are independent from one another, and a captured share does not contribute any information to the next epoch. The inability of conducting acquired information to the following epochs makes it convincing to model the probability of a successful attack as an *exponentially distributed* ran-



(a) Avg. Latency for D-RSA (b) Avg. Latency for $l = 10$ (c) Avg. Latency for $k = 2$

(d) Avg. Throughput for D-RSA (e) Avg. Throughput for $l = 10$ (f) Avg. Throughput for $k = 2$

Figure 6: Mail Server results

dom variable. Given the success rate parameter θ, the probability distribution for the attack is:

$$f(t) = \begin{cases} \frac{1}{\theta} e^{-t/\theta} & \text{if } t > 0 \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

Since the exponential distribution is *memoryless*[1] and the cryptographic key is re-shared in each epoch, we can simply assume that the input to f is the time difference from the last re-sharing moment. Then, given the length of the epoch τ, the probability of a successful attack is:

$$F(\tau, \theta) = \int_0^{\tau} f(t).dt = 1 - e^{-\tau/\theta} \quad (2)$$

Finally, assuming that the probability of capturing shares from a single VM is identical to and independent from all other VMs, the probability of capturing at least k shares from l defender VMs in an epoch is:

$$Sec(l, k, \tau, \theta) = \sum_{i=k}^{l} \binom{l}{i} (1 - e^{-\tau/\theta})^i (e^{-\tau/\theta})^{l-i} \quad (3)$$

Cost Aspect. Modeling monetary cost in HERMES is rather simple compared to the other two aspects. Assuming that the cloud provider does not charge money for the inter-VM communications, the total monetary cost is $Cost(l) = l.\beta$, where β is the unit cost of running a single VM on the cloud provider. The cost of communication with the client is also neglected, since this is not an additional cost incurred by HERMES.

Performance Aspect. The method to formalize the expected performance depends heavily on the application that HERMES is running for, and the metrics that the defender considers. For instance, one may value throughput more than the latency while running HERMES. On the other hand, the effects of changing parameters (i.e., k, l) in the mail server case study is far different than changing the same parameters in the micro benchmarking experiments. For brevity, we show the performance of HERMES for the given k and l as $Perf(l,k)$, and leave it to the defender to define the characteristics of the function.

Optimization Problem. Given the success rate parameter θ, the unit cost of a VM β, the budget limit L_{cost}, and the performance limit L_{perf}, the aim of the optimization problem is to minimize the probability of a successful attack in an epoch while keeping the total monetary cost below L_{cost} and the performance below L_{perf}. Formally, the optimization problem is:

$$\begin{aligned} \text{minimize:} \quad & Sec(l, k, \tau, \theta) \\ \text{subject to:} \quad & Cost(l) \leq L_{cost}, Perf(l,k) \leq L_{perf} \\ & l \geq k > 1, \tau > 0 \end{aligned}$$

6.2 Application to Micro Benchmarking

Modeling performance is highly dependent on the case study and the aimed configuration, thus it is challenging to apply the optimization to every single case. Instead, we targeted to optimize HERMES for 100 concurrent clients

	$\theta = 600$		$\theta = 3600$	
L_{cost}/yr	Conf.	Sec()	Conf.	Sec()
\$1820	$(2,2)$	$6.8 \cdot 10^{-5}$	$(2,2)$	$1.9 \cdot 10^{-6}$
\$3640	$(4,3)$	$2.2 \cdot 10^{-6}$	$(4,3)$	$3.7 \cdot 10^{-8}$
\$7280	$(8,5)$	$2.1 \cdot 10^{-9}$	$(8,5)$	$2.8 \cdot 10^{-13}$
\$14560	$(16,10)$	$1.1 \cdot 10^{-17}$	$(16,10)$	$2.1 \cdot 10^{-25}$

Table 5: Optimal setup and resulting successful attack probabilities in an epoch for fixed expected latency limit $L_{perf} = 150$ *msec*, and $\theta = \{600, 3600\}$

	$\theta = 600$		$\theta = 3600$	
L_{perf}	Conf.	Sec()	Conf.	Sec()
50 *msec*	$(16,6)$	$2.4 \cdot 10^{-9}$	$(16,6)$	$5.6 \cdot 10^{-14}$
100 *msec*	$(16,8)$	$2.7 \cdot 10^{-13}$	$(16,8)$	$1.7 \cdot 10^{-19}$
150 *msec*	$(16,10)$	$1.1 \cdot 10^{-17}$	$(16,10)$	$2.1 \cdot 10^{-25}$
200 *msec*	$(16,11)$	$5.4 \cdot 10^{-20}$	$(15,11)$	$4.9 \cdot 10^{-29}$

Table 6: Optimal setup and resulting successful attack probabilities in an epoch for fixed monetary budget $L_{cost} = \$14560/yr$, and $\theta = \{600, 3600\}$

in the micro benchmarking scenario, since all experiment results for the chosen configuration are given in §5.2 and App. B. For brevity, we make a further assignment of parameters by choosing re-sharing period as $\tau = 5$ *sec* and success rate parameter as $\theta = 3600$. $\tau = 5$ *sec* is the smallest value that we have tested, and is a valid value that allows HERMES to complete several computations in each epoch. Furthermore, choosing small re-sharing period will tighten the overall security, since the adversary has to complete the attack in a very short period. On the other hand, choosing θ as 3600 is due to the existing cross-VM attacks (i.e., [41, 51]), which necessitates hours to capture the cryptographic key. In an exponential distribution, expected *waiting time* to observe one success is θ. Since, we expect the attack to succeed in an hour, we assign $\theta = 3600$, representing the number of seconds in an hour. In addition, we check $\theta = 600$ to observe changes in optimal values.

In this example, we picked latency as the target performance metric to consider, assuming that the defender aimed to serve 100 concurrent clients as fast as possible. The important step to model performance is to figure out $Perf(l,k)$. To overcome this, we applied *multiple linear regression* on our experiment results, and came up with a formula that gives the *expected* latency value for the given l and k values. As it is challenging to test every possible formula, and increasing the number of variables may over-fit the training data, we chose a simple polynomial $Perf(l,k) = c_0 + c_1.l + c_2.k + c_3.(l/k)$ to model the expected latency, where the coefficients are $c_0 = 118$, $c_1 = -18$, $c_2 = 31$, and $c_3 = 7$. Finally, to observe the effects of different performance limits L_{perf}, we calculated optimal HERMES setups for $L_{perf} \in [50, 200]$. Finally, assuming that the defender will use the second cheapest VM instance on Amazon EC2, she will pay $\$0.104/hour$, which is approximately $\$910/yr$. We vary the monetary budget between $\$1820/yr$ and $\$14560/yr$ to check optimal values, which is simply $l \in [2, 16]$.

Table 5 shows the results of the optimization procedure for varying monetary budget, and fixed $L_{perf} = 150$. The results include the optimal HERMES setup and the probability of a successful attack in one epoch, for both $\theta = 3600$ and 600. We observe that as we increase the monetary budget, HERMES is allowed to run with more VMs, resulting in lower probabilities of success for the adversary. For instance, when the budget is $\$7280/yr$ and $\theta = 3600$, HERMES can be configured to run in $(8,5)$ setup, while the adversary has only $2.8 \cdot 10^{-13}$ chance to capture the partitioned cryptographic key.

Table 6 shows similar set of results, this time for fixed monetary budget of $\$14560/yr$, but varying expected performance limit L_{perf}. We deduce that as HERMES is allowed to respond slower, it can be configured to run with increased k, which decreases the attack success probability. For instance, increasing expected latency from 50 *msec* to 150 *msec* decreases the attack success probability nearly 8 and 11 fold, when θ is 600 and 3600, respectively.

Note that the probabilities are calculated for a successful attack in **one epoch**, one would question if the adversary would accomplish its goal in a longer period, say a year. For $\$7280/yr$ and an expected latency of 150 *msec* in our micro benchmarking case study, the probability of capturing the complete cryptographic key in one year is $1.8 \cdot 10^{-6}$ if the average time to capture a key is predicted as 3600 *sec*, which is a very small probability.

7 Related Work

Attacks. There exists a myriad of side-channel attacks with different assumptions and setups. The adversary may leverage observations made on the shared hardware to execute *access driven* attacks (e.g., [13, 14, 28, 43]); measure timings of certain cryptographic operations of the defender to perform *time-driven* attacks (e.g., [15, 19, 20, 34, 47]); or physically observe the defender machines and run *trace driven* attacks (e.g., [18, 26, 33]). The specific type of attacks, which HERMES aims to mitigate, is *cross-VM* side-channel attacks, in which both the defender and the adversary are customers to a third-party cloud infrastructure. Both entities initialize VMs in the cloud, where the victim's VMs are attacked by the adversary's VMs. Ristenpart et al. [41] showed the first cross-VM side-channel, in which they first *co-reside* their VMs with the defender VMs, and execute an access-driven attack to retrieve crude information (e.g., aggregate

cache usage). In another work, though not for adversarial purposes, Zhang et al. [50] present *HomeAlone* that performs a co-residency check between two VMs using classifiers on cache timing. In another attack, Zhang et al. push it one step further, and extract an ElGamal private key using cross-VM attacks [51]. Those works showed that VMs in public cloud infrastructures are vulnerable to side-channel attacks, and protection mechanisms are needed to secure private information.

Prevention. Among the variety of side-channel prevention techniques, the most popular ones are randomization-based approaches. *MIST* is one of such examples, in which the *square-and-multiply* method is extended with an additional division by a randomly chosen number [38, 45]. Other approaches include adding random noise between squaring and multiplying operations, or applying *always-multiply* techniques. To countermeasure those side-channel prevention techniques, Karlof et al. promotes *Hidden Markov Model* based cryptanalysis as a powerful tool [30]. On the other hand, Witteman et al. shows a trace driven side-channel attack to break down *always-multiply* technique and message binding in RSA [49]. Although the latter is trace driven, those two works show that even randomization based side-channel prevention approaches could have vulnerabilities that can be used by different types of adversaries.

There exist several works that aim to prevent side-channel attacks in public clouds. *HomeAlone* [50] uses co-residency checks to see if a VM is physically isolated from any other VM, and to achieve maximum physical isolation. Our work aims to prevent the leakage of private keys even if the adversary co-resides with the defender, whereas they aim to prevent access-driven side-channel attacks by assuring physical isolation. In *HyperSafe*, Wang and Jiang aim to provide hypervisor integrity throughout the execution [46]. We assume that the cloud provider and its infrastructure (including the hypervisor) are trusted. Other prevention mechanisms include [17], which aims to prevent side-channel attacks that use communication traffic; *StealthMem* that hides memory access patterns to protect private information [32]. Compared to these works, HERMES is applicable to any type of cross-VM attacks against cryptographic keys.

8 Conclusion

In this paper, we present HERMES, a novel system to protect cryptographic keys in cloud VMs. The key idea is to periodically partition a cryptographic key using additive or Shamir secret sharing. With two different case studies, we show that the overhead can be as low as 1%. With such small overhead in an average request, cryptographic keys become more leakage-resilient against any adversary. Furthermore, we model the problem of finding *optimal* parameters for the given monetary and performance constraints, which minimizes the security risk. Using our formal model, the defender can calculate the probability of a successful attack, and take precautions (e.g., increase the number of VMs, decrease epoch length). As a proof-of-concept, the current implementation of HERMES mainly focuses on the protection of the RSA private key, which is widely used in many daily web site and mail server communications. However, there exists a myriad of works on threshold signature schemes for different cryptosystems, (e.g., [21, 23, 27, 35, 36]), which may be applicable to HERMES with slight modifications.

Tables 7 and 8 show the results for the micro benchmark.

B T-RSA Details

Key partitioning: The dealer creates two strong primes $p = 2p' + 1$ and $q = 2q' + 1$, where p' and q' are also prime numbers. Next, it creates a random prime number $e > l$, and calculates $d = e^{-1} \ mod \ m$, where $m = p'q'$.

Then, the dealer creates a random polynomial $f(X) = \sum_{i=0}^{k-1} a_i X^i \in \mathbb{Z}[X]$, where $a_0 = d$, and $a_1, \ldots, a_{k-1}$ are random integers in $\mathbb{Z}$. Next, the dealer computes each party p_i's share as $s_i = f(i) \ mod \ m$. The public key is (n, e), while each party is given s_i as their share of the private key.

Using the secret key: For a given message $M \in \mathbb{Z}_n^*$, the chosen combiner selects a subset of the parties, $S = \{i_1, \ldots, i_k\} \subseteq \{1, \ldots, l\}$, where $|S| = k$, and sends M to each party in S. Each selected party p_{i_j} performs the following set of operations:

1. $\Delta = l!$
2. $\lambda_{0,i_j}^S = \Delta \frac{\prod_{i_x \in S \setminus \{i_j\}} -i_x}{\prod_{i_x \in S \setminus \{i_j\}} (i_j - i_x)}$
3. $w_{i_j} = M^{4\Delta s_{i_j} \lambda_{0,i_j}}$

λ_{0,i_j}^S is the polynomial interpolation constant for p_{i_j} in set S, where $\Delta f(0) \equiv \sum_{i_j \in S} \lambda_{0,i_j}^S f(i_j) \ mod \ m$. Once the combiner gets a partial result, w_{i_j}, from each party in S, it computes $w = \prod_{i_j \in S} w_{i_j}$. Then, it executes the extended Euclidean algorithm for e and $e' = 4\Delta^2$, and gets integers a and b, where $e'a + eb = gcd(e', e) = 1$. The greatest common divisor of e and e' is 1, since e is a prime number, and each factor of e' is smaller than e. Finally, the combiner computes $y = w^a M^b$ as the final result.

The final value y is in fact $M^d \ mod \ n$:

$$w \equiv \prod_{i_j \in S} w_{i_j} \equiv \prod_{i_j \in S} M^{4\Delta s_{i_j} \lambda_{0,i_j}} \equiv M^{4\Delta^2 d} \equiv M^{e'd} \ mod \ n$$

$$y \equiv w^a M^b \equiv M^{ae'd+b} \equiv M^{d(1-eb)+b} \equiv M^d \ mod \ n$$

Notes

[1] In a memoryless probability distribution, the cumulative probability depends on the distance from the starting time of the distribution to the current time.

FLUSH+RELOAD: a High Resolution, Low Noise, L3 Cache Side-Channel Attack

Yuval Yarom Katrina Falkner
The University of Adelaide

Abstract

Sharing memory pages between non-trusting processes is a common method of reducing the memory footprint of multi-tenanted systems. In this paper we demonstrate that, due to a weakness in the Intel X86 processors, page sharing exposes processes to information leaks. We present FLUSH+RELOAD, a cache side-channel attack technique that exploits this weakness to monitor access to memory lines in shared pages. Unlike previous cache side-channel attacks, FLUSH+RELOAD targets the Last-Level Cache (i.e. L3 on processors with three cache levels). Consequently, the attack program and the victim do not need to share the execution core.

We demonstrate the efficacy of the FLUSH+RELOAD attack by using it to extract the private encryption keys from a victim program running GnuPG 1.4.13. We tested the attack both between two unrelated processes in a single operating system and between processes running in separate virtual machines. On average, the attack is able to recover 96.7% of the bits of the secret key by observing a single signature or decryption round.

1 Introduction

To reduce the memory footprint of a system, the system software shares identical memory pages between processes running on the system. Such sharing can be based on the source of the page, as is the case in shared libraries [13, 26, 42]. Alternatively, the sharing can be based on actively searching and coalescing identical contents [6, 55]. To maintain the isolation between non-trusting processes, the system relies on hardware mechanisms that enforce read only or copy-on-write [13, 40] semantics for shared pages. While the processor ensures that processes cannot change the contents of shared memory pages, it sometimes fails to block other forms of inter-process interference.

One form of interference through shared pages results from the shared use of the processor cache. When a process accesses a shared page in memory, the contents of the accessed memory location is cached. Gullasch et al. [29] describes a side channel attack technique that utilises this cache behaviour to extract information on access to shared memory pages. The technique uses the processor's `clflush` instruction to evict the monitored memory locations from the cache, and then tests whether the data in these locations is back in the cache after allowing the victim program to execute a small number of instructions.

We observe that the `clflush` instruction evicts the memory line from all the cache levels, including from the shared Last-Level-Cache (LLC). Based on this observation we design the FLUSH+RELOAD attack—an extension of the Gullasch et al. attack. Unlike the original attack, FLUSH+RELOAD is a cross-core attack, allowing the spy and the victim to execute in parallel on different execution cores. FLUSH+RELOAD further extends the Gullasch et al. attack by adapting it to a virtualised environment, allowing cross-VM attacks.

Two properties of the FLUSH+RELOAD attack make it more powerful, and hence more dangerous, than prior micro-architectural side-channel attacks. The first is that the attack identifies access to specific memory lines, whereas most prior attacks identify access to larger classes of locations, such as specific cache sets. Consequently, FLUSH+RELOAD has a high fidelity, does not suffer from false positives and does not require additional processing for detecting access. While the Gullasch et al. attack also identifies access to specific memory lines, the attack frequently interrupts the victim process and as a result also suffers from false positives.

The second advantage of the FLUSH+RELOAD attack is that it focuses on the LLC, which is the cache level furthest from the processors cores (i.e., L2 in processors with two cache levels and L3 in processors with three). The LLC is shared by multiple cores on the same processor die. While some prior attacks do use the

LLC [47, 60], all of these attacks have a very low resolution and cannot, therefore, attain the fine granularity required, for example, for cryptanalysis.

To demonstrate the power of FLUSH+RELOAD we use it to mount an attack on the RSA [48] implementation of GnuPG [27]. We test the attack in two different scenarios. In the same-OS scenario both the spy and the victim execute as processes in the same operating system. In the cross-VM scenario, the spy and the victim execute in separate, co-located virtual machines. Both scenarios were tested in a local lab settings on otherwise idle machines.

By observing a single signing or decryption round, the attack extracts 98.7% of the bits on average in the same-OS scenario and 96.7% in the cross-VM scenario, with a worst case of 95% and 90%, respectively.

The rest of this paper is organised as follows. The next section presents background information on page sharing, cache architecture and the RSA encryption. Section 3 describes the FLUSH+RELOAD technique, followed by a description of our attack on GnuPG in Section 4. Mitigation techniques are presented in Section 5, and the related work in Section 6.

2 Preliminaries

2.1 Page Sharing

Sharing memory between processes can serve two different aims. It can be used as an inter-process communication mechanisms between two co-operating processes and it can be used for reducing memory footprint by avoiding replicated copies of identical contents. This paper focuses on the latter use.

When using *content-aware sharing*, identical pages are identified by the disk location the contents of the page is loaded from. This is the traditional form of sharing in an operating system, which is used for sharing the text segment of executable files between processes executing it and when using shared libraries [26]. Context-aware sharing has been suggested in early operating systems, such as Multics [42] and TENEX [13], and is implemented in all current major operating systems. This approach has also been suggested within the context of virtualisation hypervisors, such as Disco [15] and Satori [39].

Content-based page sharing, also called *memory de-duplication*, is a more aggressive form of page sharing. When using de-duplication, the system scans the active memory, identifying and coalescing unrelated pages with identical contents. De-duplication is implemented in the VMware ESX [54, 55] and PowerVM [17] hypervisors, and has also been implemented in Linux [6] and in Windows [33].

As memory pages can be shared between non co-operating processes, the system must protect the contents of the pages to prevent malicious processes from modifying the shared contents. To achieve this, the system maps shared pages as copy-on-write [13, 40]. Read operations on copy-on-write pages are permitted whereas write operations cause a CPU trap. The system software, which gains control of the CPU during the trap, copies the contents of the shared page, maps the copied page into the address space of the writing process and resumes the process.

While copy-on-write protects shared pages from modifications, it is not fully transparent. The delay introduced when modifying a shared page can be detected by processes, leading to a potential information leak attack. Such attacks have been implemented within virtualised environments for creating covert channels [58], for OS fingerprinting [44] and for detection of applications and data in other guests [49].

2.2 Cache Architecture

In addition to sharing memory pages, processes running on the same processor share the processor caches. Processor caches bridge the gap between the processing speed of modern processors and the data retrieval speed of the memory. Caches are small banks of fast memory in which the processor stores values of recently accessed memory cells. Due to locality of reference, recently used values tend to be used again. Retrieving these values from the cache saves time and reduces the pressure on the main memory.

Modern processors employ a cache hierarchy consisting of multiple caches. For example, the cache hierarchy of the Core i5-3470 processor, shown in Fig. 1, consists of three cache levels: L1, L2 and L3.

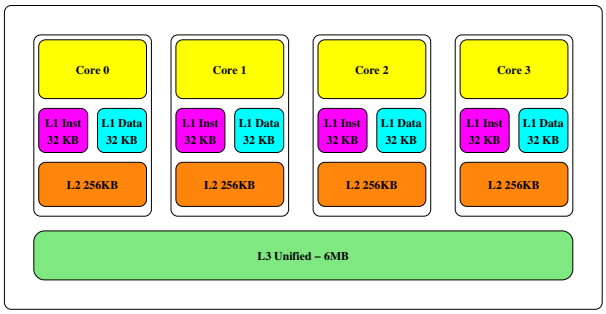

Figure 1: Intel Ivy Bridge Cache Architecture

The Core i5-3470 processor has four processing units called *cores*. Each core has a 64KB L1 cache, divided into a 32KB data cache and a 32KB instruction cache. Each core also has a 256KB L2 cache. The four cores

share a 6MB L3 cache, also known as the Last-Level Cache, or LLC.

The unit of memory in a cache is a *line* which contains a fixed number of bytes. A cache consists of multiple *cache sets* each of which stores a fixed number of cache lines. The number of cache lines in a set is the cache *associativity*. Each memory line can be cached in any of the cache lines of a single cache set. The size of cache lines in the Core i5-3470 processor is 64 bytes. The L1 and L2 caches are 8-way associative and the L3 cache is 12-way associative.

An important feature of the LLC in modern Intel processors is that it is an inclusive cache. That is, the LLC contains copies of all of the data stored in the lower cache levels. Consequently, flushing or evicting data from the LLC also remove said data from all other cache levels of the processor. Our attack exploits this cache behaviour.

Retrieving data from memory or from cache levels closer to memory takes longer than retrieving it from cache levels closer to the core. This difference in timing has been exploited for side-channel attacks. Side-channel attacks target information that an implementation of an algorithm leaks through its interaction with its environment. To exploit the timing difference, an attacker sets the cache to a known state prior to a victim operation. It can, then, use one of two methods to deduce information on the victim's operation [43]. The first method is measuring the time it takes for the victim to execute the operation. As this time depends on the state of the cache when the victim starts the operation, the attacker can deduce the cache sets accessed by the victim and, therefore, learn information on the victim [5, 9, 57]. The second approach is for the attacker to measure the time it takes for the attacker to access data after the victim's operation. This time is dependent on the cache state prior to the victim operation as well as on the changes the victim operation caused in the cache state [1, 2, 4, 14, 19, 47, 61].

Most prior work on cache side-channel attacks relies on the victim and spy executing within the same processing core. One reason for that is that many of the attacks suggested require the victim to be stopped while the spy performs the attack. To that aim, the attack is combined with an attack on the scheduler that allows the spy process to interrupt and block the victim.

Another reason for attacking within the same core is that the attacks focus on the L1 cache level, which is not shared between cores. The large size of the LLC hinders attacks both because setting it to a known state takes longer than with smaller caches and because the virtual memory used by the operating system masks the mapping of memory addresses to cache sets. Furthermore, as most of the memory activity occurs at the L1 cache level, less information can be extracted from LLC activity. Some prior works do use the LLC as an information leak channel [46, 47, 60]. However, due to the cache size, these channels have a low bandwidth.

We now proceed to describe the RSA encryption.

2.3 RSA

RSA [48] is a public-key cryptographic system that supports encryption and signing. Generating an encryption system requires the following steps:

- Randomly selecting two prime numbers p and q and calculating $n = pq$.
- Choosing a public exponent e. GnuPG uses $e = 65537$.
- Calculating a private exponent $d \equiv e^{-1} \pmod{(p-1)(q-1)}$.

The generated encryption system consists of:

- The public key is the pair (n, e).
- The private key is the triple (p, q, d).
- The encrypting function is $E(m) = m^e \bmod n$.
- The decrypting function is $D(c) = c^d \bmod n$.

CRT-RSA is a common optimisation for the implementation of the decryption function. It splits the secret key d into two parts $d_p = d \bmod (p-1)$ and $d_q = d \bmod (q-1)$, computes two parts of the message: $m_p = c^{d_p} \bmod p$ and $m_q = c^{d_q} \bmod q$. m is then computed from m_p and m_q using Garner's formula [25]:

$$h = (m_p - m_q)(q^{-1} \bmod p) \bmod p$$
$$m = m_q + hq$$

To compute the encryption and decryption functions, GnuPG versions before 4.1.14 and the related `libgcrypt` before version 1.5.3 use the square-and-multiply exponentiation algorithm [28]. Square-and-multiply computes $x = b^e \bmod m$ by scanning the bits of the binary representation of the exponent e. Given a binary representation of e as $2^{n-1}e_{n-1} + \cdots 2^0 e_0$, square-and-multiply calculates a sequence of intermediate values $x_{n-1}, \ldots, x_0$ such that $x_i = b^{\lfloor e/2^i \rfloor} \bmod m$ using the formula $x_{i-1} = {x_i}^2 b^{e_{i-1}}$. Figure 2 shows a pseudo-code implementation of square-and-multiply.

As can be seen from the implementation, computing the exponent consists of sequence of Square and Multiply operations, each followed by a Modulo Reduce. This sequence corresponds directly with the bits of the exponent. Each occurrence of Square-Reduce-Multiply-Reduce within the sequence corresponds to a bit whose value is 1. Occurrences of Square-Reduce that are not

```
 1 function exponent(b, e, m)
 2 begin
 3   x ← 1
 4   for i ← |e| − 1 downto 0 do
 5     x ← x^2
 6     x ← x mod m
 7     if (e_i = 1) then
 8       x ← xb
 9       x ← x mod m
10     endif
11   done
12   return x
13 end
```

Figure 2: Exponentiation by Square-and-Multiply

followed by a Multiply correspond to bits whose values are 0. Consequently, a spy process that can trace the execution of the square-and-multiply exponentiation algorithm can recover the exponent.

As GnuPG uses the CRT-RSA optimisation, the spy process can only hope to extract d_p and d_q. However, for an arbitrary message m, $(m - m^{ed_p})$ is a multiple of p. Hence, knowing d_p (and, symmetrically, d_q) is sufficient for factoring n and breaking the encryption [16].

3 The FLUSH+RELOAD Technique

The FLUSH+RELOAD technique is a variant of PRIME+PROBE [51] that relies on sharing pages between the spy and the victim processes. With shared pages, the spy can ensure that a specific memory line is evicted from the whole cache hierarchy. The spy uses this to monitor access to the memory line. The attack is a variation of the technique suggested by Gullasch et al. [29], which include adaptations for use in multi-core and in virtualised environments.

A round of attack consists of three phases. During the first phase, the monitored memory line is flushed from the cache hierarchy. The spy, then, waits to allow the victim time to access the memory line before the third phase. In the third phase, the spy reloads the memory line, measuring the time to load it. If during the wait phase the victim accesses the memory line, the line will be available in the cache and the reload operation will take a short time. If, on the other hand, the victim has not accessed the memory line, the line will need to be brought from memory and the reload will take significantly longer. Figure 3 (A) and (B) show the timing of the attack phases without and with victim access.

As shown in Fig. 3 (C), the victim access can overlap the reload phase of the spy. In such a case, the victim access will not trigger a cache fill. Instead, the victim will use the cached data from the reload phase. Consequently, the spy will miss the access.

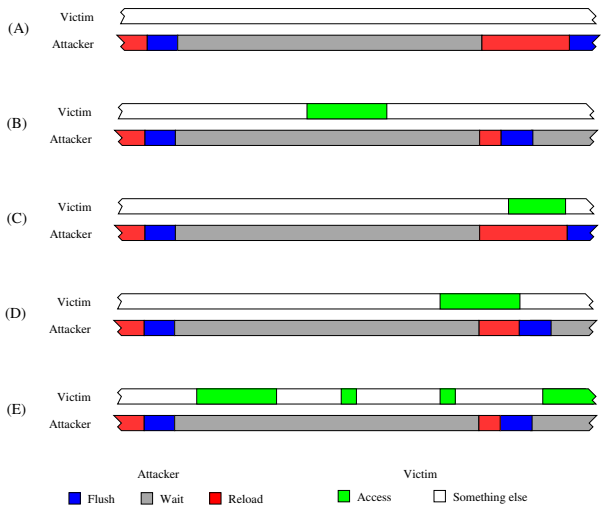

Figure 3: Timing of FLUSH+RELOAD. (A) No Victim Access (B) With Victim Access (C) Victim Access Overlap (D) Partial Overlap (E) Multiple Victim Accesses

A similar scenario is when the reload operation partially overlaps the victim access. In this case, depicted in Fig. 3 (D), the reload phase starts while the victim is waiting for the data. The reload benefits from the victim access and terminates faster than if the data has to be loaded from memory. However, the timing may still be longer than a load from the cache.

As the victim access is independent of the execution of the spy process code, increasing the wait period reduces the probability of missing the access due to an overlap. On the other hand, increasing the wait period reduces the granularity of the attack.

One way to improve the resolution of the attack without increasing the error rate is to target memory accesses that occur frequently, such as a loop body. The attack will not be able to discern between separate accesses, but, as Fig. 3 (E) shows, the likelihood of missing the loop is small.

Several processor optimisations may result in false positives due to speculative memory accesses issued by the victim's processor [34]. These optimisations include data prefetching to exploit spatial locality and speculative execution [52]. When analysing the attack results, the attacker must be aware of these optimisations and develop strategies to filter them.

Our implementation of the attack is in Figure 4. The code measures the time to read the data at a memory address and then evicts the memory line from the cache. This measurement is implemented by the inline assembly code within the `asm` command.

The assembly code takes one input, the address, which is stored in register `%ecx`. (Line 16.) It returns the time to read this address in the register `%eax` which is stored

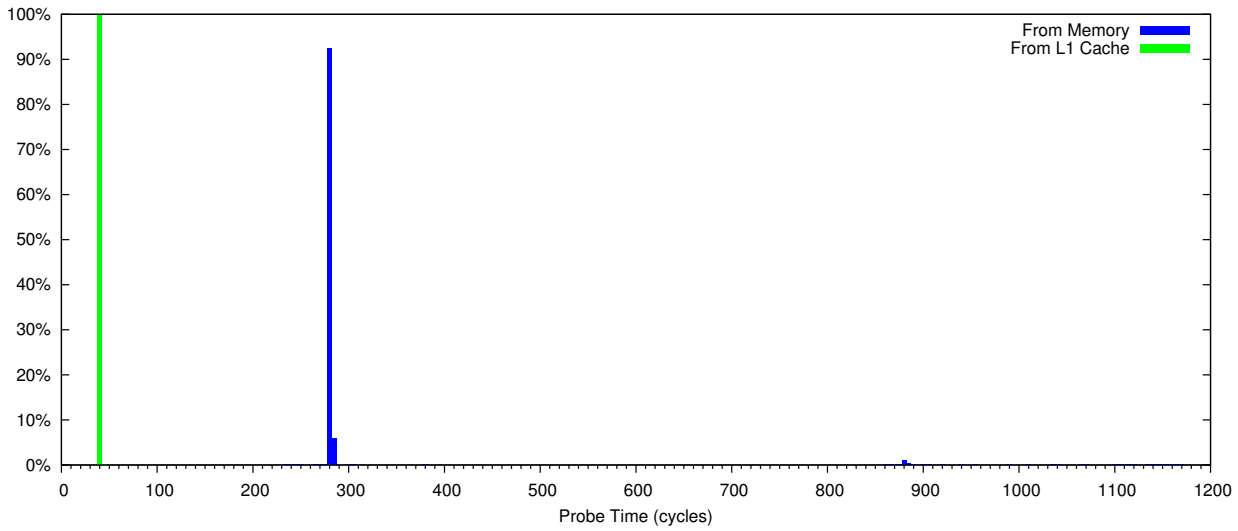

Figure 5: Distribution of Load Times.

```
 1  int probe(char *adrs) {
 2    volatile unsigned long time;
 3
 4    asm __volatile__ (
 5      "  mfence             \n"
 6      "  lfence             \n"
 7      "  rdtsc              \n"
 8      "  lfence             \n"
 9      "  movl %%eax, %%esi  \n"
10      "  movl (%1), %%eax   \n"
11      "  lfence             \n"
12      "  rdtsc              \n"
13      "  subl %%esi, %%eax  \n"
14      "  clflush 0(%1)      \n"
15      : "=a" (time)
16      : "c" (adrs)
17      :  "%esi", "%edx");
18    return time < threshold;
19  }
```

Figure 4: Code for the FLUSH+RELOAD Technique

in the variable `time`. (Line 15.)

Line 10 reads 4 bytes from the memory address in `%ecx`, i.e. the address pointed by `adrs`. To measure the time it takes to perform this read, we use the processor's time stamp counter.

The `rdtsc` instruction in line 7 reads the 64-bit counter, returning the low 32 bits of the counter in `%eax` and the high 32 bits in `%edx`. As the times we measure are short, we treat it as a 32 bit counter, ignoring the 32 most significant bits in `%edx`. Line 9 copies the counter to `%esi`.

After reading the memory, the time stamp counter is read again. (Line 12.) Line 13 subtracts the value of the counter before the memory read from the value after the read, leaving the result in the output register `%eax`.

The crux of the technique is the ability to evict specific *memory lines* from the cache. This is the function of the `clflush` instruction in line 14. The `clflush` instruction evicts the specific memory line from *all* the cache hierarchy, including the L1 and L2 caches of all cores. Evicting the line from all cores ensures that the next time the victim accesses the memory line it will be loaded into L3.

The purpose of the `mfence` and `lfence` instructions in lines 5, 6, 8 and 11 is to serialise the instruction stream. The processor may execute instructions in parallel or out of order. Without serialisation, instructions surrounding the measured code segment may be executed within that segment.

The `lfence` instruction performs partial serialisation. It ensures that load instructions preceding it have completed before it is executed and that no instruction following it executes before the `lfence` instruction. The `mfence` instruction orders all memory access, fence instructions and the `clflush` instruction. It is not, however, ordered with respect to other instructions and is, therefore, not sufficient to ensure ordering.

Intel recommends using the serialising instruction `cpuid` for that purpose [45]. However, in virtualised environments the hypervisor emulates the `cpuid` instruction. This software emulation takes too long (over 1,000 cycles) to provide the fine granularity required for the attack.

Line 18 compares the time difference between the two `rdtsc` instructions against a predetermined threshold. Loads shorter than the threshold are presumed to be served from the cache, indicating that another process has accessed the memory line since it was last flushed

from the cache. Loads longer than the threshold are presumed to be served from the memory, indicating no access to the memory line.

The threshold used in the attack is system dependent. To find the threshold for our test systems, we used the measurement code of the probe in Listing 4 to measure load times from memory and from the L1 cache level. (To measure the L1 times we removed the `clflush` instruction in line 14.) The results of 100,000 measurements of each on an HP Elite 8300 with an i5-3470 processor, running CentOS 6.5 are presented in Figure 5.

Virtually all loads from the L1 cache measure 44 cycles. (Note that this measure includes an overhead for the `rdtsc` and the fence instructions and is, therefore, much longer than a single load instruction.) Loads from memory show less constant timing. Over 98% of those take between 270 and 290 cycles. The rest are mostly spread around 880 cycles with about 200 loads measured 1140–1175 cycles. No loads from memory measured less than 200 cycles.

The timings of load operations depend on both the system architecture and the software environment. For example, on a Dell PowerEdge T420 with Xeon E5-2430 processors, loads from L1 take between 33 and 43 cycles and loads from memory take around 230 cycles. On the same architecture, within a KVM [37] guest, about 0.02% of the loads from memory take over 6,000 cycles. We believe these are caused by hypervisor activity.

The L1 measurements underestimate the probe time for data that the victim accesses. In an attack, data the victim accesses is read from the L3 cache. Intel documentation [34] states that the difference is between 22 and 39 cycles. Based on the measurement results and the Intel documentation we set the threshold to 120 cycles.

To use the FLUSH+RELOAD technique the spy and the victim processes need to share both the cache hierarchy and memory pages. In a non-virtualised environment, to share the cache hierarchy, the attacker needs the ability to execute software on the victim machine. The attacker, however, does not need elevated privileges on the victim machine. For a virtualised environment, the attacker needs access to a guest co-located on the same host as the victim guest. Techniques for achieving co-location are described by Ristenpart et al. [47]. Identifying the OS and software version in co-resident guests has been dealt with in past research [44, 49].

For sharing memory pages in system that use content-aware sharing, the attacker needs read access to the attacked executable or shared libraries. In systems that support de-duplication the attacker needs access to a copy of the attacked files. De-duplication will coalesce pages from these copies with pages from the attacked files.

4 Attacking GnuPG

In this section we describe how we use the FLUSH+RELOAD technique to extract the components of the private key from the GnuPG implementation of RSA.

We tested the attack on two hardware platforms: an HP Elite 8300, which features an Intel Core i5-3470 processor and 8GB DDR3-1600 memory and a Dell PowerEdge T420, with two Xeon E5-2430 processors and 32GB DDR3-1333 memory. On each hardware platform we experimented with two scenarios. The same-OS scenario tests the attack between two unrelated processes in the same operating system while the cross-VM scenario demonstrates that the attack works across the virtual machine isolation boundary in virtualised environments.

The same-OS tests use CentOS 6.5 Linux running on the hardware. The spy and the victim execute as two processes within that system. To achieve sharing, the spy `mmaps` the victim's executable file into the spy's virtual address space. As the Linux loader maps executable files into the process when executing them, the spy and the victim share the memory image of the mapped file. On the Dell machine we set the CPU affinity of the processes to ensure that both the victim and the spy execute on the same physical processor. We do let the processes float between the cores of the processor.

For the cross-VM scenario we used two different hypervisors: VMware ESXi 5.1 on the HP machine and Centos 6.5 with KVM on the Dell machine. In each hypervisor we created two virtual machines, one for the victim and the other for the spy. The virtual machines run CentOS 6.5 Linux. In this scenario, the spy `mmaps` a copy of the victim's executable file. Sharing is achieved through the page de-duplication mechanisms of the hypervisors. As in the same-OS scenario, on the Dell machine we set the CPU affinity of the virtual machines to ensure execution on the same physical processor.

When a pages is shared, all of the page entries in the virtual address spaces of the sharing processes map to the same physical page. As the LLC is physically tagged, entries in the cache depend only on the physical address of the shared page with no dependency on the virtual addresses in which the page is mapped. Consequently, we do not need to take care of the virtual to physical address mapping and the attack is oblivious to some diversification techniques, such as Address Space Layout Randomization (ASLR) [50].

The approach we take is to trace the execution of the victim program. For that, the spy program applies the FLUSH+RELOAD technique to memory locations within the victim's code segment. This, effectively, places probes within the victim program that are triggered whenever the victim executes the code in the probed memory lines. Tracing the execution allows the

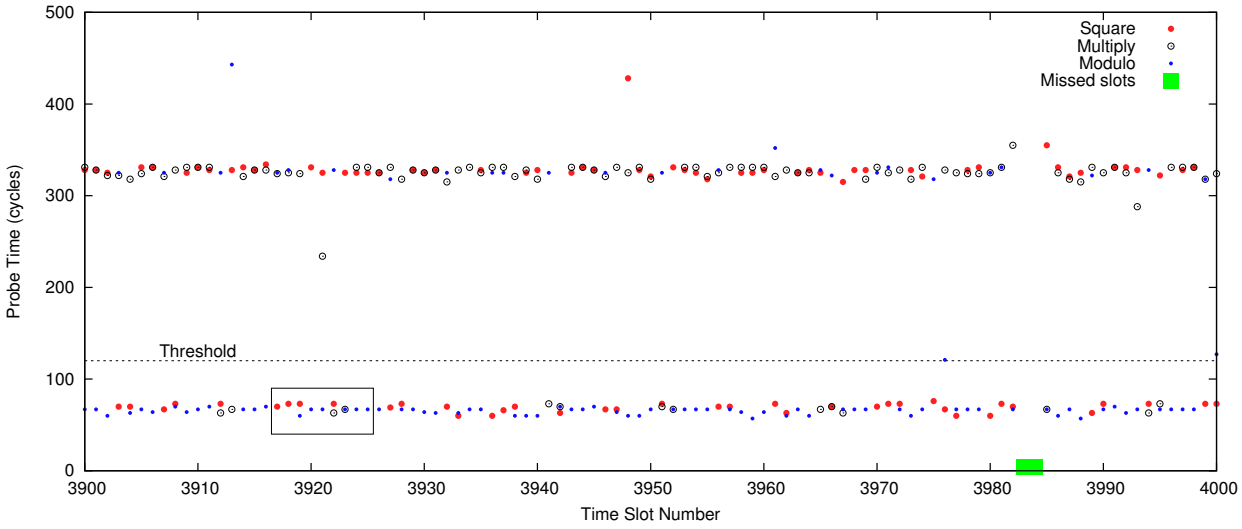

Figure 6: Time measurements of probes

spy program to infer the internal state of the victim program.

To implement the trace, the spy program divides time into fixed slots of 2,500 cycles each. In each slot it probes one memory line of the code of each of the square, multiply and modulo reduce calculations. To increase the chance of a probe capturing the access, we selected memory lines that are executed frequently during the calculation. Furthermore, to reduce the effect of speculative execution, we avoided memory lines near the beginning of the respective functions. After probing the memory lines, the spy program flushes the lines from the cache and busy waits to the end of the time slot.

We used the default build of the gpg program, which includes optimisation at -O2 level and which leaves the debugging symbols in the executable. We use the debugging symbols to facilitate the mapping of source code lines to memory addresses. In most distributions, the GnuPG executable is stripped and does not include these symbols. Attacks against stripped executables would require some reverse engineering [20] to recover this mapping. As the debugging symbols are not loaded in run time, these do not affect the victim's performance.

Measurement times for 100 time slots of the GnuPG signing with a 2,048 bit key are displayed in Figure 6. In each time slot, the spy flushes and then measures the time to read the memory lines in the Square, Multiply and Reduce functions. Measurements under the threshold indicate victim access to the respective memory lines. The exponentiations for signing takes a total of 15,690 slots or about 18ms. The CRT components used for exponentiation are 1,022 and 1,023 bits long.

Figure 7 is an enlarged view of the boxed section

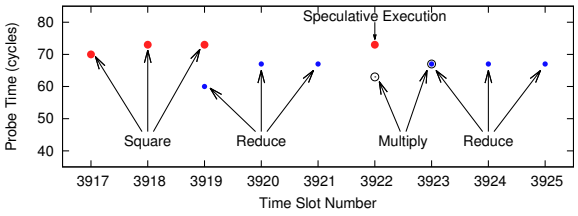

Figure 7: Section of Fig. 6

in Fig. 6. As the displayed area is below the threshold, the diagram only displays the memory lines that were retrieved from the cache, showing the activity of the GnuPG encryption. The steps of the exponentiation are clearly visible in the diagram. For example, between time slots 3,917 and 3,919 the victim was calculating a square, Time slots 3,919–3,921 are for modulo reduce calculation, multiplication in slots 3,922–3,923, and another modulo reduce in 3,923–3,925. A sequence of Square-Reduce-Multiply-Reduce indicates that during these time slots the victim was processing a set bit.

Figure 7 also demonstrates the effects of speculative execution. To improve performance, the processors tries to predict future behaviour of the program. When predicting the behaviour of the test of the bit value (Line 7 in Fig. 2), the processor does not know the value of the bit. Instead of waiting for the value to be calculated, the processor speculates that the bit might be clear and starts bringing memory lines required for the square calculation into the cache. As a result, cache lines that are part of the square calculation in Line 5 are brought into the cache, and are captured by the spy.

We have witnessed speculative execution on both the

HP and the Dell machines. Moving the probes to cache lines closer to the end of the probed functions eliminates the effects of speculative execution on the HP machine. However, speculative execution is still evident on the Dell machine.

By recognising sequences of operations, an attacker can recover the bits of the exponent. Sequences of Square-Reduce-Multiply-Reduce indicate a set bit. Sequences of Square-Reduce which are not followed by Multiply indicate a clear bit. For example, in Fig. 6, between time slots 3,903 and 3,906 the calculated sequence is Square-Reduce, which is followed by a Square, indicating that in these time slots the victim was processing a clear bit.

Continuing throughout Fig. 6 we find that the bit sequence processed in this sample is 0110011010011. Table 1 shows the time slots corresponding to each bit.

Table 1: Time Slots for Bit Sequence

Seq.	Time Slots	Value
1	3,903–3,906	0
2	3,907–3,916	1
3	3,917–3,926	1
4	3,927–3,931	0
5	3,932–3,935	0
6	3,936–3,945	1
7	3,946–3,955	1

Seq.	Time Slots	Value
8	3,956–3,960	0
9	3,961–3,969	1
10	3,970–3,974	0
11	3,975–3,979	0
12	3,980–3,988	1
13	3,989–3,998	1

System activity may cause the spy to miss time slots. The spy identifies missed time slot by noting jumps in the cycle counter. For example, In the run used for generating Fig. 6, the spy missed time slots 3,983 and 3,984. In this instance, the missed bits were not enough to hide the information on the bit processed during these time slots. However, if more slots are missed, data on bits of the private key exponent will be lost resulting in capture errors.

To measure the prevalence of capture errors, we used our spy program to observe and capture 1,000 signatures on each of the test configurations. We used a single invocation of a spy program to capture all the signatures in each system configuration. The GnuPG victim was executed from a shell in another window. Except for ensuring that the spy executes while running the signatures, the executions of the spy and of GnuPG are not synchronised.

For each observed signature, the spy outputs a text line representing the observed probes in each time slot. We used a shell script to parse this output and compared the results against the ground truth. The results are summarised in Table 2 and in Fig. 8. (For clarity, we trim Fig. 8 at 30% and 100 erroneous bits. A total of 15 samples have capture errors of more than 100 bits and the probability of no errors for the HP-CentOS configuration is 33%.)

Table 2: Statistics on Bit Errors in Capture

Hardware	HP Elite 8300		Dell PowerEdge T420	
Software	CentOS	VMware	CentOS	KVM
Average	1.41	26.55	25.12	66.12
Median	1	25	24	65
Max	15	196	96	190

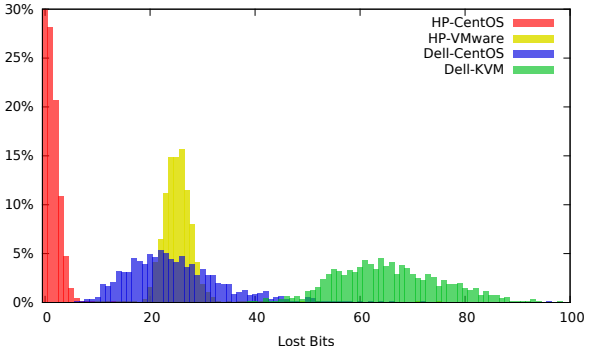

Figure 8: Distribution of Bit Errors in Capture

The shell script overestimates the number of errors. For example, due to the missing time slots, the script does not identify bit 12 in Table 1. We have manually inspected a few samples of capture output and estimate that manual inspection can reduce the number of errors by 25%-50%. Yet, the use of an automated script allows us to examine a large number of results.

On the HP machine we observe better results and significantly less noise than on the Dell machine. We believe this to be a consequence of the more advanced optimisations of the Xeon processor of the Dell machine. On each machine, results for the same-OS configuration are better than those for the cross-VM attack due to the added processing of the virtualisation layer.

Even accounting for the better results expected from manual inspection, the number of errors may be too big for a naïve brute force attack. Several strategies can be used to reduce the search space and to recover the private key. One such strategy is to rely on the nature of CRT-RSA exponentiation. As discussed in Section 2.3, an attacker only needs to recover one of the CRT components to break the encryption. By attacking the CRT component that has less errors, the attacker can reduce the search space to a more manageable size. Table 3 and Fig. 9 show the distribution of erroneous bits in the better captured CRT component in each signature. As these demonstrate, the search space is significantly reduced.

Several algorithms have been suggested for recovering the RSA exponent from partial information on the exponent bits [30, 31, 46]. These algorithms require between 27% and 70% of the bits of the exponent to recover the system key. While our attack reveals over 90% of the bits, it does not always recover the positions of

Table 3: Statistics on Bit Errors in the Better Captured CRT Component

Hardware	HP Elite 8300		Dell PowerEdge T420	
Software	CentOS	VMware	CentOS	KVM
Average	0.20	11.75	7.11	28.66
Median	0	12	6	28
Max	4	68	26	47

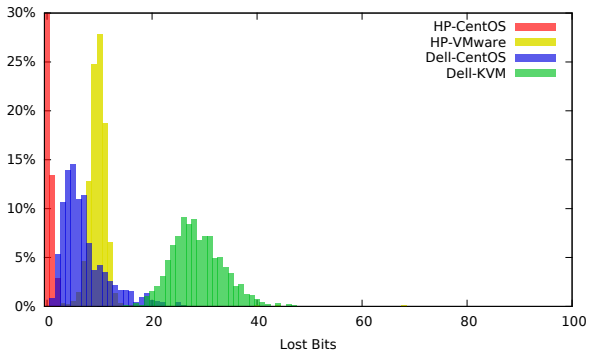

Figure 9: Distribution of Bit Errors in the Better Captured CRT Component

these bits. E.g. when a sequence of about 10 time slots is missed, this sequence can cover either one set bit or two clear bits. The attacker cannot, therefore, determine the bit positions of the following bits. Further research is required to determine whether these algorithms can be adapted to the data our attack recovers.

Another approach for recovering the key is to combine data from multiple signatures. As the positions of errors in each capture are independent, there is a small likelihood that any two captures will have errors in the same bit positions. To test this approach we manually merged the output of several pairs of observations of the spy under the Dell cross-VM scenario. When merging random pairs, we had at most a one bit error in the merged results. When merging the worst capture for the Dell cross-VM scenario with a random capture, the merged results had six bit errors, all of them in one of the CRT components and all have been identified during the process as potential errors. We, therefore, conclude that by observing two signatures, the attacker can recover the private key.

While the attack is very effective in recovering exponent bits, it does have some limitations. For the attack to work, the spy and the victim must execute on the same physical processor. For our testing, we set the processor affinity on the multi-processor system. However, in a real attack scenario the attack depends on the system scheduler.

When performing the tests, the spy and the victim were the only load on the system. Such a scenario is not representative of a real system where multiple processes are running. We expect such load to create noise that will affect the quality of capture. Furthermore, for a load that includes multiple parallel instances of GnuPG, the spy will be unable to distinguish between memory access of each instance and will be unable to recover any data.

Another limitation is the length of the secret key. On the Dell machine, probing three memory locations takes about 2,200 cycles. Hence, the attack cannot work with time slots shorter than that. With shorter key lengths, time slots of 2,200 cycles or more do not provide enough resolution to trace the victim. Consequently, recovering the private key is more difficult with shorter keys, supporting the results of Walter [56].

5 Mitigation Techniques

The attack presented here is a real, immediate threat to computer security. It, therefore, raises the very pertinent question of countermeasures. The FLUSH+RELOAD attack relies on a combination of four factors for its operation: data flow from sensitive data to memory access patterns, memory sharing between the spy and the victim, accurate, high-resolution time measurements and the unfettered use of the `clflush` instruction. Preventing any of these blocks the attack.

The lack of permission checks for using the `clflush` instruction is a weakness of the X86 architecture. Consequently, the most complete solution to the problem is to limit the power of the `clflush` instruction. The main use of the `clflush` instruction is to enforce memory coherence, e.g. when using devices that do not support memory coherence [34]. Another potential use of the instruction is to control the use of the cache for improving program performance, e.g. by flushing lines that the program knows it will not require. However, we are not aware of any actual use of the instruction for this purpose.

As the first use is, clearly, a system function and the second is based on the assumption that no other process has access to the data, we suggest restricting the use of `clflush` to memory pages to which the process has write access and to memory pages to which the system allows `clflush` access. This access control could be implemented by adding memory types that restrict flush access to the PAT (Page Attribute Table) [35, chap. 11].

The ARM architecture [7] also includes instructions to evict cache lines. However, these instructions can only be used when the processor is in an elevated privilege mode. As such, the ARM architecture does not allow user process to selectively evict memory lines and the FLUSH+RELOAD is not applicable in this architecture.

Our attack seems not to work on contemporary AMD processors, such as the A10-6800K and Opteron 6348. The code in Fig. 5 returns the same result with and without the `clflush` instruction. Replacing the second

`rdtsc` instruction (Line 12) with the similar `rdtscp` instruction fixes this issue, however, two problems prevent the use of the technique. The first problem is that data seems to linger in the cache for some time after being evicted. The second problem is that the attack does not capture accesses from other processes. A possible explanation for this behaviour is that the AMD caches are non-inclusive, i.e. data in L1 does not need to also be in L2 or L3, as is the case with the Intel caches. Consequently, evicting data from the LLC does not, necessarily, evicts it from the L1 caches of other cores. Processes executing on other cores can access data in the L1 cache without triggering a load from memory to the LLC. The attack does work on older AMD processors, such as the Opteron 2212.

Hardware based countermeasures, such as those described above cannot provide an immediate solution to the problem. They will take time to develop and will not protect existing hardware. Consequently, for immediate mitigation of the attack, software-based solutions are required.

Another possible solution is preventing sharing between the spy and the victim. Preventing page sharing between processes provides protection against the FLUSH+RELOAD attack. However, this approach goes against the trend of increased sharing in operating systems and virtualisation hypervisors. Completely eliminating page sharing would significantly increase the memory requirements of modern operating systems and is, therefore, unlikely to be a feasible solution. As a partial solution, it may be possible to avoid sharing of sensitive code by changing the program loader. Another partial solution is disabling page de-duplication, which prevents using the FLUSH+RELOAD attack between co-hosted guests in a virtualised system. This approach is recommended for public compute clouds which offer the implied promise that guests cannot interfere with each other.

Software diversification [24] is a collection of techniques that permute the locations of objects within the address spaces of processes. While most of these techniques were originally developed as a protection against memory corruption attacks, some of them can be used to prevent sharing and, consequently, to mitigate the FLUSH+RELOAD attack. More specifically, in virtualised environments, static reordering of code and data [12,24,36] can be used to create unique copies of programs in each virtual machines. As these copies are not available outside the specific virtual machine, pages of the program are not de-duplicated and sharing is prevented. Diversifying the program at run time [22] can prevent sharing of the program text even when the attacker has access to the binary file. As discussed above, the FLUSH+RELOAD technique is oblivious to the virtual to physical address mapping. Consequently, diversification techniques that rely on permuting the virtual address mapping of code pages, such as [50, 59], do not provide any protection against the attack.

FLUSH+RELOAD, like other side-channel attacks, relies on the availability of a high-resolution clock. Reducing the resolution of the clock or introducing noise to clock measurement [32, 53] can be an used as a countermeasure against the attack. The main limitation of this approach is that the attacker can use other methods for generating high resolution clocks. Examples include using data from the network or running a 'clock' process in a separate execution core.

Irrespective of the measures described above, cryptographic software should be protected against the attack. Following our disclosure [18, 38], the GnuPG team released GnuPG version 1.4.14 and `libgcrypt` version 1.5.3. These mitigate the attack using the square-and-multiply-always [21] algorithm, shown in Listing 10. The algorithm executes the square and the multiply steps for each bit, but ignores the result of the multiply step for bits of value 0.

```
function exponent(b, e, m)
begin
  x ← 1
  for i ← |e| − 1 downto 0 do
    x ← x^2
    x ← x mod m
    x' ← xb
    x' ← x' mod m
    if (e_i = 1) then
      x = x'
    endif
  done
  return x
end
```

Figure 10: Exponentiation by Square-and-Multiply-Always

When introducing instructions with no effect, care should be taken to prevent the compiler from optimising these away. In the case of the GnuPG fix, the optimiser cannot know that the added addition does not have side-effects. With the possibility of side-effects, the optimiser takes a conservative approach and invokes the function.

The implementation still contains a small section of code that depends on the value of the bit, which could, theoretically, be exploited by a cache side-channel attack. However, due to speculative execution, the processor is likely to access the section irrespective of the value of the bit. Furthermore, as this section is short and is smaller than a cache line, it is likely to fit within the same cache line as the preceding or following code. Hence, we believe that this implementation protects against the FLUSH+RELOAD attack.

This fix, however, does not protect against other forms of side-channel attack. In particular, the code is likely to be vulnerable to Branch Prediction Analysis [3]. Furthermore, as access patterns to data depend on the values of the exponent bits, the code is likely to be vulnerable to PRIME+PROBE attacks [51,61]. Like FLUSH+RELOAD, these side-channel attacks rely on data flow from secret exponent bits to memory access patterns. These attacks can be prevented by using *constant time* exponentiation, where the sequence of instructions and memory locations accessed are fixed and do not depend on the value of the exponent bits. Techniques for constant time computation have been explored in the NaCl cryptographic library [10]. The pattern of accesses to memory lines of the OpenSSL [41] implementation of RSA exponentiation is not dependent on secret exponent bits. Consequently, even though the implementation is not constant time [11], it is not vulnerable to our attack.

Constant time computation is not, however, a panacea for the problem of side-channel attacks. FLUSH+RELOAD can be applied no extract secret data from non cryptographic software. For such software, the performance costs of constant-time computation are unreasonable, hence other solutions are required.

6 Related Work

Several works have pointed out that page sharing exposes guests to information leakage, which can be exploited for implementing covert channels [58], OS fingerprinting [44] and for detecting applications and data in other guests [49]. These works exploit the copy-on-write feature of page sharing. Copy-on-write introduces a significant delay when a page is copied. Hence, by timing write operations on pages, a spy can deduce the existence of pages with identical contents in other guests. As page de-duplication is a slow process, all these attacks have a very low resolution.

Using a cache side-channel to trace the execution of a program is not a new idea [1, 2, 4, 14, 19, 29, 61]. In all of these attacks, the victim and the spy must share the execution core, either by using hyper-threading or by interleaving the execution of the victim and the spy on the same core.

Gullasch et al. [29] describes an attack on AES which traces the victim's access to the S-Boxes. Our work builds on the attack technique presented by Gullasch et al. and extends it in two ways. Gullasch et al. only applies the attack on a time-shared core and does not exploit the eviction from a shared LLC. Our attack exposes the use of a shared LLC and demonstrates that the technique can be used across cores. Additionally, Gullasch et al. uses the `cpuid` instruction to synchronise the instruction stream whereas we use fence instructions. In virtualised environments, the `cpuid` is emulated in software and this emulation takes over 1,000 cycles. With two `cpuid` instructions in each probe, the Gullasch et al. probe spans over 2,500 cycles. As our attack requires three probes within 2,500 cycles, the resolution of the Gullasch et al. code is is not high enough for implementing our cross-VM attack.

The attack in Zhang et al. [61] specifically targets virtualised environments, extracting the private ElGamal [23] key of a GnuPG decryption executing in another guest. The attack depends on a weakness in the scheduler of the Xen hypervisor [8]. The granularity of the attack is one probe in 50,000 cycles, limiting the minimum size of victim key that can be captured. The modulus in the paper is 4,096 bits long. The attack has low signal to noise ratio, and requires the use of filtering. Even with this filtering and the large modulus, the attack requires six hours of constant decryption to recover the key.

Weiß et al. [57] also describes cache timing attack in a virtualised environment. The attack is an adaptation of Bernstein's attack [9] that relies on the short constant communication time between domains in the L4 kernel.

7 Conclusions

In this paper we describe the FLUSH+RELOAD technique and how we use it to extract GnuPG private keys across multiple processor cores and across virtual machine boundaries.

It is hard to overstate the severity of the attack, both in virtualised and in non-virtualised environments. GnuPG is a very popular cryptographic package. It is used as the cryptography module of many open-source projects and is used, for example, for email, file and communication encryption. Hence, vulnerable versions of GnuPG are not safe for multi-tenant systems or for any system that may run untrusted code.

While significant, the attack on GnuPG is only a demonstration of the power of the FLUSH+RELOAD technique. The technique is generic and can be used to monitor other software. It can be used to devise other types of attacks on cryptographic software. It can also be used against other types of software. For example, it could be used to collect statistical data on network traffic by monitoring network handling code or it could monitor keyboard drivers to collect keystroke timing information.

Hence, while the GnuPG team has fixed the vulnerability in their software, their fix does not address the broader threat exposed by this paper.

The FLUSH+RELOAD technique exploits the lack of restrictions on the use of the `clflush` instruction. Not restricting the use of the instruction is a security weakness of the Intel implementation of the X86 architecture. This enables processes to interact using read-only pages.

Addressing this weakness requires a hardware fix, which, unless implemented as a microcode update, will not be applicable to existing hardware.

Preventing page sharing also blocks the FLUSH+RELOAD technique. Given the strength of the attack, we believe that the memory saved by sharing pages in a virtualised environment does not justify the breach in the isolation between guests. We, therefore, recommend that memory de-duplication be switched off.

Abstract

As a countermeasure against the famous Bleichenbacher attack on RSA based ciphersuites, all TLS RFCs starting from RFC 2246 (TLS 1.0) propose "to treat incorrectly formatted messages in a manner indistinguishable from correctly formatted RSA blocks".

In this paper we show that this objective has not been achieved yet (cf. Table 1): We present four new Bleichenbacher side channels, and three successful Bleichenbacher attacks against the *Java Secure Socket Extension (JSSE)* SSL/TLS implementation and against hardware security appliances using the *Cavium NITROX SSL accelerator chip*. Three of these side channels are timing-based, and two of them provide the first timing-based Bleichenbacher attacks on SSL/TLS described in the literature. Our measurements confirmed that all these side channels are observable over a switched network, with timing differences between 1 and 23 microseconds. We were able to successfully recover the `PreMasterSecret` using three of the four side channels in a realistic measurement setup.

TLS impl.	Side channel	Queries & Efficiency	
		Queries	Time
OpenSSL	timing	$O(2^{40})$	n.a.
JSSE	error message	177,000	12 h
JSSE	timing	18,600	19.5 h
Cavium	timing	7371	41 h

Table 1: Overview on Bleichenbacher side channels and attacks. In case of timing based side channels, *Queries* denotes the number of queries sent to the Bleichenbacher oracle $\mathcal{O}$ (see below); the actual number of requests sent to the TLS server (and thus the attack duration) depend on the network quality. Even though we found timing differences in the OpenSSL implementation, the attack revealed not to be practical due to the weakness of the oracle.

1 Introduction

SSL/TLS is, due to its enormous importance, a major target for attacks. During the last years, novel attack techniques (targeting the TLS Record Layer) have been discovered (see e.g. [21]). However, one of the most famous attacks is still Bleichenbacher's chosen-ciphertext attack on the TLS handshake [5], exploiting side channels of the RSA decryption process (see Section 3). Formal models don't cover this attack: The first full security proof of the TLS-RSA handshake [17] assumes that the RSA decryption implementation is ideal without any side channels.

Bleichenbacher's Attack. Bleichenbacher's attack is an adaptive chosen-ciphertext attack on the RSA PKCS#1 v1.5 encryption padding scheme (denoted by PKCS#1 in the following). The only prerequisite for the attack is the presence of a side channel at the TLS server which allows to distinguish PKCS#1 compliant from non-compliant ciphertexts. An attacker with access to such a side channel can proceed as follows: He records the TLS handshake of the target connection, and extracts the RSA-PKCS#1 encrypted `ClientKeyExchange` message c. Then he iteratively creates new ciphertexts $c', c'', \ldots$ from c. These are sent to the TLS server as part of a new handshake, and the server's responses are observed. With each successful query, i.e. a query c^* which is PKCS#1 compliant, the attacker can reduce the interval in which the original plaintext is located in. He repeats these steps until the interval only contains one integer, thus decrypting the ciphertext c. Daniel Bleichenbacher successfully applied this attack to SSL 3.0 [5] in 1998.

In three of the four presented attacks we are dealing with timing based side channels, so we have to repeat measurements to statistically eliminate random noise. In the following, we use an abstraction to deal with this fact: A Bleichenbacher *oracle* $\mathcal{O}$ receives a candidate ciphertext c^* as input and makes use of a side channel (e.g. by

repeating measurements) to finally output whether c^* is PKCS#1 compliant or not (see Figure 3).

Countermeasures. Soon after the publication of the original Bleichenbacher attack in 1998, error messages were unified and the TLS standards introduced the following countermeasure: If the decrypted message structure is not compliant, the TLS server generates a random `PreMasterSecret`, and performs all subsequent handshake computations with this value.[1] This countermeasure was described in TLS versions 1.0 [9] and 1.1 [10]. TLS 1.2 [11] improves this by prescribing that a random number must *always* be generated, independently of the PKCS#1 compliance of the incoming ciphertext. This should ensure equal processing times for compliant and non-compliant ciphertexts.

Novel Side Channels. In this paper we analyze several widely used TLS implementations for their vulnerability against Bleichenbacher attacks and show that the implemented countermeasures are not sufficient: We describe four new Bleichenbacher oracles, and analyze their sources (see Table 1). Additionally, the strength of these oracles is evaluated and three of these oracles are shown to be strong enough to mount Bleichenbacher attacks in practice. This finally led to the decryption of previously recorded SSL/TLS sessions.

The first side channel is caused by an implementation bug in the *Java Secure Socket Extension (JSSE)* – Java's built-in SSL/TLS implementation. In JSSE a different error message can be triggered if the two most significant bytes are PKCS#1 compliant, but the `PreMasterSecret` shows up to be of invalid length. We were able to successfully exploit this and decrypt a `PreMasterSecret` with a few thousand queries.

The second side channel is based on conspicuous timing differences in the *OpenSSL* implementation during PKCS#1 processing. The source of this side channel is hard to determine: Our working assumption suggests that it is based on the additional time consumption of choosing a random value. Following the description of Bleichenbacher countermeasures in TLS versions 1.0 and 1.1, this random value is only generated if the decrypted `PreMasterSecret` is not PKCS#1 compliant. The timing difference (in the range of few microseconds) caused by the unequal treatment of random number generation (depending on the PKCS#1 compliance of the ciphertexts) may be the cause for this side channel. We were able to reliably measure a timing difference in the range of one microsecond over a LAN and to reliably detect plaintexts containing valid `PreMasterSecret` values.

The third side channel is based on the fact that Java's `Exception` handling and error processing can be a time consuming task: Whenever the resulting plaintext is not PKCS#1 compliant, an `Exception` is raised by *JSSE* forcing random `PreMasterSecret` generation. The resulting timing difference is significantly higher (in the range of 20 microseconds) and can be measured over a LAN. This qualifies the side channel for practical attacks under real-world conditions.

The fourth side channel was found in widely used *F5 BIG-IP* and *IBM Datapower* products which rely on the *Cavium NITROX SSL accelerator chip*. It allowed to distinguish invalid messages from messages starting with `0x??02` (where `0x??` represents an arbitrary byte). Since the original Bleichenbacher algorithm does not handle this case, we derived a novel variant of the algorithm and evaluated that it can decrypt 2048-bit ciphertexts with only 4700 queries to an oracle.

Contribution. The contributions of this paper can be summarized as follows:

- *Impact.* We analyze several widely used SSL/TLS implementations and identify four new Bleichenbacher side channels, three of them timing-based. We describe three successful Bleichenbacher attacks which completely break JSSE and NITROX based SSL/TLS accelerators.

- *Novelty.* We describe the first timing based Bleichenbacher attacks against a TLS implementation. We present a novel variant of the original Bleichenbacher algorithm to handle specific server behavior and show that this variant results in a much better attack performance.

- *Insight.* We show that `Exception` handling may cause large timing differences, measurable over a LAN. This observation is in general important for development of side channel free (cryptographic) implementations in object oriented languages.

- *Methodology.* Our research was conducted using a novel framework for SSL/TLS inspection and penetration, called T.I.M.E., which may be of independent interest.

Responsible Disclosure. All vulnerabilities were communicated to the vendors' security teams and sent together with fix proposals. They were fixed or are going to be fixed in the newest releases.

[1] This leads to a fatal error when checking the `ClientFinished` (because of different `PreMasterSecret` at client and server side), but it does not allow the attacker to distinguish valid from invalid ciphertexts based on server error messages.

2 SSL/TLS

The Secure Sockets Layer (SSL) protocol was invented 1994 by Netscape Communications, and later (1999) renamed to Transport Layer Security (TLS) by the IETF. It evolved to be the de facto standard for secure data transmission over the Internet and is mostly used, but not limited, to secure HTTP traffic.

SSL/TLS mainly consists of two components: the *Handshake Protocol* to negotiate security primitives and key material, and the *Record Layer* where the payload (HTTP, IMAP, ...) is encrypted and integrity protected.

Record Layer. The Record Layer is initiated with the `NULL` ciphersuite, where no cryptographic protection is applied at all. Then the handshake is executed, until the `ChangeCiperSpec` message is sent by one party. Immediately after sending this message, this party switches the Record Layer to the negotiated parameters (algorithms and keys) and enables the negotiated security algorithms.

Subsequently, all messages sent through the TLS channel are secured by the selected cipher suite algorithms and the computed key material. Regarding integrity and confidentiality the Record Layer relies on a MAC-then-PAD-then-Encrypt scheme ([22] gives a detailed overview on this topic and highlights the pitfalls). The payload data is integrity protected by a (keyed H)MAC, padded if required, and finally encrypted.

Handshake Protocol. This protocol is used to negotiate the cryptographic primitives and keys. The different primitives are bundled in *cipher suites*. A *cipher suite* defines the algorithms for *(a)* key exchange or key agreement, *(b)* encryption (and, if necessary, the mode of operation) and *(c)* MAC (Message Authentication Code). Thus, the cipher suite `TLS_RSA_WITH_DES_CBC_SHA` uses (a) RSA encryption for key exchange, (b) DES encryption in CBC mode for encryption and (c) a SHA-1 based HMAC for integrity to protect the payload.

Figure 1 illustrates a typical (RSA-based) handshake without mutual authentication, between a client and a server. All cipher suites supported by the client are listed in the `ClientHello` message, and one of these suites is chosen by the server in the `ServerHello` message. The server's public key for RSA encryption is sent in the `Certificate` message and the ciphertext of the `PreMasterSecret` chosen by the client is contained in the `ClientKeyExchange` message. After this message, both - client and server - are ready to switch to encrypted mode (by sending a `ChangeCiperSpec` message). The final two *`Client-/Server`*`Finished` messages (containing a cryptographic checksum over all previously exchanged handshake messages) are already encrypted.

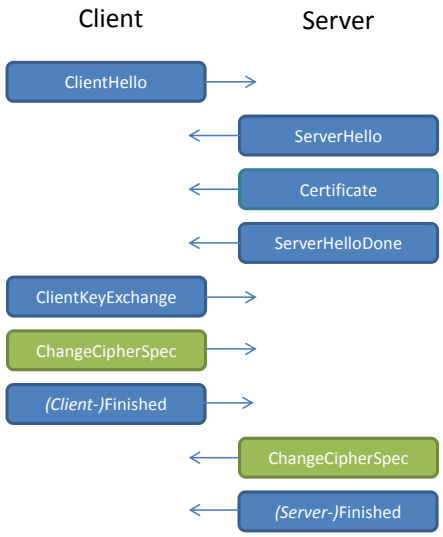

Figure 1: SSL/TLS handshake with RSA Key Exchange

Other Protocols. The *ChangeCipherSpec Protocol* is used to activate channel protection (switch to negotiated cipher suite and related key material), whereas the *Alert Protocol* is responsible for signalizing errors and failures.

Libraries and Appliances. The work presented in this paper focuses on the most common open source libraries and SSL/TLS appliances listed below.

OpenSSL.[2] As a widely used open source library OpenSSL is applied by many applications (such as the Apache Webserver's default module for SSL/TLS).

Java Secure Socket Extension (JSSE).[3] This library is the standard implementation of SSL/TLS for the Java platform, provided as part of the Java Runtime Environment. Java based applications are very likely to use it.

GnuTLS.[4] GnuTLS is another open source library for SSL/TLS available under GPL.

***IBM Datapower* and *F5 BIG-IP*.** These two products are widely used Web application firewalls and security appliances. Their SSL/TLS processing is handled using a *Cavium NITROX SSL accelerator chip*.

3 Bleichenbacher's Attack

In 1998, Daniel Bleichenbacher presented an adaptive chosen-ciphertext attack on protocols using the RSA PKCS #1 encryption standard [5]. He exemplarily applied his attack to the SSL v3.0 protocol. Through different error messages returned from the SSL server, Blei-

[2] `http://www.openssl.org`

[3] `http://docs.oracle.com/javase/7/docs/technotes/guides/security/jsse/JSSERefGuide.html`

[4] `http://www.gnutls.org`

chenbacher was able to identify ciphertexts where the plaintext started with 0x00 02. Thus, he used the SSL server as a (partial) decryption oracle $\mathcal{O}$ and was able to decrypt an encrypted PreMasterSecret, from which all SSL/TLS session keys are derived [11]. Soon after this discovery, the error messages were unified in order to close this side channel. Later, the attack was reenabled by Klíma, Pokorný and Rosa [16] through a different side channel, fixed again and finally remained unexploitable for nearly 10 years.

In order to describe the basic attack, we will first give an overview of the PKCS#1 encryption padding scheme and its usage in SSL/TLS to secure the PreMasterSecret. Afterwards, the attack and the countermeasures are presented. Throughout this section we write $|a|$ to denote the byte-length of a string a, and $a||b$ to denote concatenation of a and b. We let (N,e) be an RSA public key, with corresponding secret key d.

3.1 PKCS#1 v1.5 Encryption Padding

PKCS#1 v1.5. The basic task of the PKCS#1 v1.5 encryption padding scheme is to prepend a random padding string PS ($|PS| > 8$) to a message k, and then apply the RSA encryption function:

1. The encrypter takes a message k and chooses a random, non-zero string PS, where $|PS| > 8$ and $|PS| = \ell - 3 - |k|$.
2. The cleartext block is $m = 00||02||PS||00||k$. By interpreting this string as an integer $m < N$,
3. the ciphertext is computed as $c = m^e \bmod N$.

To decrypt such a ciphertext, the decrypter first computes $m = c^d \bmod N$. Afterwards, it is checked whether the decrypted message m has a correct PKCS#1 format. This message $m = m_1||m_2||...||m_{|m|}$ is PKCS#1 compliant if ($x \geq 10$):

$$\begin{aligned} m_1 &= \texttt{0x00} \\ m_2 &= \texttt{0x02} \\ \texttt{0x00} &\notin \{m_3,\ldots,m_x\} \\ \texttt{0x00} &\in \{m_{x+1},\ldots,m_{|m|}\} \end{aligned} \tag{1}$$

PKCS#1 usage in TLS. In case of TLS, PKCS#1 is used for encapsulation of the PreMasterSecret exchanged during a handshake which consists of 48 bytes. The first two bytes of the PreMasterSecret contain a two-byte version number $maj||min$ (e.g., $maj = 0x03$, $min = 0x01$ for TLS 1.0). The remaining bytes are chosen by the client at random. Figure 2 gives an example of a PreMasterSecret (PMS) padded to be encrypted with a 2048-bit RSA key.

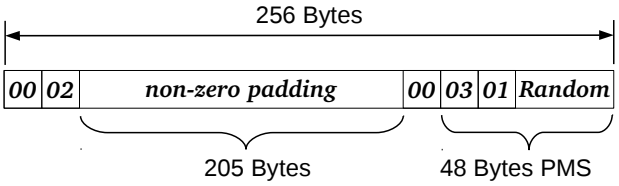

Figure 2: PKCS#1 padding applied to a PMS to be encrypted with a 2048-bit RSA key

We say that a PKCS#1 compliant message m is *TLS compliant* if:

$$\begin{aligned} |k| &= 48 \\ k_1||k_2 &= maj||min \end{aligned} \tag{2}$$

3.2 Basic Attack Idea.

Bleichenbacher's attack enables an adversary, who is in possession of a ciphertext c_0, to recover the encrypted plaintext m_0. The only prerequisite for this attack is the ability to access an oracle $\mathcal{O}$ that decrypts a ciphertext c and responds with 1 or 0, depending on whether the decrypted message m starts with 0x00 02 or not:

$$\mathcal{O}(c) = \begin{cases} 1 & \text{if } m = c^d \mod N \text{ starts with } \texttt{0x00 02} \\ 0 & \text{otherwise.} \end{cases}$$

If the oracle answers with 1, the adversary knows that $2B \leq m \leq 3B-1$, where $B = 2^{8(\ell-2)}$. The algorithm is based on the malleability of the RSA encryption scheme which allows the following blinding:

$$c = (c_0 \cdot s^e) \bmod N = (m_0 s)^e \bmod N$$

The attacker queries the oracle with c. If the oracle responds with 0, the attacker increments s and repeats the previous step. Otherwise, the attacker learns that

$$2B \leq m_0 s - rN < 3B$$

for some r. This allows the attacker to reduce the set of possible solutions to

$$\frac{2B+rN}{s} \leq m_0 < \frac{3B+rN}{s}$$

By iteratively choosing new values for s, querying the oracle, and computing new r values, the attacker narrows down the interval which contains the original m_0 value. He repeats these steps until only one solution in the interval is left. We refer to the original paper [5] for details.

3.3 Impact of Oracle Type on Attack Performance

The oracle $\mathcal{O}$ needed for the attack can be based on different side channels. For example, it can be provided by a server responding with different error messages based on the PKCS#1 compliance. If the server identifies a message as PKCS#1 compliant, the attacker knows the message starts with 0x00 02.

Bleichenbacher tested his attack against an SSL server which strictly checked the PKCS#1 format (see Equation 1). He needed about one million messages to decrypt an arbitrary ciphertext (1024-bit RSA). However, the attack performance varies. Bleichenbacher's algorithm relies solely on the knowledge that the first two message bytes are equal to 0x00 02. If an oracle is constructed from an application which verifies only the first two bytes of the decrypted message (0x00 02), we get a very "strong" oracle and the attack performs well. On the other hand, if an application checks also different properties such as TLS protocol version conformity (see Equation 2), the oracle can respond with 0 even if the first two bytes are equal to 0x00 02 (e.g., if the extracted `PreMasterSecret` is of invalid length). Such a behavior leads to false negatives which slow down the attack performance. The oracle is "weak".

The oracle strength can be measured using a probability that the oracle responds with 1 when a given decrypted message starts with 0x00 02. Suppose $P(A)$ defines a probability that the first two bytes of the decrypted message are 0x00 02. $P(1|A)$ is a probability that the oracle answers with 1, in case that the decrypted message starts with 0x00 02. Suppose we work with a 1024 bit RSA key. For an oracle strictly checking the PKCS#1 compliance (first eight bytes do not contain 0x00, but one of the following 118 bytes contains 0x00), the probability can be computed as:

$$P^{1024}_{PKCS}(1|A) = \left(\frac{255}{256}\right)^{8} \cdot \left(1 - \left(\frac{255}{256}\right)^{118}\right) \approx 0.36$$

Different oracle types and their impact on the attack performance were analyzed by Bardou et al. [4]. In addition, they improved Bleichenbacher's attack by a factor of four. An improved attack running with the discussed oracle needs about 15,000 queries to decrypt a PKCS#1 compliant message (more queries are needed to decrypt an arbitrary message).

3.4 Countermeasures

Due to its importance, Bleichenbacher's attack is directly addressed in the TLS standard [11]. The basic idea of the proposed countermeasure is to continue the processing with a randomly generated `PreMasterSecret` every time the message structure is invalid or decryption failed completely. This ensures unified error messages of the server. Algorithm 1 describes the implementation of this countermeasure as proposed in TLS 1.2 [11]:

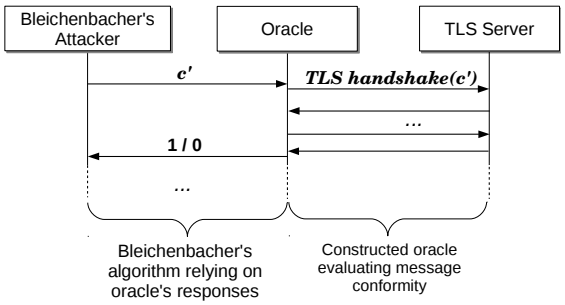

Figure 3: Bleichenbacher's attack algorithm relies on an oracle returning 1 or 0 according to the message validity.

Algorithm 1 A (simplified) countermeasure against Bleichenbacher's attack proposed in the TLS standard [11].

1: generate a random PMS_R
2: decrypt the ciphertext: $m := dec(c)$
3: **if** ($(m \neq 00||02||PS||00||k)$ OR $(|k| \neq 48)$
OR $(k_1||k_2 \neq maj||min)$ **then**
4: proceed with $PMS := PMS_R$
5: **else**
6: proceed with $PMS := k$
7: **end if**

This countermeasure ensures that *each* ciphertext decryption reveals a `PreMasterSecret` which is used in the handshake processing. Thus, the attacker cannot distinguish between valid and invalid ciphertexts. Note that a random `PreMasterSecret` is generated every time, independently from the ciphertext validity. This ensures equal processing times of valid and invalid ciphertexts.

4 SSL/TLS Penetration Testing

Given the importance of PKCS#1 format processing in SSL/TLS, it is important how Bleichenbacher countermeasures are implemented in real-world applications.

4.1 Attack Challenges

We investigate ways of turning a seemingly secure SSL/-TLS server into an oracle $\mathcal{O}$ suitable for Bleichenbacher's attack. The attack is sketched in Figure 3: The attacker communicates with $\mathcal{O}$ and suggests ciphertexts. $\mathcal{O}$ sends these ciphertexts to the server by performing a TLS handshake, evaluates its responses, and returns 1 or 0 according to the PKCS#1 conformity.

The oracle can be based on different side channels. First, *noisy* TLS servers responding with different error messages represent a direct oracle $\mathcal{O}_D$. Second, even if the server does not respond with different error messages, its processing logic can cause different timings while handling valid and invalid ciphertexts. These *silent* checks can be used to construct a timing oracle $\mathcal{O}_T$.

When constructing an oracle $\mathcal{O}$, we have to face the following challenges:

1. $\mathcal{O}$ must not respond with false positives: ciphertexts falsely identified as valid cause Bleichenbacher's algorithm to end up in a wrong internal state from which the algorithm cannot recover.

2. $\mathcal{O}$ should respond with as few false negatives as possible: valid ciphertexts falsely identified as invalid slow down the attack performance.

3. $\mathcal{O}$ should require as few requests as possible.

4.2 T.I.M.E.

This research was enabled by a new framework called T.I.M.E. - TLS Inspection Made Easy (for details see [20]). The framework implements a TLS client stack in Java with means to intercept the communication and TLS protocol flow at any time through predefined hookpoints. It allows altering TLS messages in an object based representation or, if necessary, even at bit level. This renders deep analysis of TLS, simulating complex attack scenarios, or trigger bugs only occurring in usually hard to provoke operation states possible. The framework proved to be well suited for the creation of a large amount of test cases, even in complex attack scenarios. The modularity allows a quick test case creation and automated testing for vulnerabilities of many different TLS implementations with comparably little effort. A comprehensive reporting engine eases the analysis even when working with large amounts of test cases and scanning targets.

Architecture. Figure 4 illustrates the T.I.M.E. architecture. It consists of the following main parts:

- SSL/TLS Stack and Network Stack handle the communication between the framework and the remote SSL/TLS server.

- The Attack Engine consists of different attack modules including one for Bleichenbacher's attack. It contains the attack logic and test cases for triggering different server behavior to identify bugs in the server's SSL/TLS stack.

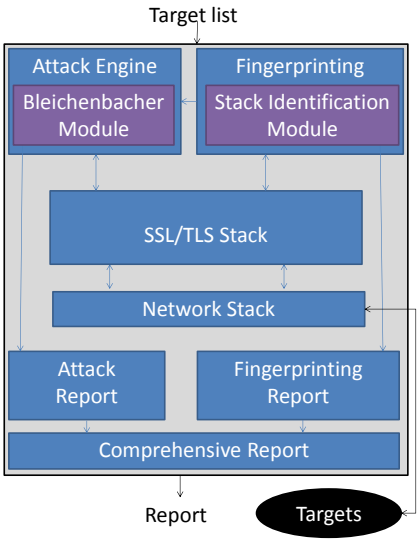

Figure 4: T.I.M.E. architecture

- The Fingerprinting Engine generates specifically formatted messages and triggers different server behavior which is analyzed to identify the SSL/TLS implementation and its version. The description of this engine is out of scope of this paper.

- The Reporting Module generates attack and fingerprinting reports.

The whole process of intercepting a running communication is event based. An application is able to register for events of interest, in this case e.g. the `ClientKeyExchange` message and `Alerts`. The workflow notifies each observer about occurring events. Once an observer is notified, the execution control is passed to this observer. The observer can manipulate the current message or internal states of the stack and return the control back to the workflow. The communication is paused until the observer returns control. Once returned the workflow continues immediately with processing.

The interaction between server, attack module and the handshake workflow of T.I.M.E. is illustrated in Figure 5.

The Bleichenbacher attack logic is built directly upon the stack and can be used to modify messages during the TLS handshake. The modified messages are used to trigger different server behavior. This allows to check for obvious vulnerabilities to Bleichenbacher's attack.

4.3 Test Environment

As we are performing timing attacks over a network, special care must be taken for the measurement setup. Measuring precise processing times from remote is challenging because of the jitter induced by busy network

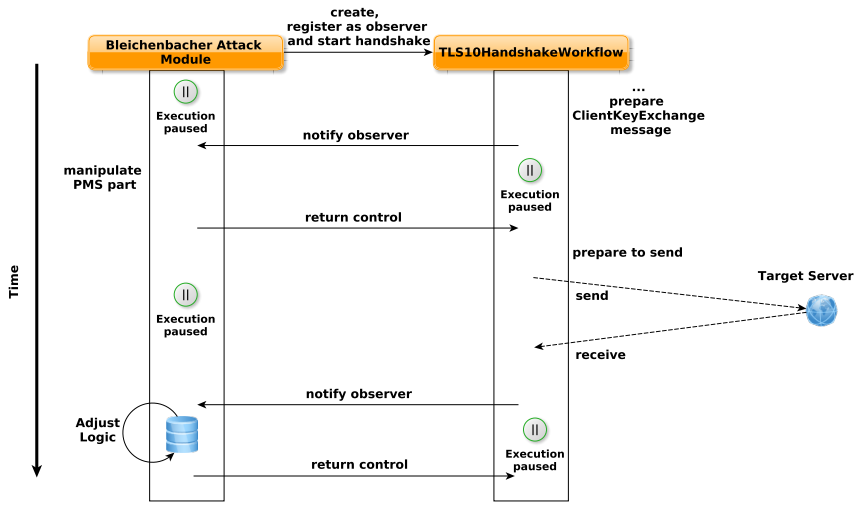

Figure 5: Interaction between the components. The Bleichenbacher Attack Module instantiates a `TLS10HandshakeWorkflow` object (part of the T.I.M.E. framework), registers as an observer for the `ClientKeyExchange` and `Alert` messages and finally starts the workflow. Every time one of these messages occurs the handshake is paused and the Bleichenbacher Attack Modules gains control. It either modifies the encrypted `PreMasterSecret` or analyzes the response message. Finally, it returns the control back to the workflow which continues with the handshake.

components, by the remote machine and by the measuring client. We also wanted to perform our attacks in a realistic scenario, in which the attacker has full control over the measuring machine, but only limited control over the network quality. We therefore ran the measurement machine with a stripped down Ubuntu 12.04 LTS Linux where we disabled CPU halting (boot parameter `idle=poll`) and CPU frequency scaling (fixing the CPU frequency using the `cpufreq` tools). Both settings are not uncommon in data centers that trade faster response times for higher power consumption. We used a Realtek 8139-based networking card with no support for interrupt coalescing. Note that this configuration likely optimizes the quality of the timing measurements, but it is not a necessary requirement. For a comprehensive analysis of hardware choices and configuration settings for timing measurements over networks see [8].

It is realistic to assume that the attacker has some limited control over the network. For example, if the connection from the attacker's machine to the target machine is of bad quality, the attacker can often rent (or compromise) a machine nearby the target machine and launch the attack from there (consider cloud-based scenarios). We therefore used a network setting in which the attacking and target machine are in the same (productive) University campus LAN connected through a Cisco Catalyst 2950 switch. This setting emulates the environment of a common co-location center or a cloud system where the attacker might even be able to rent a virtual machine that runs on the same hardware as the target machine [23].

If we use the attack module for triggering different TLS server messages, the whole T.I.M.E. tool set is placed on a single machine and communicates as a client with the remote TLS server. For timing measurement we had to act differently after we found out that T.I.M.E. provides no reliable base for highly fine grained time measurement. Thus, we decided to split the Bleichenbacher logic and the TLS logic into separate modules. Figure 6 illustrates this setup. On the left, we see the Bleichenbacher attack module that triggers and executes the attack. The Bleichenbacher logic generates new ciphertexts and hands it over to the measurement module.

To test if a TLS implementation has a suitable timing leak that allows the creation of a timing-based oracle, one has to measure the delay between the `ClientKeyExchange` message and the arrival of the `HANDSHAKE_FAILURE` message (the server performs PKCS#1 checking during this period). High precise timing measurement is not possible in Java (the JVM itself causes a significant *noise* which falsifies the results). Thus, we modified the lightweight *MatrixSSL* C implementation[5] to execute the TLS handshake and measure the timing delays in clock ticks by using the RDTSC assembler directive.

We used the timing analysis tool NetTimer[6] to evaluate the server response times. This tool implements a

[5] `http://www.matrixssl.org/`
[6] `http://sebastian-schinzel.de/nettimer`

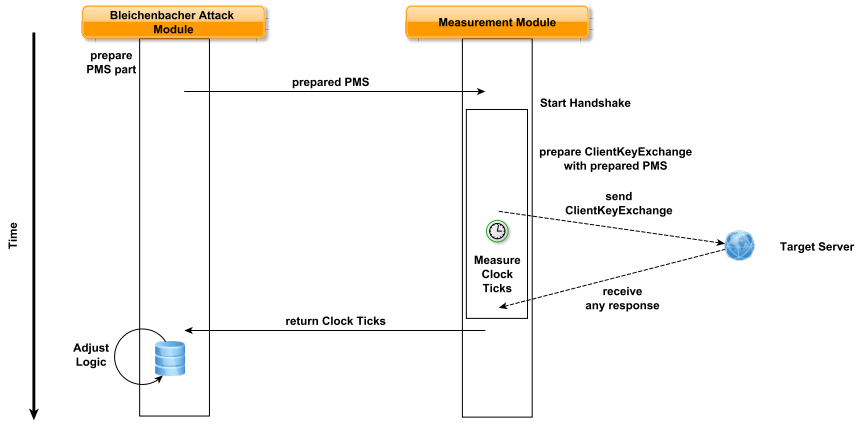

Figure 6: Architecture for measuring timing differences. The enhanced T.I.M.E. framework is split into two parts: The Bleichenbacher Attack Module and the Measurement Module based on the MatrixSSL library.

variant of Crosby's box hypothesis test, which was found to perform well for analyzing network delay measurements [8]. With this setup, we were able to reliably distinguish timing differences of a few hundred nanoseconds over a LAN with one thousand repeated measurements. This confirms that the findings of [8] not only hold for artificial UDP ping-pong protocols, but also for real-world TCP-based protocols.

4.4 Methodology

Our methodology during evaluation of Bleichenbacher's attack on a specific implementation can be summarized in the following steps.

Triggering Different Server Behaviors. In Section 3.1 we described how an encrypted ciphertext is processed on a TLS server. This process includes several validation and unpadding steps. If one of these steps is implemented incorrectly, a side channel might arise. Thus, we first implemented different T.I.M.E. test cases that aim to trigger different server behavior which could lead to a practical oracle $\mathcal{O}$. These test cases include:

1. A TLS compliant message, see Equation 2.
2. A PKCS#1 compliant message which is not TLS compliant, see Equation 1. Such a message can include a wrong TLS version number or a `PreMasterSecret` with an invalid length.
3. A non-PKCS#1 compliant message: Such a message can for example start with a non-zero byte or can be missing the `0x00` byte after the random padding of the message.

We cover all three cases and send the encrypted messages to the target TLS server and observe if the server responds with different error messages or timing behavior. As we analyze open source TLS frameworks, we are able to combine the automatic analysis of the T.I.M.E. framework with an additional source code review.

Analyzing Oracle Strength. We analyze if the discovered side channel can be used to construct a practical (*Strong*) Bleichenbacher oracle. This can be achieved by considering two factors. First, the probability that the oracle responds with 1 if the decrypted message starts with `0x00 02`. Second, in case of a timing oracle, how many server requests are needed to distinguish a valid from an invalid ciphertext.

Performing the Attack. In order to assess the practicability and performance of the attack using a constructed oracle, we use the oracle in a real attack execution and report on the number of oracle queries. For this purpose, we implemented the Bleichenbacher attack [5] as T.I.M.E. test case and extended it with the trimming and skipping holes methods from [4].

5 First Side Channel: Error Messages in JSSE

Automated evaluation of JSSE with T.I.M.E. revealed a new side channel which could be used to construct a noisy oracle $\mathcal{O}_{D-JSSE}$ leading to a successful Bleichenbacher attack. In general, the side channel is caused by an improper padding check and the subsequent `PreMasterSecret` processing. This behavior enabled us to force the server to respond with different alerts while processing differently formatted PKCS#1 messages: `INTERNAL_ERROR` and `HANDSHAKE_FAILURE`.

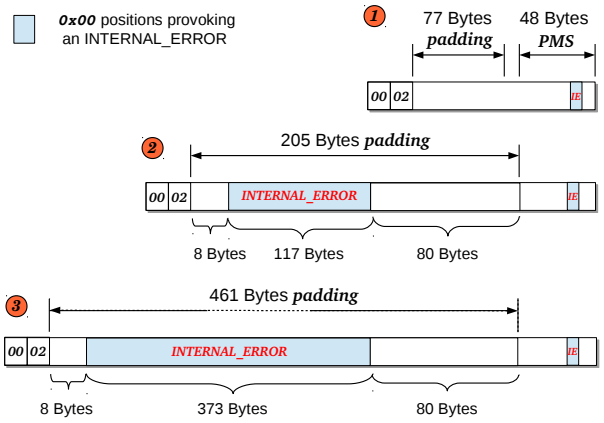

Figure 7: If a decrypted message contains a 0x00 byte preceded with non-0x00 bytes in at least one of the marked positions, JSSE responds with an INTERNAL_ERROR alert. The depicted messages are of 1024 (1), 2048 (2), and 4096 (3) bit length.

Side Channel Analysis. In the following, we analyze the attack on the server with a 2048 bit (256 bytes) key. Similar analysis could be applied to other key sizes.

Due to a fixed length of the PreMasterSecret (*PMS*), the padding string length can easily be determined to be 205 bytes (see Figure 2). These bytes must not include a 0x00 byte. The T.I.M.E. framework enabled us to test the JSSE implementation with specifically formatted messages. The analysis revealed that 0x00 bytes inserted at specific padding positions cause an internal ArrayIndexOutOfBoundsException leading to a different TLS alert message. The exception was caused when the PreMasterSecret length check was not correctly applied (cf. Algorithm 1, line 3). Propagation of the unchecked ArrayIndexOutOfBoundsException to the surface lead to the communication abort, the server responded with an INTERNAL_ERROR alert.

More precisely, our test revealed that changing either the first 8 or last 80 padding bytes led to a correct HANDSHAKE_FAILURE alert. Changing one of the remaining padding bytes to 0x00 caused a different INTERNAL_ERROR alert. This was caused by the MasterSecret computation initialized with a PreMasterSecret of an incorrect length. By applying 2048 bit RSA keys, the number of bytes causing an INTERNAL_ERROR alert is equal to 117 (depicted in Figure 7). In case of 4096 bit keys, this number is equal to 373 (see Figure 7).

In addition to the positions described above in 2048 and 4096 bit long ciphertexts, our analysis revealed that there is also a chance to attack 1024 bit ciphertexts directly. Independently of the applied key size, the server responded with an INTERNAL_ERROR if the second to last byte ($m_{|m|-1}$) contained 0x00 and the preceding bytes do not contain 0x00.

The different alert messages offered a new oracle $\mathcal{O}_{D-JSSE}$ responding with 1 (INTERNAL_ERROR) or 0 (HANDSHAKE_FAILURE) according to the structure of the decrypted PreMasterSecret.

Oracle Strength. In the following, we evaluate the probability for 2048 and 4096 bit random messages starting with 0x00 02 to contain a structure causing an INTERNAL_ERROR alert. Let n be the byte size of the PKCS#1 message and $|PMS|$ the PreMasterSecret length. The number of bytes provoking an INTERNAL_ERROR can be derived as:

$$x = n - 3 - |PMS| - 8 - 80.$$

Let us consider that the first two message bytes are 0x00 02. The probability that the following 8 padding bytes are non-zero and at least one of the following x bytes becomes 0x00 (and thus the server responds with an INTERNAL_ERROR alert) is:

$$P_{D-JSSE}(1|A) = \left(\frac{255}{256}\right)^8 \cdot \left(1 - \left(\frac{255}{256}\right)^x\right)$$

For key sizes of 2048 and 4096 bits (256 and 512 bytes) it results in:

$$P^{2048}_{D-JSSE}(1|A) = \left(\frac{255}{256}\right)^8 \cdot \left(1 - \left(\frac{255}{256}\right)^{117}\right) \approx 0.356$$

$$P^{4096}_{D-JSSE}(1|A) = \left(\frac{255}{256}\right)^8 \cdot \left(1 - \left(\frac{255}{256}\right)^{373}\right) \approx 0.744$$

This means that a JSSE server ($\mathcal{O}_{D-JSSE}$) using a 2048 bit RSA key responds with a probability of $P^{2048}_{D-JSSE}(1|A) \approx 35.6\%$ with 1 (INTERNAL_ERROR), if the decrypted PreMasterSecret message starts with 0x00 02. In case of using 4096 bit keys, the oracle is even more permissive. It responds with a probability of $P^{4096}_{D-JSSE}(1|A) \approx 74.4\%$ if the message starts with 0x00 02. These probabilities suggest a low number of false negatives, leading to an efficient Bleichenbacher attack.

On the other hand, when applying 1024 bit long RSA keys, $\mathcal{O}_{D-JSSE}$ is much less permissive. It responds with an INTERNAL_ERROR only if 0x00 is positioned just before the last byte. Thus, the probability $P^{1024}_{D-JSSE}(1|A)$ can be computed as:

$$P^{1024}_{D-JSSE}(1|A) = \left(\frac{255}{256}\right)^{124} \cdot \left(\frac{1}{256}\right) \approx 0.0024$$

	Mean	Median
2048 bit RSA key	176,797	37,399
4096 bit RSA key	73,710	27,744

Table 2: Number of required queries to execute an optimized Bleichenbacher's attack on a JSSE server using 2048 bit and 4096 bit RSA keys.

Attack Evaluation. We used this oracle to perform a Bleichenbacher attack – the experiment was repeated 1,000 times. Results of this evaluation confirm the findings of our theoretical analysis from the previous section: Executing the attack using a less restrictive oracle with a 4096 bit RSA key leads to fewer oracle queries. We needed about 177,000 queries to a JSSE server applying 2048 bit keys and about 74,000 queries to a JSSE server applying 4096 bit keys. See Table 2 for details.

We performed full `PreMasterSecret` recovery attacks against a TLS server working with 2048 bit keys. With our T.I.M.E. framework we were able to send about 3.85 server queries per second. Thus, sending 177,000 requests lasted about 12 hours. The attack was performed on localhost.[7]

Performance evaluation of an oracle using 1024 bit keys resulted in hundreds of millions of oracle queries. This is caused by the high restrictiveness of $\mathcal{O}_{D-JSSE}$ when applying keys of this length.

Mitigation. We communicated this problem to the Oracle Security response team and the bug was assigned CVE-2012-5081. The attack is fixed with the *Oracle Java SE Critical Patch October 2012 – Java SE Development Kit 6, Update 37 (JDK 6u37)*.

6 Second Side Channel: Timing Differences in OpenSSL

The discovery of the aforementioned vulnerability in JSSE motivated to investigate the source code of open source SSL/TLS frameworks. We reviewed JSSE, GnuTLS and OpenSSL and found that they do not implement the countermeasure against Bleichenbacher's attack as proposed by the TLS 1.2 specification [11].

Side Channel Analysis. The countermeasure against this attack is mostly implemented as depicted in Algorithm 1. The important observation is that the random key is generated if, and only if, the received key is not

[7]Improving the T.I.M.E. sending performance would result in much faster attack executions. This was however not the primary goal of our work.

Algorithm 2 Improper implementation of the countermeasure against Bleichenbacher's attack (suggested by TLS 1.0 and TLS 1.1) possibly causing a timing side channel in all the analyzed implementations.

1: decrypt the ciphertext: $m := dec(c)$
2: **if** ($(m \neq 00||02||PS||00||k)$ OR $(|k| \neq 48)$
OR $(k_1||k_2 \neq maj||min)$ **then**
3: generate a random PMS_R
4: proceed with $PMS := PMS_R$
5: **else**
6: proceed with $PMS := k$
7: **end if**

TLS compliant (see Equation 2). Thus, the random key generation and the assignment create a new timing side channel that leaks information about the TLS compliance of a received `PreMasterSecret`. These processing steps have independently been observed and criticized by Matthew Green [18].

Oracle Strength. *Timing Reliance.* We tested the timing differences between valid and invalid ciphertexts with OpenSSL 0.98. Figure 8 shows the filtered results of our timing analysis over a LAN with 5,000 measurements. The results suggest that we can distinguish TLS compliant and non-PKCS#1 compliant ciphertexts. We could achieve similar results for OpenSSL 1.01.

Even though the results clearly showed constant differences of about 1.5 microseconds, we are not sure if the root cause of these differences is additional random number generation. The OpenSSL code contained sev-

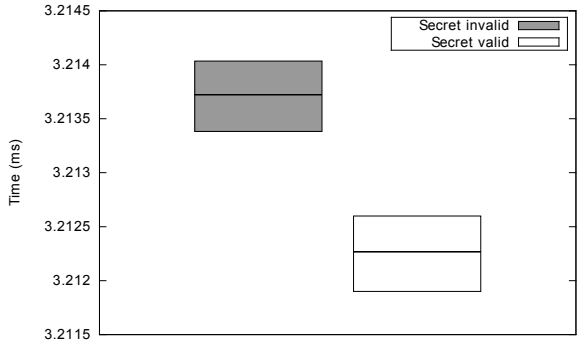

Figure 8: Timing measurement results for OpenSSL 0.98. The valid secret refers to a TLS compliant ciphertext. The invalid secret refers to a non-PKCS#1 compliant ciphertext. In the non-PKCS#1 compliant structure the first byte (which should be `0x00`) was altered to `0x08` to provoke a random number generation on the TLS server.

eral additional branches and loops in the PKCS#1 processing which could blur our results. The analysis of this problem showed up to be very difficult and related to compile flags. Despite this uncertainty, our measurements clearly show that a side channel exists.

Probability Analysis. The analyzed timing behavior can be used to construct an oracle

$$\mathcal{O}_{T-rand}(c) = \begin{cases} 1 & \text{TLS compliant} \\ 0 & \text{non-TLS compliant (with an additional random number generation)} \end{cases}$$

However, it does not lead to a practical attack. An oracle created from this timing leak is very "weak". It responds to an oracle request with 1 if, and only if, the decrypted ciphertext is TLS compliant (see Equation 2). For a 2048 bit key, the probability that an oracle responds with 1 in case that the decrypted message starts with `0x00 02` is very low:

$$P^{2048}_{T-rand}(1|A) = \left(\frac{255}{256}\right)^{205} \cdot \left(\frac{1}{256}\right)^{3} \approx 2.7 \cdot 10^{-8}$$

The reason is that 205 padding bytes must be non-zero and the following bytes must contain `0x00`$||maj||min$. See Figure 2.

Attack Evaluation. $\mathcal{O}_{T-rand}$ is very "weak" and did not allow to execute a practical Bleichenbacher attack. We were only able to estimate the number of oracle queries. According to Bleichenbacher and Bardou et al. [5, 4], the number of oracle queries for the complete attack can be computed as:

$$(2^{17} + 16 \cdot 256)/P_{T-rand} = 5 \cdot 10^{12}$$

Mitigation. The mitigation is described in RFC 5246 [11]. Algorithm 1 illustrates the correct processing: A random value should always be generated, *before* processing the decrypted data.

7 Third Side Channel: Internal Exception

We decided to search for different side channels leading to more practical oracles. As pointed out by James Manger on the official JOSE (JSON Object Signing and Encryption) mailing list,[8] an additional side channel could arise from an improper `Exception` handling in Java's PKCS#1 implementation.

[8] `http://www.ietf.org/mail-archive/web/jose/current/msg01936.html`

Side Channel Analysis. The Java PKCS#1 implementation strictly checks the message format according to Equation 1. The message must start with `0x00 02`, contain at least eight non-zero padding bytes, and a `0x00` byte indicating the end of the padding string. If this format is correct, the secret is extracted. Otherwise, a `BadPaddingException` is thrown. The method code can be found in Listing 9.

```
1  /**
2   * PKCS#1 v1.5 unpadding (blocktype 1 and 2).
3   */
4   private byte[] unpadV15(byte[] padded)
5    throws BadPaddingException {
6      int k = 0;
7      if (padded[k++] != 0) {
8        throw new BadPaddingException(
9         "Data must start with zero");
10     }
11     if (padded[k++] != type) {
12       throw new BadPaddingException(
13        "Blocktype mismatch: " + padded[1]);
14     }
15     while (true) {
16       int b = padded[k++] & 0xff;
17       if (b == 0) {
18         break;
19       }
20       if (k == padded.length) {
21         throw new BadPaddingException(
22          "Padding string not terminated");
23       }
24       if ((type == PAD_BLOCKTYPE_1)
25        && (b != 0xff)) {
26         throw new BadPaddingException(
27          "Padding byte not 0xff: " + b);
28       }
29     }
30     int n = padded.length - k;
31     if (n > maxDataSize) {
32       throw new BadPaddingException(
33        "Padding string too short");
34     }
35     byte[] data = new byte[n];
36     System.arraycopy(padded,
37      padded.length - n, data, 0, n);
38     return data;
39   }
```

Figure 9: Java's PKCS# v1.5 method for format check and padding removal can throw a BadPaddingException - *Source: sun.security.rsa.RSAPadding*

With our T.I.M.E. framework we investigated the JSSE server implementation which internally uses the PKCS#1 unpadding method described above. We sent PKCS#1 compliant and non-PKCS#1 compliant messages to the JSSE server and found that with non-PKCS#1 compliant messages an *additional* `Exception` could be provoked. The `Exception` was correctly handled by the JSSE logic and did not result in a distinguish-

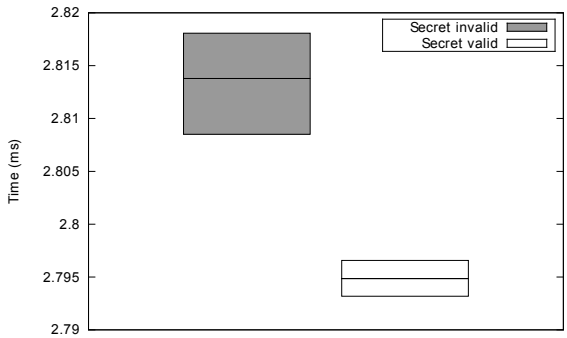

Figure 10: Timing measurement results for Java 1.7 (JSSE). The valid secret refers to a PKCS#1 compliant ciphertext. The invalid secret refers to a non-PKCS#1 compliant ciphertext. In the non-PKCS#1 compliant structure the first byte (which should be 0x00) was altered to 0x08 to provoke an exception on the TLS server.

able error message. Thus, it did not help to create a direct PKCS#1 validation oracle. However, `Exception` handling in Java (as well as in other object oriented languages) can introduce timing delays and thus slow down the whole application. Throwing, catching, and handling an `Exception` are time consuming tasks and thus lead to additional processing time.

Oracle Strength. *Timing Reliance.* We analyzed the timing differences between processing PKCS#1 compliant and non-PKCS#1 compliant messages on TLS servers running on Java 1.6 and 1.7 platforms. Figure 10 shows the filtered results of our time measurement with 5,000 queries. The results show differences of about 20 microseconds.

Probability Analysis. This behavior allows us to construct a new timing oracle:

$$\mathcal{O}_{T-exc}(c) = \begin{cases} 1 & \text{PKCS\#1 compliant} \\ 0 & \text{non-PKCS\#1 compliant (with an additional internal exception handling)} \end{cases}$$

$\mathcal{O}_{T-exc}$ is very permissive and much stronger than $\mathcal{O}_{T-rand}$, because it contains fewer plaintext validity checks. When working with 2048-bit keys, this oracle responds to a request starting with `0x00 02` with 1 with the following probability:

$$P^{2048}_{T-exc}(1|A) = \left(\frac{255}{256}\right)^{8} \cdot \left(1 - \left(\frac{255}{256}\right)^{246}\right) \approx 0.6$$

Applying such an oracle results in much lesser queries and can thus be expected to be used for a practical attack.

Attack Evaluation. We used this timing oracle $\mathcal{O}_{T-exc}$ to perform a real Bleichenbacher attack in a switched LAN and proved the practicability of $\mathcal{O}_{T-exc}$. The attack on OpenJDK 1.6 took about 19.5 hours and 18,600 oracle queries.[9] About 20% of PKCS#1 compliant messages were identified as non-PKCS#1 compliant. The attack on Java 1.7 took about 55 hours and 20,662 queries. The larger number of queries and the longer processing time are caused by a higher value of false negatives (about 50%). The oracle identified about 467 PKCS#1 compliant messages incorrectly.

Mitigation. The object oriented architecture and especially the `Exception` handling of the JSSE implementation makes fixing the timing leak challenging. A common implementation pattern for RSA decryption is to provide a (generic) function to which the ciphertext is passed which returns the plaintext on success or an `Exception` otherwise. As stated, the generation of the `Exception` creates a detectable timing difference. Preparing an `Exception` at function entry, but not throwing it, leads to a smaller time difference, but might still be exploitable.

As a consequence we implemented a time constant PKCS#1 processing for SSL/TLS and proposed it as a fix for this issue to Oracle. The bug was assigned CVE-2014-411 and it was fixed with the *Oracle Java SE Critical Patch January 2014 – Java SE 7, Update 45* (and with the previous versions *Java SE 5u55* and *6u65*).

We verified that a similar timing behavior based on an additional exception is observable in a widespread BouncyCastle library.[10] BouncyCastle is implemented in two languages: Java and C#. We tested both implementations and locally invoked BouncyCastle PKCS#1 decryption methods. We could observe timing differences of about 20 microseconds between valid and invalid PKCS#1 messages in the Java and C# BouncyCastle version. This proved that the described timing behavior is not Java specific, and can be found in other object-oriented languages as well. We developed a patch for the Java version of BouncyCastle. We contacted the BouncyCastle developers with the proposed patch in March 2014.

8 Fourth Side Channel: Unexpected Timing Behavior by Hardware Appliances

The performance and practicability of the previous attacks motivated us to analyze further TLS stacks. We

[9] One oracle query is not equal to one server request. In order to respond to an oracle query, $\mathcal{O}_{T-exc}$ issued in our scenario up to 750 real server requests. It evaluated the response times and decided if the ciphertext was valid or not. See Figure 3.

[10] `https://www.bouncycastle.org`

had a chance to evaluate the behavior of *F5 BIG-IP* and *IBM Datapower* which use the *Cavium NITROX SSL accelerator chip*. Automated evaluation with our T.I.M.E. framework revealed that it was possible to execute a *complete* handshake, even though the encoded `PreMasterSecret` was of an incorrect format. More precisely, *F5 BIG-IP* and *IBM Datapower* did not verify the first byte of the PKCS#1 message and accepted messages which started with `0x??02` (where `0x??` represents an arbitrary byte).

Side Channel Analysis. This behavior does not lead to a direct attack. In order to correctly complete a handshake flow and receive a *Server*`Finished` message, an authenticated *Client*`Finished` message has to be sent to the server. Otherwise, the analyzed server responds with a `HANDSHAKE_FAILURE` message. Since the Bleichenbacher attacker is not in possession of the `PreMasterSecret`, he is not able to authenticate the *Client*`Finished` message and thus cannot trigger different messages. However, the server behavior strongly indicated that there could be a leakage in the PKCS#1 processing. Even though this leakage did not lead to different server responses, we assumed we could observe timing differences.

In comparison to the analysis described in the previous sections, we had no chance to review the code, because it is not publicly available. This turned our work to a black-box analysis and made it much harder.

Oracle Strength. We had a chance to evaluate the timing behavior of an *IBM Datapower* directly in our lab. The measurement machine was connected with a router to the *IBM Datapower* appliance.[11] We created different TLS requests based on our methodology (TLS compliant requests, PKCS#1 compliant requests, invalid requests etc.), and sent these requests to the server while the measurement machine observed the response times. The response times were finally compared using the NetTimer library.

The comparison of the response times confirmed our predictions and we could see clear timing differences by processing our TLS requests. The most visible timing difference was produced by requests starting with `0x??02`, see Figure 11. Based on this timing difference, the server behavior allowed to construct a new timing oracle:

$$\mathcal{O}_{T-hard} = \begin{cases} 1 & \text{starts with } \texttt{0x??02} \\ 0 & \textit{otherwise} \end{cases}$$

[11] In comparison to the previous measurements, the router did not route real traffic so our experiments were executed in a "lab" scenario.

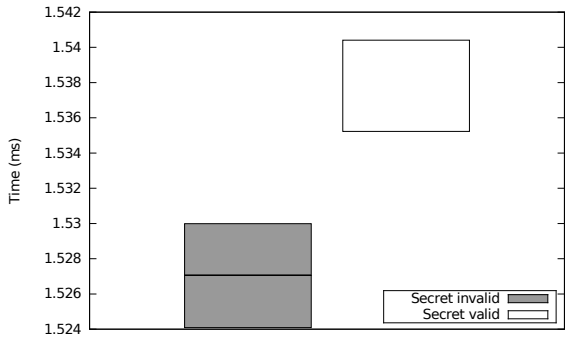

Figure 11: Timing measurement results for our *IBM Datapower*. The valid secret refers to a message, which starts with `0x??02`, where `0x??` indicates an arbitrary byte. The invalid secret refers to a message starting with different bytes.

However, this oracle is not compliant to the oracle used by Bleichenbacher. It responds with 1 to the request starting with `0x0102`, `0x0202`, `0x0302`, ... Thus, we needed to modify and adapt the original algorithm to handle this special case. This novel variant is described in Section 9.

Attack Evaluation. We evaluated the performance of our algorithm using a test oracle behaving like $\mathcal{O}_{T-hard}$. We repeated our experiment 500 times, with a 2048 bit RSA key. We needed about 4700 queries (median) to decrypt a ciphertext. This high performance is caused by the higher number of intervals the oracle accepts. Manger's attack [19] also reveals similar behavior.

We used the constructed timing oracle $\mathcal{O}_{T-hard}$ to perform a real attack on an *IBM Datapower* appliance. Our attacker needed 7371 oracle queries. The oracle correctly evaluated 2033 valid ciphertexts, while 1290 valid ciphertexts were incorrectly evaluated as invalid. The attack lasted 41 hours. The timing oracle $\mathcal{O}_{T-hard}$ issued about 4,000,000 server queries in total.

Mitigation. We communicated our findings to the vendors in November 2013. The current state of these issues can be tracked on their websites. F5 tracks this problem in their Bugzilla database under ID 435652. IBM gives their customers information about the current state in the Security Bulletin: SSL/TLS side channel attack on WebSphere DataPower (CVE-2014-0852).[12]

Since the Cavium products are used by other vendors like Cisco, Citrix or Juniper Networks, we assume that many other products were vulnerable, too.[13]

[12] `http://www.ibm.com/support/docview.wss?uid=swg21678204`

[13] `http://www.cavium.com/winning_products.html`

9 Novel Bleichenbacher Attack Variant

In the previous section we described a new oracle $\mathcal{O}_{T-hard}$. The oracle responds with 1 if a decrypted message starts with `0x??02`, where `0x??` represents an arbitrary byte. Such an oracle is not strong enough to implement Bleichenbacher's attack. The original algorithm from [5] is not able to tolerate false positives, it requires an oracle responding with 1 *only if* the decrypted message starts with `0x0002`. Note that $\mathcal{O}_{T-hard}$ is much weaker, as it responds with 1 if the message starts with `0x??02`. In the following we describe a novel variant of Bleichenbacher's attack, which is more robust than the original one and works also with the weaker oracle $\mathcal{O}_{T-hard}$.

We assume that the original message is PKCS#1 compliant and lies in the interval $[2B, 3B)$, where $B = 2^{8(\ell-2)}$. In this case the Bleichenbacher algorithm sets the starting interval containing the message of interest $m_0 \in [a,b]$, where $a = 2B$ and $b = 3B$

In the first step, the original algorithm searches for values $s > (2B+N)/3B$ such that $c = (c_0 \cdot s^e) \bmod N$ is decrypted to a PKCS#1 compliant message. This is not possible by applying $\mathcal{O}_{T-hard}$, since the oracle would respond with many false positives. We know that if $\mathcal{O}_{T-hard}$ responds with 1, the decrypted message starts with `0x0002`, `0x0102`, ... or `0xFF02`. This means the message lies in one of the following intervals: $[2B, 3B)$, $[258B, 259B)$, $[514B, 515B)$, ... If we start the algorithm with a large s value, we can easily produce a message from one of those intervals.

The basic idea behind our algorithm is to use the additional intervals and make the search more fine-grained. For this purpose, we define q, where $q \in \{1 \ldots (N/256B)\}$. In the first step, we set $r_0 = 0$ and iteratively search s_{ij} values by setting $q_j = 1 \ldots (N/256B)$:

$$\frac{2B + r_i N + q_j(256B)}{b} \leq s_{ij} < \frac{3B + r_i N + q_j(256B)}{a}.$$

We send $(c_0 \cdot s_{ij}^e) \bmod N$ to the server and observe its response. With each valid request, we can reduce the interval, where the original plaintext m_0 lies in:

$$a = max\left(a, \frac{2B + r_i N + q_j(256B)}{s_{ij}}\right)$$

$$b = min\left(b, \frac{3B + r_i N + q_j(256B)}{s_{ij}}\right)$$

Afterwards, we increment r and repeat the same steps for $q = 1 \ldots (N/256B)$.

The algorithm repeats these steps and reduces the possible solutions for m_0, until only one solution is left.

10 Other TLS Stacks

During our research we also analyzed other SSL/TLS implementations. *Microsoft Schannel* (Secure Channel) revealed no significant timing differences and behaves quite differently to any other stack: In case of processing errors of any kind, the connection is immediately terminated instead of sending alert messages. The timing measurements were too noisy to distill boundaries for distinguishing different processing branches. Due to the fact that the product is closed-source a code analysis was not possible.

11 Related Work

In this section we give a short overview on scientific publications analyzing side channel attacks and security of SSL/TLS. For a comprehensive list of SSL/TLS attacks we refer to [21].

Bleichenbacher Attacks. After publication of the original attack [5], several variants were discovered. Klima et al. found out that a strict verification of the TLS version number in the `PreMasterSecret` can lead to a side channel enabling Bleichenbacher's attack [16]. In [4] Bardou, Focardi, Kawamoto, Simionato, Steel and Tsay significantly improved Bleichenbacher's attack, and applied it to other PKCS#1-based environments.

Although Daniel Bleichenbacher conjectured that there might be timing-based side channels for Bleichenbacher attacks, they were discovered only for other protocols. For example, Jager et al. [13] describe a practical timing-based Bleichenbacher attack against implementations of the XML Encryption standard. They were able to exploit this side channel over a very noisy network (Planetlab) which was possible because timing differences could be increased by the attacker. During their research, they measured timing differences in the order of milliseconds whereas we had to cope with microseconds.

Timing Attacks on SSL/TLS. In 2003, Brumley and Boneh described an attack based on a timing side channel SSL/TLS [7], applicable if RSA is used for key exchange. Based on timing differences during processing of specially crafted `ClientKeyExchange` messages the private key of a server could successfully be extracted. Additionally, in 2011 Brumley and Tuveri [6] successfully attacked ECDSA based TLS connections (only OpenSSL stacks) by exploiting performance tweaks of the implementation.

Recent Attacks on SSL/TLS. The BEAST attack by Rizzo and Duong exploits predictable initialization vectors used by AES-CBC in TLS 1.0 [24]. The CRIME attack of the same authors shows that application of a compression method on plaintexts transported over SSL/-TLS can lead to serious practical attacks. Both attacks were theoretically discussed before [3, 15]. The authors showed how to apply them practically in specific scenarios by exploiting additional side channels. AlFardan and Paterson presented the Lucky13 padding oracle attack on AES-CBC [2] which exploits timing differences revealed by the HMAC computation over the decrypted data.

To practically deploy these attacks, a strong attacker is needed who is able to force the victim to *repeatedly* send the *same* data to the server. In contrast, our attacks exploit new side channels to mount Bleichenbacher's attack which enables to decrypt the whole `PreMasterSecret` (and thus the whole SSL/TLS session) without the need to control the user's client software.

Theoretical Results on TLS Security. After publication of Bleichenbacher's paper, the security of encoding schemes for RSA-based TLS was discussed intensively. However, due to the fact that the `Finished` messages are sent encrypted, no full security proof for TLS was available prior to 2012. In [12], a new security model (ACCE) was introduced by Jager et al., and a full proof for TLS-DHE with mutual authentication was given.

One year later, Krawczyk et al. gave a proof for the two remaining families of ciphersuites, TLS-RSA and TLS-DH, and for server-only authentication [17]. They prove security against Bleichenbacher attacks by proposing the following countermeasure: The server should use the `ClientFinished` message as a Message Authentication Code (MAC) for the `ClientKeyExchange` message. Only if `ClientFinished` is verified successfully, the server should continue the handshake by making further computations.

These two papers contain extensive related work sections, where all previous theoretical publications on TLS can be found. Theoretical security proofs must be treated carefully: The results can only be applied to practical implementations if all preconditions are satisfied, and if all cryptographic building blocks are implemented in an ideal way (i.e. yielding no side channels). Our results thus do not contradict the proofs, but simply show that the implementations of the building blocks are not ideal.

12 Future Work

TLS for non-HTTP protocols. The search for new error or timing-based side channels can be broadened to cover cryptographic protocol implementations in other application scenarios. Especially, protocols that use parts or concepts of SSL/TLS, such as EAP-TLS [1] or SSL/-TLS stacks of other languages and frameworks provide space for further investigation.

```
1  /**
2   * PKCS#1 v2.1 OAEP unpadding (MGF1).
3   */
4   private byte[] unpadOAEP(byte[] padded)
5    throws BadPaddingException {
6      byte[] EM = padded;
7      int hLen = lHash.length;
8
9      if (EM[0] != 0) {
10         throw new BadPaddingException(
11           "Data must start with zero");
12     }
13     ...
```

Figure 12: OAEP unpadding function of Java 7.

OAEP Comes to the Rescue. Many problems related to the *old* PKCS#1 are supposed to disappear with the introduction of OAEP [14]. However, during our research we also found problems in Java's OAEP processing. Listing 12 shows the code of Java's `RSAPadding.java` class which contains the logic for OAEP processing.

Line 9-12 outline a conditional branch that could be used to apply Manger's attack [19]. Patching is required. This example shows that OAEP is only of help if implemented correctly, i.e. without side channels.

We notified Oracle about this issue. The code was patched in the Java release from April 2014.

13 Conclusion

The problem of side channels leaking partial information about cryptographic computations seems to be much more persistent than expected: Error messages from standard libraries, and especially timig issues make generic solutions impossible.

The results of this paper show that Bleichenbacher attacks can still be used to break SSL/TLS implementations. Timing side channels underline the need for cryptographic libraries with branch independent, nearly time constant execution paths. The uncovered side channels motivate for the development of cryptographic penetration testing tools, able to detect such implementation deficiencies in the development phase.

Our results are alarming, especially when considering that Bleichenbacher attacks are known for about 15 years. They also show that PKCS#1 compliance checking is of prime importance to the security of a TLS implementations: Strict checks on TLS-PKCS#1 compli-

ance as performed by OpenSSL prevent Bleichenbacher attacks, even if side channels are present.

The question whether the introduction of RSA-OAEP padding would solve the problem still remains open: Only if RSA-OAEP is implemented without any side channels, the cryptographic features of this padding scheme can be enforced.

Acknowledgements

We would like to thank Graham Steel for providing us their improved Bleichenbacher attack code [4], and the security teams of Oracle, Cavium, IBM and F5 for their cooperation.

Furthermore, we would like to thank Tibor Jager, Christian Mainka, James Manger, and anonymous reviewers for their comments.

Abstract

We present Burst ORAM, the first oblivious cloud storage system to achieve both practical response times and low total bandwidth consumption for bursty workloads. For real-world workloads, Burst ORAM can attain response times that are nearly optimal and orders of magnitude lower than the best existing ORAM systems by reducing online bandwidth costs and aggressively rescheduling shuffling work to delay the bulk of the IO until idle periods.

We evaluate our design on an enterprise file system trace with about 7,500 clients over a 15 day period, comparing to an insecure baseline encrypted block store without ORAM. We show that when baseline response times are low, Burst ORAM response times are comparably low. In a 32TB ORAM with 50ms network latency and sufficient bandwidth capacity to ensure 90% of requests have baseline response times under 53ms, 90% of Burst ORAM requests have response times under 63ms, while requiring only 30 times the total bandwidth consumption of the insecure baseline. Similarly, with sufficient bandwidth to ensure 99.9% of requests have baseline responses under 70ms, 99.9% of Burst ORAM requests have response times under 76ms.

1 Introduction

Cloud computing allows customers to outsource the burden of data management and benefit from economy of scale, but privacy concerns hinder its growth [3]. Encryption alone is insufficient to ensure privacy in storage outsourcing applications, as information about the contents of encrypted records may still leak via data access patterns. Existing work has shown that access patterns on an encrypted email repository may leak sensitive keyword search queries [12], and that accesses to encrypted database tuples may reveal ordering information [5].

Oblivious RAM (ORAM), first proposed in a groundbreaking work by Goldreich and Ostrovsky [8, 9], is a cryptographic protocol that allows a client to provably hide access patterns from an untrusted storage server. Recently, the research community has focused on making ORAM schemes practical for real-world applications [7, 11, 21, 23–25, 27]. Unfortunately, even with recent improvements, ORAMs still incur substantial bandwidth and response time costs.

Many prior ORAM works focus on minimizing bandwidth consumption. Several recent works on cloud-based ORAMs achieve low bandwidth costs using a large amount of client-side storage [11, 23, 24]. Others rely on expensive primitives like PIR [17] or additional assumptions such as trusted hardware [15] or non-colluding servers [22] to reduce bandwidth costs.

To be practical, ORAM must also minimize response times observed by clients for each request. We propose Burst ORAM, a novel ORAM that dramatically reduces response times for realistic workloads with bursty characteristics. Burst ORAM is based on ObliviStore [23], the most bandwidth-efficient existing ORAM.

Burst ORAM uses novel techniques to minimize the *online* work of serving requests and delay *offline* block shuffling until idle periods. Under realistic bursty loads, Burst ORAM achieves orders of magnitude shorter response times than existing ORAMs, while retaining total bandwidth costs less than 50% higher than ObliviStore's.

During long bursts, Burst ORAM's behavior automatically and gracefully degrades to be similar to that of ObliviStore. Thus, even in a worst-case workload, Burst ORAM's response times and bandwidth costs are competitive with those of existing ORAMs.

We simulate Burst ORAM on a real-world corporate data access workload (7,500 clients and 15 days) to show that it can be used practically in a corporate cloud storage environment. We compare against an insecure baseline encrypted block store without ORAM and show that when baseline response times are low, Burst ORAM response times are also low. In a 32TB ORAM with 50ms network latency and sufficient bandwidth capacity to ensure 90% of requests have baseline response times un-

der 53ms, 90% of Burst ORAM requests have response times under 63ms. Similarly, with sufficient bandwidth to ensure 99.9% of requests have baseline responses under 70ms, 99.9% of Burst ORAM requests have response times under 76ms. Existing works exhibit response times on the order of seconds or higher, due to high bandwidth [11, 23, 25, 28] or computation [17] requirements. To our knowledge, our work is the first to evaluate ORAM response times on a realistic, bursty workload.

As in previous ORAM schemes, we do not seek to hide the timing of data requests. Thus, we assume request start times and durations are known. To ensure security, we do not allow the IO scheduler to make use of the data access sequence or other sensitive information. We analyze Burst ORAM security in Section 6.4.

1.1 Burst ORAM Contributions

Burst ORAM introduces several techniques for reducing response times and keeping bandwidth costs low that distinguish it from ObliviStore and other predecessors.

Novel scheduling policies. Burst ORAM prioritizes the *online* work that must be complete before requests are satisfied. If possible, our scheduler delays shuffle work until off-peak times. Delaying shuffle work consumes client-side storage, so if a burst is sufficiently long, client space will fill, forcing shuffling to resume. By this time, there are typically multiple shuffle jobs pending.

We use a greedy strategy to prioritize jobs that free the most client-side space per unit of shuffling bandwidth consumed. This strategy allows us to sustain lower response times for longer during an extended burst.

Reduced online bandwidth costs. We propose a new *XOR technique* that reduces the online bandwidth cost from $O(\log N)$ blocks per request in ObliviStore to nearly 1, where N is the outsourced block count. The XOR technique can also be applied to other ORAM implementations such as SR-ORAM [26] (see Appendix B).

Level caching. We propose a new technique for using additional available client space to store small levels from each partition. By caching these levels on the client, we are able to reduce total bandwidth cost substantially.

1.2 Related Work

Oblivious RAM was first proposed in a seminal work by Goldreich and Ostrovsky [9]. Since then, a fair amount of theoretic work has focused on improving its asymptotic performance [1, 4, 10, 11, 13, 18, 19, 21, 24, 27]. Recently, there has been much work designing and optimizing ORAM for cloud-based storage outsourcing settings, as noted below. Different ORAMs provide varying trade-offs between bandwidth cost, client/server storage, round complexity, and computation.

ORAM has been shown to be feasible for secure (co-)processor prototypes, which prevent information leakage due to physical tampering [6, 15, 16, 20]. Since on-chip trusted cache is expensive, such ORAM schemes need constant or logarithmic client-side storage, such as the binary-tree ORAM [21] and its variants [7, 17, 25].

In cloud-based ORAMs, the client typically has more space, capable of storing $O(\sqrt{N})$ blocks or a small amount of per-block metadata [10, 23, 24, 28] that can be used to reduce ORAM bandwidth costs. Burst ORAM also makes such client space assumptions.

Online and offline costs for ORAM were first made explicit by Boneh et al. [1] They propose a construction that has $O(1)$ online but $O(\sqrt{N})$ overall bandwidth cost. The recent Path-PIR work by Mayberry et al. [17] mixes ORAM and PIR to achieve $O(1)$ online bandwidth cost with an overall bandwidth cost of $O(\log^2 N)$ with constant client memory. Unfortunately, the PIR is still computationally expensive, so their scheme requires more than 40 seconds for a read from a 1TB database [17]. Burst ORAM has $O(1)$ online and $O(\log N)$ overall bandwidth cost, without the added overhead of PIR.

Other ORAMs that do not rely on trusted hardware or non-colluding servers have $\Omega(\log N)$ online bandwidth cost including works by Williams, Sion, et al. [27, 28]; by Goodrich, Mitzenmacher, Ohrimenko, and Tamassia [10, 11]; by Kushilevitz et al. [13]; and by Stefonov, Shi, et al. [21, 23–25]. Burst ORAM handles bursts much more effectively by reducing the online cost to nearly 1 block transfer per block request during a burst, greatly reducing response times.

2 Preliminaries

2.1 Bandwidth Costs

Bandwidth consumption is the primary cost in many modern ORAMs, so it is important to define how we measure its different aspects. Each block transferred between the client and server is a single unit of IO. We assume that blocks are large in practice (at least 1KB), so transferred meta-data (block IDs) have negligible size.

Definition 1 *The* bandwidth cost *of a storage scheme is given by the average number of blocks transferred in order to read or write a single block.*

We identify bandwidth costs by appending X to the number. A bandwidth cost of 2X indicates two blocks transferred per request, which is twice the cost of an unprotected scheme. We consider *online*, *offline*, *effective*, and *overall* IO and bandwidth costs, where each cost is given by the average amount of the corresponding type of IO.

Online IO consists of the block transfers needed before a request can be safely marked as satisfied, assuming the scheme starts with no pending IO. The *online bandwidth cost* of a storage scheme without ORAM is just 1X — the

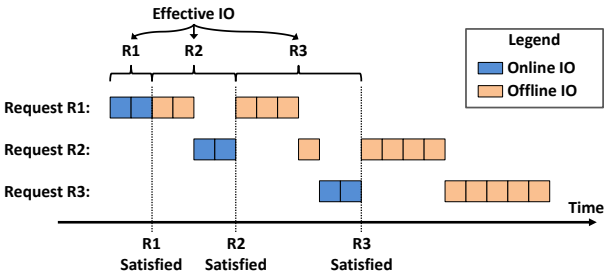

Figure 1: Simplified scheme with sequential IO and contrived capacity for delaying offline IO. 3 requests require same online (2), offline (5), and overall (7) IO. Online IO for R1 is handled immediately, so R1's effective IO is only 2. R2 waits for 2 units of offline IO from R1, so its effective IO is 4. R3 waits for the rest of R1's offline IO, plus one unit of R2's offline IO, so its effective IO is 6.

IO cost of downloading the desired block. In ORAM it may be higher, as additional blocks may be downloaded to hide the requested block's identity.

Offline IO consists of transfers needed to prepare for subsequent requests, but which may be performed after the request is satisfied. Without ORAM, the *offline bandwidth cost* is 0X. In ORAM it is generally higher, as additional *shuffle IO* is needed to obliviously permute blocks in order to guarantee privacy for future requests.

Overall IO / bandwidth cost is just the sum of the online and offline IO / bandwidth costs, respectively.

Effective IO consists of all online IO plus any pending offline IO from previous requests that must be issued before the next request can be satisfied. Without ORAM, effective IO and online IO are equal. In traditional ORAMs, offline IO is issued immediately after each request's online IO, so effective and overall IO are equal. In Burst ORAM, we delay some offline IO, reducing each request's effective IO as illustrated in Figure 1. Smaller effective costs mean less IO between requests, and ultimately shorter response times.

ORAM reads and writes are indistinguishable, so writes have the same bandwidth costs as reads.

2.2 Response Time

The *response time* of a block request (ORAM read/write operation) is defined as the lapse of wall-clock time between when the request is first issued by the client and when the client receives a response. The *minimum* response time is the time needed to perform all online IO. Response times increase when offline IO is needed between requests, increasing effective IO, or when requests are issued rapidly in a burst, delaying later requests.

2.3 ObliviStore ORAM

Burst ORAM builds on ObliviStore [23], so we give an overview of the scheme here. A full description of the ObliviStore system and its ORAM algorithm spans about 55 pages [23, 24], so we describe it at a high level, focusing only on components relevant to Burst ORAM.

Partitions and levels. ObliviStore stores N logical data blocks. Each block is encrypted using a standard symmetric key encryption scheme before it is stored on the server. Every time a block is uploaded by the client, it is re-encrypted using a new nonce to prevent linking.

ObliviStore securely splits blocks into $O(\sqrt{N})$ *partitions* of $O(\sqrt{N})$ blocks each. Each partition is an ORAM consisting of $O(\log N)$ *levels* with $2,4,8,\ldots,O(\sqrt{N})$ blocks each. Newly created levels are filled with half encrypted real blocks and half encrypted dummies, randomly permuted so that reals and dummies are indistinguishable to the server. Each level is occupied only half the time on average. The client has space to store $O(\sqrt{N})$ blocks and the locations of all N blocks.

Requests. When the client makes a block request, whether a read or write, the block must first be downloaded from the appropriate partition. To maintain obliviousness, ObliviStore must fetch one block from every non-empty level in the target partition ($O(\log N)$ blocks of *online* IO). Only one fetched block is real, and the rest are dummies, except in the case of early shuffle reads described below. Once a dummy is fetched, it is discarded, and new dummies are created later as needed. ObliviStore securely processes multiple requests in parallel, enabling full utilization of available bandwidth capacity.

Eviction. Once the real block is fetched, it is updated or returned to the client as necessary, then ranodmly assigned to a new partition p. The block is not immediately uploaded, but is scheduled for *eviction* to p and stored in a client-side *data cache*. An independent eviction process later obliviously evicts the block from the cache to p. The eviction triggers a write operation on p's ORAM, which creates or enlarges a *shuffling job* for p.

Shuffling Jobs. Each partition p has at most one pending *shuffle job*. A job consists of downloading up to $O(\sqrt{N})$ blocks from p, permuting them on the client with recent evictions and new dummies, and uploading. Shuffle jobs incur *offline* IO, and vary in *size* (amount of IO) from $O(1)$ to $O(\sqrt{N})$. Intuitively, to ensure that non-empty levels have at least one dummy left, we must re-shuffle a level once half its blocks have been removed. Larger levels need shuffling less often, so larger jobs occur less frequently, keeping offline bandwidth costs at $O(\log N)$.

Shuffle IO scheduling. A fixed amount of $O(\log N)$ shuffle IO is performed after each request to amortize the work required for large jobs. The IO for jobs from multi-

ple partitions may be executed in parallel: while waiting on reads for one partition, we may issue reads or writes for another. Jobs are started in the order they are created.

Early shuffle reads. *Early shuffle reads*, referred to as *early cache-ins* or *real cache-ins* in ObliviStore, occur when a request needs to fetch a block from a level, but at least half the level's original blocks have been removed. In this case, we cannot guarantee that any dummies remain. Thus, early shuffle reads must be treated as real blocks and stored separately by the client until they are returned to the server as part of a shuffle job. We call such reads *early shuffle reads* since the blocks would have eventually been read during a shuffle job. Early shuffle reads are infrequent, but made possible since ObliviStore performs requests while shuffling is in progress.

Level compression. ObliviStore uses a technique called *level compression* [24] to compress blocks uploaded during shuffling. It allows the client to upload k real and k dummy blocks using only k blocks of bandwidth without revealing which k are dummies. Level compression reduces only the offline (shuffling) bandwidth cost.

3 Overview of our Approach

Traditional ORAMs focus on reducing average and worst-case *overall bandwidth costs* (per-request overall IO). However, even the most bandwidth-efficient schemes [23, 24] suffer from a 20X–35X bandwidth cost.

In this paper, we instead focus on reducing *effective* IO by reducing online IO and delaying offline IO. We can then satisfy bursts of requests quickly, delaying most IO until idle periods. Figure 2 illustrates this concept.

Our approach allows many bursts to be satisfied with nearly a 1X effective bandwidth cost. That is, during the burst, we transfer just over one block for every block requested. After the burst we do extra IO to catch up on shuffling and prepare for future requests. Our approach maintains an overall bandwidth cost less than 50% higher than [23, 24] in practice (see Figure 12 in Section 7).

Bursts. Intuitively, a burst is a period of frequent block requests from the client preceded and followed by relatively idle periods. Many real-world workloads exhibit bursty patterns (e.g. [2, 14]). Often, bursts are not discrete events, such as when multiple network file system users are operating concurrently. Thus we handle bursts fluidly: the more requests issued at once, the more Burst ORAM tries to delay offline IO until idle periods.

Challenges. We are faced with two key challenges when building a burst-friendly ORAM system. The first is ensuring that we maintain security. A naive approach to reducing online IO may mark requests as satisfied before enough blocks are read from the server, leaking information about the requested block's identity.

The second challenge is ensuring that we maximally utilize client storage and available bandwidth while avoiding deadlock. An excessively aggressive strategy that delays too much IO may use so much client space that we run out of room to shuffle. It may also under-utilize available bandwidth, increasing response times. On the other hand, an overly conservative strategy may under-utilize client space or perform shuffling too early, delaying online IO and increasing response times.

Techniques and Outline. In Burst ORAM, we address these challenges by combining several novel techniques. In Section 4 we introduce our XOR technique for reducing online bandwidth cost to nearly 1X. We also describe our techniques for prioritizing online IO and delaying offline/shuffle IO until client memory is nearly full. In Section 5 we show how Burst ORAM prioritizes efficient shuffle jobs in order to delay the bulk of the shuffle IO even further, ensuring that we minimize effective IO during long bursts. We then introduce a technique for using available client space to cache small levels locally to reduce shuffle IO in both Burst ORAM and ObliviStore.

In Section 6 we discuss the system-level techniques used in Burst ORAM, and present its design in detail. In Section 7, we evaluate Burst ORAM's performance through micro-benchmarks and extensive simulations.

4 Prioritizing and Reducing Online IO

Existing ORAMs require high online and offline bandwidth costs to obscure access patterns. ObliviStore must fetch one block from every level in a partition (see Section 2.3), requiring $O(\log N)$ online IO per request. Figure 3 (left) illustrates this behavior. After each request, ObliviStore also requires $O(\log N)$ offline/shuffle IO. Since ObliviStore issues online and offline IO before satisfying the next request, its effective IO is high, leading to large response times during bursts. Other ORAMs work differently, such as Path ORAM [25] which organizes data as a tree, but still have high effective costs. We now show how Burst ORAM achieves lower effective bandwidth costs and response times than ObliviStore.

4.1 Prioritizing Online IO

One way we achieve low response times in Burst ORAM is by prioritizing online IO over shuffle IO. That is, we suppress shuffle IO during bursts, delaying it until idle periods. Requests are satisfied once online IO finishes,[1] so prioritizing online IO allows us to satisfy all requests before any shuffle IO starts, keeping response times low even for later requests. Figure 2 illustrates this behavior.

During the burst, we continue processing requests by fetching blocks from the server, but since shuffling is suppressed, no blocks are uploaded. Thus, we must resume shuffling once client storage fills. Section 5.2 dis-

[1] Each client write also incurs a read, so writes still incur online IO.

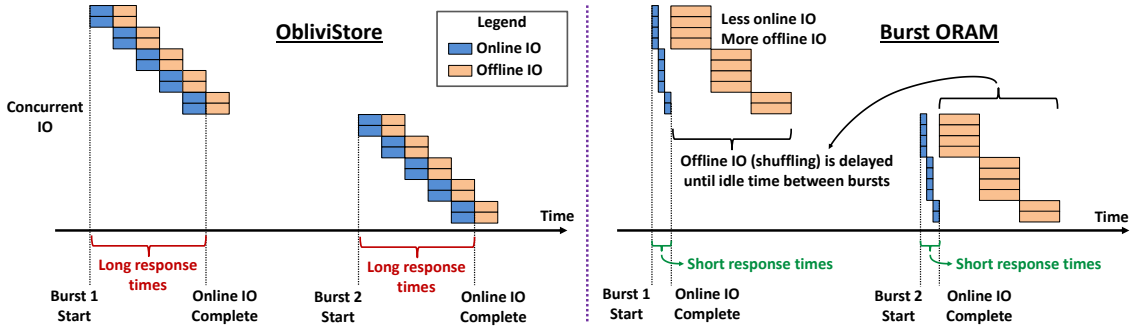

Figure 2: **Reducing response time.** Because Burst ORAM (right) does much less online IO than ObliviStore (left) and delays offline IO, it is able to respond to ORAM requests much faster. In this (overfly simplified) illustration, the bandwidth capacity is enough to transfer 4 blocks concurrently. Both ORAM systems do the same amount of IO.

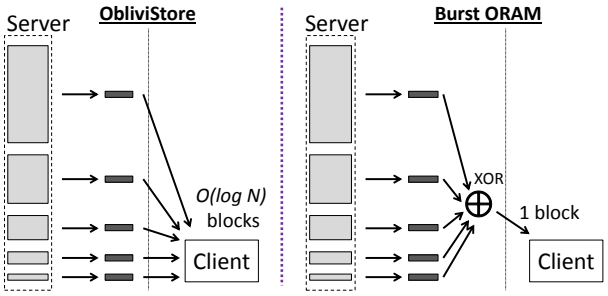

Figure 3: **Reducing online cost.** In ObliviStore (left) the online bandwidth cost is $O(\log N)$ blocks of IO on average. In Burst ORAM (right), we reduce online IO to only one block, improving handling of bursty traffic.

cusses how to delay shuffle IO even further. Section 6 details changes from the ObliviStore design required to avoid deadlock and fully utilize client space.

When available bandwidths are large and bursts are short, the response time saved by prioritizing online IO is limited, as most IO needed for the burst can be issued in parallel. However, when bandwidth is limited or bursts are long, the savings can be substantial. With shuffle IO delayed until idle times, online IO dominates the effective IO, becoming the bottleneck during bursts. Thus we can further reduce response times by reducing online IO.

4.2 XOR Technique: Reducing Online IO

We introduce a new mechanism called the *XOR technique* that allows the Burst ORAM server to combine the $O(\log N)$ blocks fetched during a request into a single block that is returned to the client (Figure 3 right), reducing the online bandwidth cost to $O(1)$.

If we fetched only the desired block, we would reveal its identity to the server. Instead, we XOR all the blocks together and return the result. Since there is at most one real block among the $O(\log N)$ returned, the client can locally reconstruct the dummy block values and XOR them with the returned block to recover the encrypted real block. XOR technique steps are shown in Figure 4.

4.2.1 XOR Technique Details

In Burst ORAM, as in ObliviStore, each request needs to retrieve a block from a single *partition*, which is a simplified hierarchical ORAM resembling those in [9]. The hierarchy contains $L \approx \frac{1}{2}\log_2 N$ levels with real-block capacities $1, 2, 4, \ldots, 2^{L-1}$ respectively.

To retrieve a requested block, the client must fetch exactly one block from each of the L levels. The XOR technique requires that the client be able to reconstruct dummy blocks, and that dummies remain indistinguishable from real blocks. We achieve this property by encrypting a real block b residing in partition p, level ℓ, and offset *off* as $\mathsf{AES}_{sk_{p,\ell}}(off||B)$. We encrypt a dummy block residing in partition p, level ℓ, and offset *off* as $\mathsf{AES}_{sk_{p,\ell}}(off)$. The key $sk_{p,\ell}$ is specific to partition p and level ℓ, and is randomized every time ℓ is rebuilt.

For simplicity, we start by considering the case without early shuffle reads. In this case, exactly one of the L blocks requested is the encryption of a real block, and the rest are encryptions of dummy blocks. The server XORs all L encrypted blocks together into a single block X_Q that it returns to the client. The client knows which blocks are dummies, and knows p, ℓ, off for each block, so it reconstructs all the encrypted dummy blocks and XORs them with X_Q to obtain the encrypted requested/real block.

4.2.2 Handling early shuffle reads

An early shuffle read occurs when we need to read from a level with no more than half its original blocks remaining. Since such early shuffle reads may be real blocks, they cannot be included in the XOR. Fortunately, the number of blocks in a level is public, so the server already knows which levels will cause early shuffle reads. Thus, the server simply returns early shuffle reads individually, then XORs the remaining blocks, leaking no information about the access sequence.

1. Client issues block requests to server, one per level
2. Server, to satisfy request
   (a) Retrieves and returns early shuffle reads
   (b) XORs remaining blocks together into single *combined* block and returns it
3. Client, while waiting for response
   (a) Regenerates encrypted dummy block for each non-early-shuffle-read
   (b) XORs all dummies to get *subtraction* block
4. Client receives combined block from server and XORs with subtraction block to get requested block
5. Client decrypts requested block

Figure 4: XOR Technique Steps

Since each early shuffle read block must be transferred individually, early shuffle reads increase online IO. Fortunately, early shuffle reads are rare, even while shuffling is suppressed during bursts, so the online bandwidth cost stays under 2X and near 1X in practice (see Figure 7).

4.2.3 Comparison with ObliviStore

ObliviStore uses *level compression* to reduce shuffle IO. When the client uploads a level to the server, it first compresses the level down to the combined size of the level's real blocks. Since half the blocks are dummies, half the upload shuffle IO is eliminated. For details on level compression and its security, see [24].

Unfortunately, Burst ORAM's XOR technique is incompatible with level compression due to discrepancies in the ways dummy blocks must be formed. The XOR technique requires that the client be able to reconstruct dummy blocks locally, so in Burst ORAM, each dummy's position determines its contents. In level compression, each level's dummy block contents are a function of the level's real block contents. Since the client cannot know the contents of all real blocks in the level, it cannot reconstruct the dummies locally.

Level compression and the XOR technique yield comparable overall IO reductions, though level compression performs slightly better. For example, the experiment in Figure 8 incurs roughly 23X and 26X overall bandwidth cost using level compression and XOR respectively. However, the XOR technique reduces *online* IO, while level compression reduces *offline* IO, so the XOR technique is more effective at reducing response times.

5 Scheduling and Reducing Shuffle IO

In Burst ORAM, once client space fills, we must start shuffling in order to return blocks to the server and continue the burst. If we are not careful about shuffle IO scheduling, we may immediately start doing large amounts of IO, dramatically increasing response times.

In this section, we show how Burst ORAM schedules shuffle IO so that jobs that free the most client space using the least shuffle IO are prioritized. Thus, at all times, Burst ORAM issues only the minimum amount of effective IO needed to continue the burst, keeping response times lower for longer. We also show how to reduce overall IO by locally caching the smallest levels from each partition. We start by defining *shuffle jobs*.

5.1 Shuffle Jobs

In Burst ORAM, as in ObliviStore, shuffle IO is divided into per-partition *shuffle jobs*. Each job represents the work needed to shuffle a partition p and upload blocks evicted to p. A shuffle job is defined by five entities:

- A partition p to which the job belongs
- Blocks evicted to but not yet returned to p
- Levels to read blocks from
- Levels to write blocks to
- Blocks already read from p (early shuffle reads)

Each shuffle job moves through three phases:

Creation Phase. We create a shuffle job for p when a block is evicted to p following a request. Every job starts out *inactive*, meaning we have not started work on it. If another block is evicted to p, we update the sets of eviction blocks and read/write levels in p's inactive job.

When Burst ORAM *activates* a job, it moves the job to the *Read Phase*, freezing the eviction blocks and read/write levels. Subsequent evictions to p will create a new *inactive* shuffle job. At any time, there is at most one active and one inactive shuffle job for each partition.

Read Phase. Once a shuffle job is activated, we begin fetching all blocks still on the server that need to be shuffled. That is, all previously unread blocks from all the job's read levels. Once all such blocks are fetched, they are *shuffled* with all blocks evicted to p and any early shuffle reads from the read levels. Shuffling consists of adding/removing dummies, pseudo-randomly permuting the blocks, and then re-encrypting each block. Once shuffling completes, we move the job to the *Write Phase*.

Write Phase. Once a job is shuffled we begin storing all shuffled blocks to the job's write levels on the server. Once all writes finish, the job is marked complete, and Burst ORAM is free to activate p's inactive job, if any.

5.2 Prioritizing Efficient Jobs

Since executing shuffle IO delays the online IO needed to satisfy requests, we can reduce response times by doing as little shuffling as is needed to free up space. The hope is that we can delay the bulk of the shuffling until an idle period, so that it does not interfere with pending requests.

By the time client space fills, there will be many partitions with inactive shuffle jobs. Since we can choose jobs in any order, we can minimize the up-front shuffling work by prioritizing the most *efficient* shuffle jobs: those

that free up the most client space per unit of shuffle IO. The space freed by completing a job for partition p is the number of blocks evicted to p plus the number of early shuffle reads from the job's read levels. Thus, we can define shuffle job efficiency as follows:

$$\text{Job Efficiency} = \frac{\#\text{ Evictions} + \#\text{ Early Shuffle Reads}}{\#\text{ Blocks to Read} + \#\text{ Blocks to Write}}$$

Job efficiencies vary substantially. Most jobs start with 1 eviction and 0 early shuffle reads, so their relative efficiencies are determined strictly by the sizes of the job's read and write levels. If the partition's bottom level is empty, no levels need be read, and only the bottom must be written, for an overall IO of 2 an an efficiency of 0.5. If instead the bottom 4 levels are occupied, all 4 levels must be read, and the 5th level written, for an total of roughly 15 reads and 32 writes, yielding a much lower efficiency of just over 0.02. Both jobs free equal amounts of space, but the higher-efficiency job uses less IO.

Since small levels are written more often than large ones, efficient jobs are common. Further, by delaying an unusually inefficient job, we give it time to accumulate more evictions. While such a job will also accumulate more IO, the added write levels are generally small, so the job's efficiency tends to improve with time. Thus, prioritizing efficient jobs reduces shuffle IO during the burst, thereby reducing response times.

Unlike Burst ORAM, ObliviStore does not use client space to delay shuffling, so there are fewer shuffle jobs to choose from at any one time. Thus, job scheduling is less important and jobs are chosen in creation order. Since ObliviStore is concerned with throughput, not response times, it has no incentive to prioritize efficient jobs.

5.3 Reducing Shuffle IO via Level Caching

Since small, efficient shuffle jobs are common, Burst ORAM spends a lot of time accessing small levels. If we use client space to locally cache the smallest levels of each partition, we can eliminate the shuffle IO associated with those levels entirely. Since levels are shuffled with a frequency inversely proportional to their size, each is responsible for roughly the same fraction of shuffle IO. Thus, we can greatly reduce shuffle IO by caching even a few levels from each partition. Further, since caching a level eliminates its early shuffle reads, which are common for small levels, caching can also reduce online IO.

We are therefore faced with a tradeoff between using client space to store requested blocks, which reduces response times for short bursts, and using it for local level caching, which reduces overall bandwidth cost.

5.3.1 Level Caching in Burst ORAM

In Burst ORAM, we take a conservative approach, and cache only as many levels as are guaranteed to fit in the worst case. More precisely, we identify the maximum number λ such that the client could store all real blocks from the smallest λ levels of every partition even if all were full simultaneously. We cache levels by only updating an inactive job when the number of evictions is such that all the job's write levels have index at least λ.

Since each level is only occupied half the time, caching λ levels consumes at most half of the client's space on average, leaving the rest for requested blocks. As we show experimentally in Section 7, level caching greatly reduces overall bandwidth cost, and can even reduce response times since it avoids early shuffle reads.

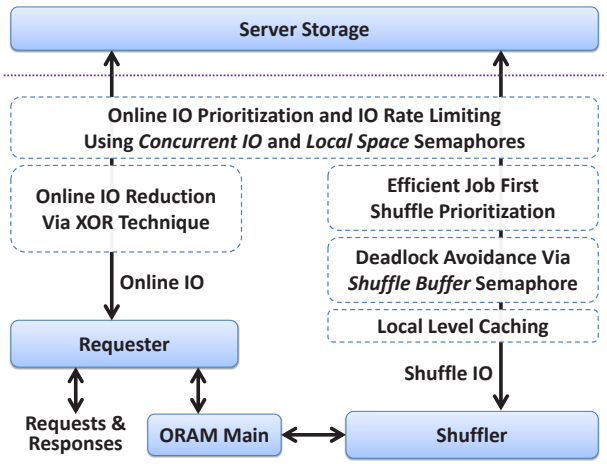

Figure 5: **Burst ORAM Architecture.** Solid boxes represent key system components, while dashed boxes represent functionality and the effects of the system on IO.

6 Detailed Burst ORAM Design

The Burst ORAM design is based on ObliviStore, but incorporates many fundamental functional and system-level changes. For example, Burst ORAM replaces or revises all the semaphores used in ObliviStore to achieve our distinct goal of online IO prioritization while maintaining security and avoiding deadlock. Burst ORAM also maximizes client space utilization, implements the XOR technique to reduce online IO, revises the shuffler to schedule efficient jobs first, and implements level caching to reduce overall IO.

6.1 Overall Architecture

Figure 5 presents the basic architecture of Burst ORAM, highlighting key components and functionality. Burst ORAM consists of two primary components, the online *Requester* and the offline *Shuffler*, which are controlled by the main event loop *ORAM Main*. Client-side memory allocation is shown in Figure 6.

ORAM Main accepts new block requests (reads and writes) from the client, and adds them to a *Request*

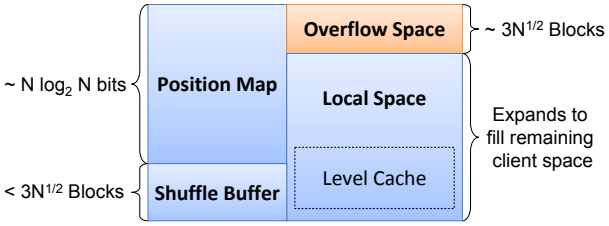

Figure 6: **Burst ORAM Client Space Allocation.** Fixed client space is reserved for the position map and shuffle buffer. A small amount of overflow space is needed for blocks assigned but not yet evicted (*data cache* in [24]). Remaining space is managed by *Local Space* and contains evictions, early shuffle reads, and the level cache.

Queue. On each iteration, ORAM Main tries advancing the Requester first, only advancing the Shuffler if the Requester needs no IO, thereby prioritizing online IO. The Requester and Shuffler use *semaphores* (Section 6.2) to regulate access to network bandwidth and client space.

The *Requester* reads each request from the Request Queue, identifies the desired block's partition, and fetches it along with any necessary dummies. To ensure oblivious behavior, the Requester must wait until all dummy blocks have been fetched before marking the request satisfied. All Requester IO is considered *online*.

The *Shuffler* re-encrypts blocks fetched by the Requester, shuffles them with other blocks, and returns them to the server. The Shuffler is responsible for managing shuffle jobs, including prioritizing efficient jobs and implementing level caching. All IO initiated by the shuffler is considered *offline* or *shuffle* IO.

6.2 Semaphores

Resources in Burst ORAM are managed via *semaphores*, as in ObliviStore. Semaphores are updated using only server-visible information, so ORAM can safely base its behavior on semaphores without revealing new information. Since Burst ORAM gives online IO strict priority over shuffle IO, our use of semaphores is substantially different than ObliviStore's, which tries to issue the same amount of IO after each request. ObliviStore uses four semaphores: *Shuffling Buffer*, *Early Cache-ins*, *Eviction*, and *Shuffling IO*. In Burst ORAM, we use three:

- *Shuffle Buffer* manages client space reserved for blocks from active shuffle jobs, and differs from ObliviStore's *Shuffling Buffer* only in initial value.
- *Local Space* manages all remaining space, combining ObliviStore's *Early Cache-in* and *Eviction* semaphores.
- *Concurrent IO* manages concurrent block transfers based on network link capacity, preventing the Shuffler from starving the Requester. It differs fundamentally from ObliviStore's *Shuffling IO* semaphore, which manages per-request shuffle IO.

***Shuffle Buffer* semaphore.** *Shuffle Buffer* gives the number of blocks that may be added to the client's shuffle buffer. We initialize it to double the maximum partition size (under $2.4\sqrt{N}$ total for $N > 2^{10}$), to ensure that the shuffle buffer is large enough to store at least two in-progress shuffle jobs. When *Shuffle Buffer* reaches 0, the Shuffler may not issue additional reads.

***Local Space* semaphore.** *Local Space* gives the number of blocks that may still be stored in remaining client space (space not reserved for the position map or shuffle buffer). If *Local Space* is 0, the Requester may not fetch more blocks. Blocks fetched by the Requester count toward *Local Space* until their partition's shuffle job is activated and they are absorbed into *Shuffle Buffer*. Once a block moves from *Local Space* to *Shuffle Buffer*, it is considered *free* from the client, and more requests may be issued. The more client space, the higher *Local Space*'s initial value, and the better our burst performance.

***Concurrent IO* semaphore.** *Concurrent IO* is initialized to the network link's block capacity. Queuing a block transfer decrements *Concurrent IO*, and completing a transfer increments *Concurrent IO*. The Shuffler may only initiate a transfer if *Concurrent IO* > 0. However, the Requester may continue to initiate transfers and decrement *Concurrent IO* even if it is negative. This mechanism ensures that no new shuffle IO starts while there is sufficient online IO to fully utilize the link. If no online IO starts, *Concurrent IO* eventually becomes positive, and shuffle IO resumes, ensuring full utilization.

6.3 Detailed System Behavior

We now describe the interaction between ORAM Main, the Requester, the Shuffler, and the semaphores in detail. Accompanying pseudocode can be found in Appendix A.

ORAM Main (Algorithm 1). Incoming read and write requests are asynchronously added to the Request Queue. During each iteration, ORAM Main first tries to advance the Requester, which attempts to satisfy the next request from the Request Queue. If the queue is empty, or *Local Space* too low, ORAM Main advances the Shuffler instead. This mechanism suppresses new shuffle IO during a new burst of requests until the Requester has fetched as many blocks as possible.

For each request, we evict v blocks to randomly chosen partitions, where v is the *eviction rate*, set to 1.3 as in ObliviStore [23]. When evicting, if the Requester has previously assigned a block to be evicted to partition p, then we evict that block. If there are no assigned blocks, then to maintain obliviousness we evict a new dummy block instead. Eviction does not send a block to the server immediately. It merely informs the Shuffler that

the block is ready to be shuffled into p.

Requester (Algorithm 2). To service a request, the Requester first identifies the partition and level containing the desired block. It then determines which levels require early shuffle reads, and which need only standard reads. If *Local Space* is large enough to accommodate the retrieved blocks, the requester issues an asynchronous request for the necessary blocks Else, control returns to ORAM Main, giving the Shuffler a chance to free space.

The server asynchronously returns the early shuffle read blocks and a single *combined* block obtained from all standard-read blocks using the XOR technique (Section 4). The Requester extracts the desired block from the combined block or from an early shuffle read block, then updates the block (write) or returns it to the client (read). The Requester then assigns the desired block for eviction to a randomly chosen partition.

Shuffler (Algorithm 3). The Shuffler may only proceed if *Concurrent IO* > 0. Otherwise, there is pending online IO, which takes priority over shuffle IO, so control returns to ORAM Main without any shuffling.

The Shuffler places shuffle jobs into three queues based on phase. The *New Job Queue* holds inactive jobs, prioritized by efficiency. The *Read Job Queue* holds active jobs for which some reads have been issued, but not all reads are complete. The *Write Job Queue* holds active jobs for which all reads, not writes, are complete.

If all reads have been issued for all jobs in the *Read Job Queue*, the Shuffler *activates* the most efficient job from the *New Job Queue*, if any. *Activating* a job moves it to the *Read Job Queue* and freezes its read/write levels, preventing it from being updated by subsequent evictions. It also moves the job's eviction and early shuffle read blocks from *Local Space* to *Shuffle Buffer*, freeing up *Local Space* to handle online requests. By ensuring that all reads for all active jobs are issued before activating new jobs, we avoid hastily activating inefficient jobs.

The Shuffler then tries to decrement *Shuffle Buffer* to determine whether a shuffle read may be issued. If so, the Shuffler asynchronously fetches a block for a job in the *Read Job Queue*. If not, the Shuffler asynchronously writes a block from a job in the *Write Job Queue* instead. Unlike reads, writes do not require *Shuffle Buffer* space, so they can always be issued. The Shuffler prioritizes reads since they are critical prerequisites to activating new jobs and freeing up *Local Space*. The equally costly writes can be delayed until *Shuffle Buffer* space runs out.

Once all reads for a job complete, the job is *shuffled*: dummy blocks are added as needed, then all are permuted and re-encrypted. We then move the job to the *Write Job Queue*. When all writes finish, we mark the job complete and remove it from the *Write Job Queue*.

6.4 Burst ORAM Security

We assume the server knows *public* information such as the values of each semaphore and the start and end times of each request. The server also knows the level configuration of each partition and the size and phase of each shuffle job, including which encrypted blocks have been read from and written to the server. We must prevent the server from learning the contents of any encrypted block, or anything about which plaintext block is being requested. Thus, the server may not know the location of a given plaintext block, or even the prior location of any previously requested encrypted block.

All of Burst ORAM's publicly visible actions are, or appear to the server to be, independent of the client's sensitive data access sequence. Since Burst ORAM treats the server as a simple block store, the publicly visible actions consist entirely of deciding when to transfer which blocks. Intuitively, we must show that each action taken by Burst ORAM is either deterministic and dependent only on public information, or appears random to the server. Equivalently, we must be able to generate a sequence of encrypted block transfers that appears indistinguishable from the actions of Burst ORAM using only public information. We now show how each Burst ORAM component meets these criteria.

ORAM Main & Client Security. ORAM Main (Algorithm 1) chooses whether to advance the Requester or the Shuffler, and depends on the size of the request queue and the *Local Space* semaphore. Since the number of pending requests and the semaphores are public, ORAM Main is deterministic and based only on public information. For each eviction, the choice of partition is made randomly, and exactly one block will always be evicted. Thus, every action in Algorithm 1 is either truly random or based on public information, and is trivial to simulate.

Requester Security. The Requester (Algorithm 2) must first identify the partition containing a desired block. Since the block was assigned to the partition randomly and this is the first time it is being retrieved since it was assigned, the choice of partition appears random to the server. Within each partition, the requester deterministically retrieves one block from each occupied level. The choice from each level appears random, since blocks were randomly permuted when the level was created.

The Requester singles out early shuffle reads and returns them individually. The identity of levels that return early shuffle reads is public, since it depends on the number of blocks in the level. The remaining blocks are deterministically combined using XOR into a single returned block. Finally, the request is marked satisfied only after all blocks have been returned, so request completion time depends only on public information.

The Requester's behavior can be simulated using only

public information by randomly choosing a partition and randomly selecting one block from each occupied level. Blocks from levels with at most half their original blocks remaining should be returned individually, and all others combined using XOR and returned. Once all blocks have been returned, the request is marked satisfied.

Shuffler Security. As in ObliviStore, Shuffler (Algorithm 3) operations depend on public semaphores. Job efficiency, which we use for prioritizing jobs, depends on the number of blocks to be read and written to perform shuffling, as well as the number of early shuffle reads and blocks already *evicted* (not *assigned*). The identity of early shuffle read levels and the number of evictions is public. Further, the number of reads and writes depends only on the partition's level configuration. Thus, job efficiency and job order depend only on public information. Since the Shuffler's actions are either truly random (e.g. permuting blocks) or depend only on public information (i.e. semaphores), it is trivial to simulate.

Client Space. Since fetched blocks are assigned randomly to partitions, but evicted using an independent process, the number of blocks awaiting eviction may grow. The precise number of such blocks may leak information about where blocks were assigned, so it must be kept secret, and the client must allocate a fixed amount of space dedicated to storing such blocks (see *Overflow Space* in Figure 6). ObliviStore [23] relies on a probabilistic bound on overflow space provided in [24]. Since Burst ORAM uses ObliviStore's assignment and eviction processes, the bound holds for Burst ORAM as well. Level caching uses space controlled by the *Local Space* semaphore, so it depends only on public information.

7 Evaluation

We ran simulations comparing response times and bandwidth costs of Burst ORAM with ObliviStore and an insecure baseline, using real and synthetic workloads.

7.1 Methodology

7.1.1 Baselines

We compare Burst ORAM and its variants against two baselines. The first is the ObliviStore ORAM described in [23], including its level compression optimization. For fairness, we allow ObliviStore to use extra client space to locally cache the smallest levels in each partition. The second baseline is an insecure scheme without ORAM in which blocks are encrypted, but access patterns are not hidden. It transfers exactly one block per request.

We evaluate Burst ORAM against ObliviStore since ObliviStore is the most bandwidth-efficient existing ORAM scheme. Other schemes require less client storage [25], but incur higher bandwidth costs, and thus would yield higher response times. We did not include results from Path-PIR [17] because it requires substantially larger block sizes to be efficient, and its response times are dominated by the orthogonal consideration of PIR computation. Path-PIR reports response times in the 40–50 second range for comparably-sized databases.

7.1.2 Metrics

We evaluate Burst ORAM and our baselines using *response time* and *bandwidth cost* as metrics (see Section 2). We measure average, maximum, and p-percentile response times for various p. A p-percentile response time of t seconds indicates that p percent of the requests were satisfied with response times under t seconds.

We explicitly measure online, effective, and overall bandwidth costs. In the insecure baseline, all are 1X, so response times are minimal. However, if a burst has high enough frequency to saturate available bandwidth, requests may still pile up, yielding large response times.

7.1.3 Workloads

We use three workloads. The first consists of an endless burst of requests all issued at once, and compares changes in bandwidth costs of each scheme as a function of burst length. The second consists of two identical bursts with equally-spaced requests, separated by an idle period. It shows how response times change in each scheme before and after the idle period.

The third workload is based on the NetApp Dataset [2, 14], a corporate workload containing file system accesses from over 5000 corporate clients and 2500 engineering clients during 100 days. The file system uses 22TB of its 31TB of available space. More details about the workload are provided in the work by Leung et al. [14].

Our NetApp workload uses a 15 day period (Sept. 25 through Oct. 9) during which corporate and engineering clients were active. Requested chunk sizes range from a few bits to 64KB, with most at least 4KB [14]. Thus, we chose a 4KB block size. In total, 312GB of data were requested using $8.8 \cdot 10^7$ 4KB queries.

We configure the NetApp workload ORAM with a 32TB capacity, and allow 100GB of client space, for a usable storage increase of 328 times. For Burst ORAM and ObliviStore, at least 33GB is consumed by the position map, and only 64GB is used for local block storage. The total block count is $N = 2^{33}$. Blocks are divided into $\lfloor 2^{17}/3 \rfloor$ partitions to maximize server space utilization, each with an upper-bound partition size of 2^{18} blocks.

7.2 Simulator

We evaluated Burst ORAM's bandwidth costs and response times using a detailed simulator written in Java. The simulator creates an asynchronous event for each block to be transferred. We calculate the transfer's expected end time from the network latency, the network bandwidth, and the number of pending transfers.

Our simulator also measures results for ObliviStore and the insecure baseline. In all schemes, block requests are time-stamped as soon as they arrive, and serviced as soon as possible. Requests pile up indefinitely if they arrive more frequently than the scheme can handle them.

Burst ORAM's behavior is driven by semaphores and appears data-independent to the server. Each request reads from a partition that appears to be chosen uniformly at random, so bandwidth costs and response times depend only on request arrival times, not on requested block IDs or contents. Thus, the simulator need only store counters representing the number of remaining blocks in each level of each partition, and can avoid storing block IDs and contents explicitly.

Since the simulator need not represent blocks individually, it does not measure the costs of encryption, looking up block IDs, or performing disk reads for blocks. Thus, measured bandwidth costs and response times depend entirely on network latency, bandwidth capacity, request arrival times, and the scheme itself.

7.2.1 Extrapolating Results to Real-World Settings

Burst ORAM can achieve near-optimal performance for realistic bursty traffic patterns. In particular, in many real-life cases bandwidth is overprovisioned to ensure near-optimal response time under bursts – for the insecure baseline. However, in between bursts, most of the bandwidth is not utilized. Burst ORAM's idea is leveraging the available bandwidth in between bursts to ensure near-optimal response time during bursts.

Our simulation applies mainly to scenarios where the client-server bandwidth is the primary bandwidth bottleneck (i.e., client-server bandwidth is the narrowest pipe in the system), which is likely to be the case in a real-life outsourced storage scenario, such as a corporate enterprise outsourcing its storage to a cloud provider. While the simulation assumes that there is a single server, in practice, the server-side architecture could be more complicated and involve multiple servers interacting with each other. But as long as server-server bandwidth is not the bottleneck, our simulation results would be applicable. Similarly, we assume that the server's disk bandwidth is not a bottleneck. This is likely the case if fast Solid State Drives (SSD) are employed. For example, assuming 4KB blocks and only one such array of SSDs with a 100μs random 4KB read latency, our single-array throughput limits us to satisfying $10,000$ requests per second. In contrast, even a 1Gbps network connection lets us satisfy only $32,000$ requests per second. Thus, with even six such arrays ($3\log_2 N$ SSDs total), assigning roughly $\sqrt{N}/6$ partitions to each array, we can expect the client-server network to be the bottleneck.

Other than bandwidth, another factor is inherent system latencies, e.g., network round-trip times, or inherent disk latencies. Under the same overall bandwidth configuration, increased latency is unlikely to affect the near-optimality of Burst ORAM– while they would increase Burst ORAM's total response times, we would expect a comparable increase in response times for the insecure baseline.

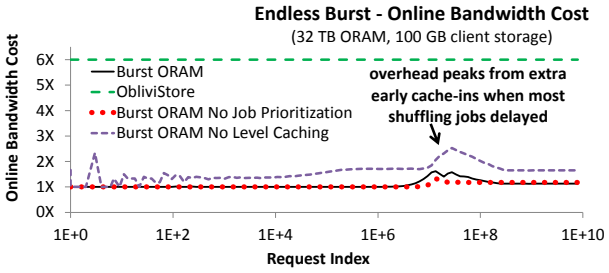

Figure 7: Online bandwidth costs as a burst lengthens. Burst ORAM maintains low online cost regardless of burst length, unlike ObliviStore.

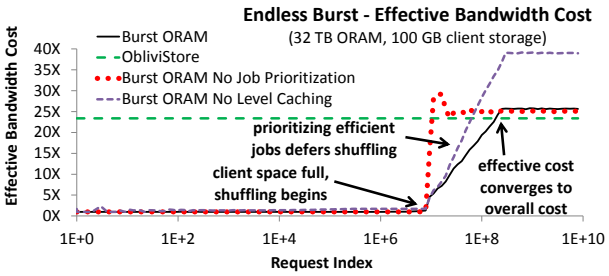

Figure 8: Effective bandwidth costs as burst grows. Burst ORAM handles most bursts with $\sim$1X effective cost. Effective costs converge to overall costs for long bursts.

7.3 Endless Burst Experiments

For the endless burst experiments, we use a 32TB ORAM with $N = 2^{33}$ 4KB blocks and 100GB client space. We issue 2^{33} requests at once, then start satisfying requests in order using each scheme. We record the bandwidth costs of each request, averaged over requests with similar indexes and over three trials. Figures 7 and 8 show online and effective costs, respectively. The insecure baseline is not shown, since its online, effective, and overall bandwidth costs are all 1.

Figure 7 shows that Burst ORAM maintains 5X–6X lower online cost than ObliviStore for bursts of all lengths. When Burst ORAM starts to delay shuffling, it incurs more early shuffle reads, increasing online cost, but stays well under 2X on average. Burst ORAM effective costs can be near 1X because writes associated with requests are not performed until blocks are shuffled.

Burst ORAM defers shuffling, so its effective cost stays close to its online cost until client space fills, while ObliviStore starts shuffling immediately, so its effective

cost stays constant (Figure 8). Thus, response times for short bursts will be substantially lower in Burst ORAM than in ObliviStore.

Eventually, client space fills completely, and even Burst ORAM must shuffle continuously to keep up with incoming requests. This behavior is seen at the far right of Figure 8, where each scheme's effective cost converges to its overall cost. Burst ORAM's XOR technique results in slightly higher overall cost than ObliviStore's level compression, so Burst ORAM is slightly less efficient for very long bursts. Without local level caching, Burst ORAM spends much more time shuffling the smallest levels, yielding the poor performance of *Burst ORAM No Level Caching*.

If shuffle jobs are started in arbitrary order, as for *Burst ORAM No Prioritization*, the amount of shuffling per request quickly increases, pushing effective cost toward overall cost. However, by prioritizing efficient shuffle jobs as in *Burst ORAM* proper, more shuffling can be deferred, keeping effective costs lower for longer, and maintaining shorter response times.

7.4 Two-Burst Experiments

Our Two-Burst experiments show how each scheme responds to idle time between bursts. We show that Burst ORAM uses the idle time effectively, freeing up as much client space as possible. The longer the gap between bursts, the longer Burst ORAM maintains low effective costs during Burst 2.

Figure 9 shows response times during two closely-spaced bursts, each of $\sim 2^{27}$ requests spread evenly over 72 seconds. The ORAM holds $N = 2^{25}$ blocks, and the client has space for 2^{18} blocks. Since we must also store early shuffle reads and reserve space for the shuffle buffer, the client space is not quite enough to accommodate a single burst entirely. We simulate a 100Mbps network connection with 50ms latency.

All ORAMs start with low response times during Burst 1. ObliviStore response times quickly increase due to fixed shuffle work between successive requests. Burst ORAMs delay shuffle work, so response times stay low until client space fills. Without level caching, additional early shuffle reads cause early shuffling and thus premature spikes in response times.

When Burst 1 ends, the ORAMs continue working, satisfying pending requests and catching up on shuffling during the idle period. Longer idle times allow more shuffling and lower response times at the start of Burst 2. None of the ORAMs have time to fully catch up, so response times increase sooner during Burst 2. ObliviStore cannot even satisfy all Burst 1 requests before Burst 2 starts, so response times start high on Burst 2. Burst ORAM does satisfy all Burst 1 requests, so it uses freed client space to efficiently handle early Burst 2 requests.

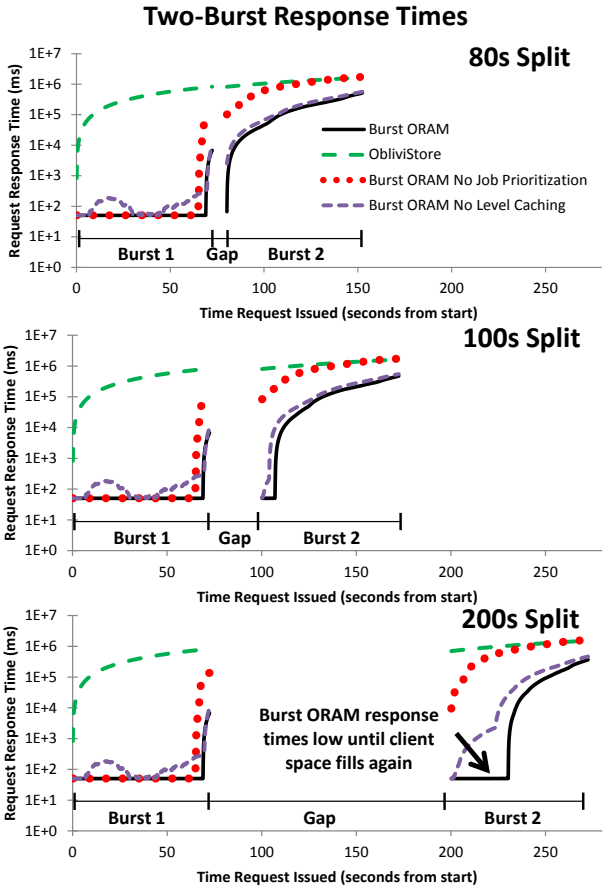

Figure 9: Response times during two same-size bursts of just over 2^{17} requests spread evenly over 72 seconds. Client has space for at most 2^{18} blocks. No level caching causes early spikes due to extra early shuffle reads.

Clearly, Burst ORAM performs better with shuffle prioritization, as it allows more shuffling to be delayed to the idle period, satisfying more requests quickly in both bursts. Burst ORAM also does better with local level caching. Without level caching, we start with more available client space, but the extra server levels yield more early shuffle reads to store, filling client space sooner.

7.5 NetApp Workload Experiments

The NetApp experiments show how each scheme performs on a realistic, bursty workload. Burst ORAM exploits the bursty request patterns, minimizing online IO and delaying shuffle IO to achieve near-optimal response times far lower than ObliviStore's. Level caching keeps Burst ORAM's overall bandwidth costs low.

Figure 10 shows 99.9-percentile response times for several schemes running the 15-day NetApp workload for varying bandwidths. All experiments assume a 50ms network latency. For most bandwidths, Burst ORAM response times are orders of magnitude lower than those

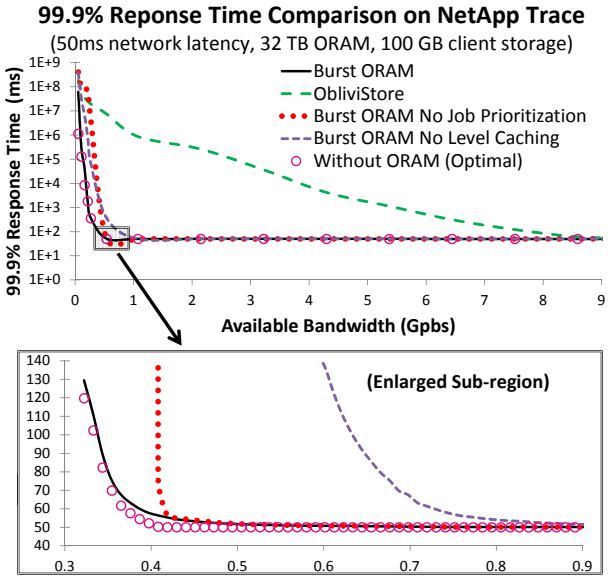

Figure 10: (Top) Burst ORAM achieves short response times in bandwidth-constrained settings. Since ObliviStore has high effective cost, it requires more available client-server bandwidth to achieve short response times. (Bottom) Burst ORAM response times are comparable to those of the insecure (without ORAM) scheme.

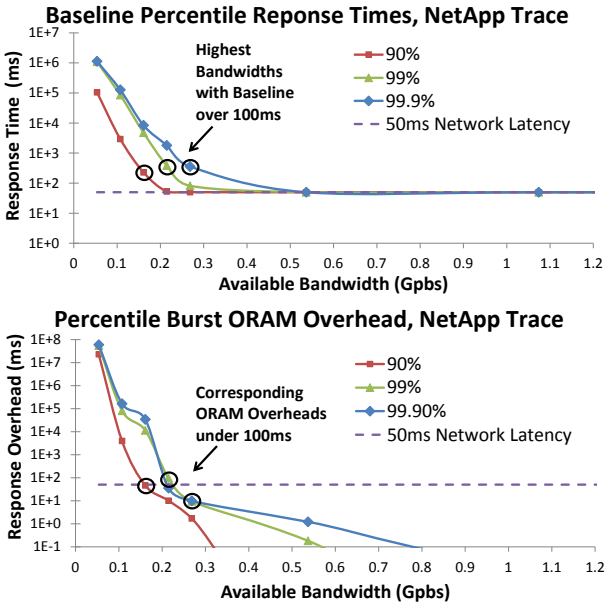

Figure 11: (Top) Insecure baseline (no ORAM) p-percentile response times for various p. (Bottom) Overhead (difference) between insecure baseline and Burst ORAM's p-percentile response times. Marked nodes show that when baseline p-percentile response times are $<$ 100ms, Burst ORAM overhead is also $<$ 100ms.

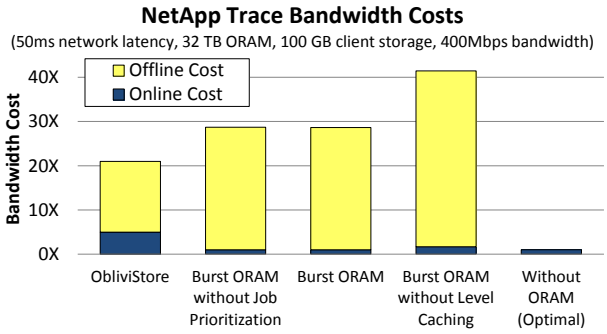

Figure 12: To achieve shorter response times, Burst ORAM incurs higher overall bandwidth cost than ObliviStore, most of which is consumed during idle periods. Level caching keeps bandwidth costs in check. Job prioritization does not affect overall cost, but does reduce effective costs and response times (Figures 8, 10).

of ObliviStore and comparable to those of the insecure baseline. Shuffle prioritization and level caching noticeably reduce response times for bandwidths under 1Gbps.

Figure 11 compares p-percentile response times for p values of 90%, 99%, and 99.9%. It gives absolute p-percentile response times for the insecure baseline, and differences between the insecure baseline and Burst ORAM p-percentile response times (Burst ORAM *overhead*). When baseline response times are low, Burst ORAM response times are also low across multiple p.

The NetApp dataset descriptions [2, 14] do not specify the total available network bandwidth, but since it was likely sufficient to allow decent performance, we expect from Figure 10 that it was at least between 200Mbps and 400Mbps. Figure 12 compares the overall bandwidth costs incurred by each scheme running the NetApp workload at 400Mbps. Costs for other bandwidths are similar. Burst ORAM clearly achieves an online cost several times lower than ObliviStore's.

Level caching reduces Burst ORAM's overall cost from 42X to 29X. Burst ORAM's higher cost is due to a combination of factors needed to achieve short response times. First, Burst ORAM uses the XOR technique, which is less efficient overall than ObliviStore's mutually exclusive level compression. Second, Burst ORAM handles smaller jobs first. Such jobs are more efficient in the short-term, but since they frequently write blocks to small levels, they create more future shuffle work. In ObliviStore, such jobs are often delayed during a large job, so fewer levels are created, reducing overall cost.

8 Conclusion

We have presented Burst ORAM, a novel Oblivious RAM scheme based on ObliviStore and tuned for practical response times on bursty workloads. We presented a

novel ORAM architecture for prioritizing online IO, and introduced the XOR technique for reducing online IO. We also introduced a novel scheduling mechanism for delaying shuffle IO, and described a level caching mechanism that uses extra client space to reduce overall IO.

We simulated Burst ORAM on a real-world workload and showed that it incurs low online and effective bandwidth costs during bursts. Burst ORAM achieved near-optimal response times that were orders of magnitude lower than existing ORAM schemes.

A Pseudocode

Algorithms 1–4 give pseudocode for Burst ORAM, using the notation summarized in Table 1. The algorithms are described in detail in Section 6, but we clarify some of the code and notation below.

The efficiency of shuffle job J_p is given by:

$$E_{J_p} = \frac{V_{J_p} + A_{J_p}}{R_{J_p} + W_{J_p}}. \quad (1)$$

C_p represents the state of partition p at the time p's last shuffle job completed, and determines the current set of occupied levels in p. V_p represents the number of blocks that have been evicted to p, since p's last shuffle job completed. $C_p + V_p$ determines which levels would be occupied if p were to be completely shuffled.

V_{J_p} represents the number of evicted blocks that will be shuffled into p by J_p. Thus, C_p and V_{J_p} together determine J_p's read and write levels.

If J_p is inactive, it is updated whenever V_p changes, setting $V_{J_p} \leftarrow V_p$ (Algorithm 1, Line 25). However, we

Table 1: Algorithm Notation

v	Eviction rate: blocks evicted per request
λ	Number of levels cached locally
p	A partition
V_p	# blocks evicted to p since p's last shuffle end
C_p	p's state after last shuffle (shuffled evictions)
b	Block ID
$D(b)$	Plaintext contents of b
$E(b)$	Encrypted contents of b
$S(b)$	Server address/ID of b
$P(b)$	Partition containing b, or random if none
$L(b)$	Level containing b, or $\perp$ if none
Q	IDs of standard-read blocks to fetch
C	IDs of early shuffle read blocks to fetch
X_Q	Combined block (XOR of all blocks in Q)
X'_Q	Subtraction block (XOR of dummies in Q)
J_p	Shuffle job for p
V_{J_p}	Number of evicted blocks J_p will shuffle
E_{J_p}	Efficiency of J_p
A_{J_p}	Number of early shuffle reads for J_p
R_{J_p}	Total blocks remaining to be read for J_p
W_{J_p}	Total blocks to write for J_p
NJQ	New Job Queue
RJQ	Read Job Queue
WJQ	Write Job Queue

implement level caching by skipping those updates to J_p that would cause J_p to write to levels with indexes less than λ (Algorithm 1, Line 23). Once J_p is active, V_{J_p} is no longer updated. When J_p completes, p's state is updated to reflect the blocks shuffled in by J_p, setting $C_p \leftarrow C_p + V_{J_p}$ (Algorithm 3, Line 37).

If p has no inactive shuffle job, the job is created following the first eviction to p that would allow updating (Algorithm 1, Line 24). If p has no active job, the inactive job moves to the *New Job Queue* (NJQ) as soon as the job is created (Algorithm 1, Line 27), where it stays until the job is activated. If p does have an active shuffle job, the inactive job is not added to NJQ until the active job completes (Algorithm 3, Line 38).

Thus, NJQ contains only inactive shuffle jobs for those partitions with no active job, ensuring that any job in NJQ may be activated. NJQ is a priority queue serving the most efficient jobs first. Job efficiency may change while the job is in NJQ, since V_{J_p} can still be updated.

B Reducing Online Costs of SR-ORAM

We now briefly describe how SR-ORAM [26] can benefit from our XOR technique. Like ObliviStore, SR-ORAM requires only a single round-trip to satisfy a request, and has online bandwidth cost $O(\log N)$. SR-ORAM uses an

Algorithm 1 Pseudocode for Client and ORAM Main

```
1:  function ClientRead(b)
2:      Append b to RequestQueue
3:      On RequestCallback(D(b)), return D(b)
4:  procedure Write(b, d)
5:      Append b to RequestQueue
6:      On RequestCallback(D(b)), write d to D(b)
7:  procedure ORAM Main
8:      RequestMade ← false
9:      if RequestQueue ≠ ∅ then
10:         b ← Peek(RequestQueue)
11:         if Fetch(b) then                ▷ Request Issued
12:             RequestMade ← true
13:             Pop(RequestQueue)
14:             MakeEvictions
15:     if RequestMade = false then
16:         TryShuffleWork
17: procedure MakeEvictions
18:     PendingEvictions = PendingEvictions + v
19:     while PendingEvictions ≥ 1 do
20:         p ← random partition
21:         Evict new dummy or assigned real block to p
22:         V_p = V_p + 1
23:         if shuffling p only writes levels ≥ λ then
24:             J_p ← p's inactive job ▷ Create if needed
25:             V_{J_p} ← V_p
26:             if p has no active job then
27:                 NJQ = NJQ ∪ J_p
28:         PendingEvictions = PendingEvictions − 1
```

encrypted Bloom filter to let the server obliviously check whether each level contains the requested block. The server retrieves the requested block from its level, and client-selected dummies from all others. Since at most one block is real, the server can XOR all the blocks together and return a single combined block.

One difference in SR-ORAM is that the client *does not* know a priori which level contains the requested block. Thus, SR-ORAM must be modified to include the level index of each retrieved block in its response. To allow the client to easily reconstruct dummies, we must also change SR-ORAM to generate the contents of each dummy block as in Burst ORAM. Since the client knows the indexes of the dummy blocks it requested from each level, it can infer the real block's level from the server's response. The client then reconstructs the all dummy block contents and XORs them with the returned block to obtain the requested block, as in Burst ORAM.

SR-ORAM is a synchronous protocol, so it has no notion equivalent to early shuffle reads. Thus, the XOR technique reduces SR-ORAM's online bandwidth cost from $O(\log N)$ to 1. The reduction in overall

Algorithm 2 Pseudocode for Requester

```
1:  function FETCH(b)
2:      P(b), L(b) ← position map lookup on b
3:      Q = ∅, C = ∅
4:      for level ℓ ∈ P(b) do
5:          if ℓ is non-empty then
6:              b_ℓ ← b if ℓ = L(b)
7:              b_ℓ ← ID of next dummy in ℓ if ℓ ≠ L(b)
8:              if ℓ more than half full then
9:                  Q ← Q ∪ S(b_ℓ)            ▷ Standard read
10:             else
11:                 C ← C ∪ S(b_ℓ)            ▷ Early shuffle read
12:     Ret ← |C| + MAX(|Q|, 1)               ▷ # blocks to return
13:     if Not TRYDEC(Local Space, Ret) then
14:         return false                      ▷ Not enough space for blocks
15:     DEC(Concurrent IO, Ret)
16:     Issue asynch. request for (C, Q) to server
17:     When done, server calls:
18:         FETCHCALLBACK(E(C), XOR of E(Q))
19:     return true
20: procedure FETCHCALLBACK({E(c_i)}, X_Q)
21:     INC(Concurrent IO, 1)
22:     if b ∈ Q then
23:         X'_Q ← ⊕{E(q_i) | S(q_i) ∈ Q, q_i ≠ b}
24:                ▷ Subtraction block, computed locally
25:         E(b) ← X_Q ⊕ X'_Q
26:     if b ∈ C then
27:         E(b) ← E(c_i) where c_i = b
28:     D(b) ← decrypt E(b)
29:     Assign b for eviction to random partition
30:     REQUESTCALLBACK(D(b))
```

cost is negligible, as SR-ORAM has an offline cost $O(\log^2 N \log\log N)$. SR-ORAM contains only one hierarchy of $O(\log N)$ levels, so XOR incurs only $O(\log N)$ extra storage cost for the level-specific keys, fitting into SR-ORAM's logarithmic client storage.

Algorithm 3 Pseudocode for Shuffler

```
1:  procedure TRYSHUFFLEWORK
2:      if Not TRYDEC(Concurrent IO, 1) then
3:          return
4:      ReadIssued, WriteIssued ← false
5:      if All reads for jobs in RJQ issued then
6:          TRYACTIVATE                       ▷ Try to add job to RJQ
7:      if J_p ∈ RJQ has not issued read b_R then
8:          if TRYDEC(Shuffle Buffer, 1) then
9:              Issue asynch. request for S(b_R)
10:             When done: READCALLBACK(E(b_R))
11:             ReadIssued ← true
12:     if !ReadIssued and J_p ∈ WJQ has write b_W then
13:         Write E(b_W) to server
14:         When done, call WRITECALLBACK(S(b_W))
15:         WriteIssued ← true
16:     if Not ReadIssued and Not WriteIssued then
17:         INC(Concurrent IO, 1)             ▷ No shuffle work
18: procedure TRYACTIVATE
19:     if NJQ ≠ ∅ then
20:         J_p ← PEEK(NJQ)                   ▷ Most efficient job
21:         if TRYDEC(Shuffle Buffer, V_{J_p} + A_{J_p}) then
22:             Mark J_p active               ▷ V_{J_p} frozen
23:             INC(Local Space, V_{J_p} + A_{J_p})
24:             Move J_p from NJQ to RJQ
25: procedure READCALLBACK(E(b_R))
26:     INC(Concurrent IO, 1)
27:     Decrypt E(b_R), place D(b_R) in Shuffle Buffer
28:     if all reads in J_p have finished then
29:         Create dummy blocks to get W_{J_p} blocks total
30:         Permute and re-encrypt the blocks
31:         Move J_p from RJQ to WJQ
32: procedure WRITECALLBACK(S(b_W))
33:     INC(Concurrent IO, 1)
34:     if all writes in J_p have finished then
35:         Mark J_p complete
36:         Remove J_p from WJQ
37:         Update C_p ← C_p + V_{J_p}, V_p ← V_p − V_{J_p}
38:         Add p's inactive job, if any, to NJQ
```

Algorithm 4 Pseudocode for semaphores

```
1: procedure DEC(Semaphore, Quantity)
2:     Semaphore ← Semaphore − Quantity
3: procedure INC(Semaphore, Quantity)
4:     Semaphore ← Semaphore + Quantity
5: function TRYDEC(Semaphore, Quantity)
6:     if Semaphore < Quantity then return false
7:     DEC(Semaphore, Quantity); return true
```

TRUESET: Faster Verifiable Set Computations*

Abstract

Verifiable computation (VC) enables thin clients to efficiently verify the computational results produced by a powerful server. Although VC was initially considered to be mainly of theoretical interest, over the last two years impressive progress has been made on implementing VC. Specifically, we now have open-source implementations of VC systems that handle *all* classes of computations expressed either as circuits or in the RAM model. Despite this very encouraging progress, new enhancements in the design and implementation of VC protocols are required to achieve truly practical VC for real-world applications.

In this work, we show that for functions that can be expressed efficiently in terms of set operations (e.g., a subset of SQL queries) VC can be enhanced to become drastically more practical: We present the design and prototype implementation of a novel VC scheme that achieves orders of magnitude speed-up in comparison with the state of the art. Specifically, we build and evaluate TRUESET, a system that can verifiably compute any polynomial-time function expressed as a circuit consisting of "set gates" such as *union*, *intersection*, *difference* and *set cardinality*. Moreover, TRUESET supports hybrid circuits consisting of both set gates and traditional arithmetic gates. Therefore, it does not lose any of the expressiveness of previous schemes—this also allows the user to choose the most efficient way to represent different parts of a computation. By expressing set computations as polynomial operations and introducing a novel Quadratic Polynomial Program technique, our experiments show that TRUESET achieves prover performance speed-up ranging from **30x** to **150x** and up to **97**% evaluation key size reduction compared to the state-of-the-art.

1 Introduction

Verifiable Computation (VC) is a cryptographic protocol that allows a client to outsource expensive computation tasks to a worker (e.g., a cloud server), such that the client can verify the result of the computation in less time than that required to perform the computation itself. Cryptographic approaches for VC [5, 6, 7, 12, 13, 14, 21] are attractive in that they require no special trusted hardware or software on the server, and can ensure security against arbitrarily malicious server behavior, including software/hardware bugs, misconfigurations, malicious insiders, and physical attacks.

Due to its various applications such as secure cloud computing, the research community has recently made impressive progress on Verifiable Computation, both on the theoretical and practical fronts. In particular, several recent works [2, 3, 9, 23, 25, 26, 29] have implemented Verifiable Computation for general computation tasks, and demonstrated promising evidence of its efficiency. Despite this encouraging progress, performance improvement of orders of magnitude is still required (especially on the time that the server takes to compute the proof) for cryptographic VC to become truly practical.

Existing systems for Verifiable Computation are built to accommodate any language in NP: Specifically, functions/programs are represented as either circuits (Boolean or arithmetic) or sets of constraints and cryptographic operations are run on these representations. While such an approach allows us to express any polynomial-time computation, it is often not the most efficient way to represent common computation tasks encountered in practice. For example, Parno et al. [23] point out that the behavior of their construction deteriorates abruptly for functionalities that have "bad" arithmetic circuit representation and Braun et al. [9] recognize that their scheme is not quite ready for practical use, restricting their evaluations to "smaller scales than would occur in real applications."

In order to reduce the practical cost of Verifiable Computation, we design and build TRUESET. TRUESET is an efficient and *provably secure* VC system that specializes in handling *set-centric* computation tasks. It allows us to

model computation as a *set circuit*—a circuit consisting of a combination of set operators (such as intersection, union, difference and sum), instead of just arithmetic operations (such as addition and multiplication in a finite field). For computation tasks that can be naturally expressed in terms of set operations (e.g., a subset of SQL database queries), our experimental results suggest *orders-of-magnitude* performance improvement in comparison with existing VC systems such as Pinocchio [23]. We now present TRUESET's main contributions:

Expressiveness. TRUESET retains the expressiveness of existing VC systems, in that it can support arbitrary computation tasks. Fundamentally, since our set circuit can support intersection, union, and set difference gates, the set of logic is complete[1]. Additionally, in Section 4.4, we show that TRUESET can be extended to support circuits that have a mixture of arithmetic gates and set gates. We achieve this by introducing a "split gate" (which, on input a set, outputs the individual elements) and a "merge gate" (which has the opposite function of the split gate).

Input-specific running time. One important reason why TRUESET significantly outperforms existing VC systems in practice is that it achieves *input-specific* running time for proof computation and key generation. Input-specific running time means that the running time of the prover is proportional to the size of the current input.

Achieving input-specific running time is not possible when set operations are expressed in terms of Boolean or arithmetic circuits, where one must account for worst-case set sizes when building the circuit: For example, in the case of intersection, the worst case size of the output is the minimum size of the two sets; in the case of union, the worst case size of the output is the sum of their sizes. Note that this applies not only to the set that comprises the final outcome of the computation, but to every intermediate set generated during the computation. As a result, existing approaches based on Boolean or arithmetic circuits incur a large blowup in terms of circuit size when used to express set operations. In this sense, TRUESET also achieves *asymptotic* performance gains for set-centric computation workloads in comparison with previous approaches.

TRUESET achieves input-specific running time by encoding a set of cardinality c as a polynomial of degree c (such an encoding was also used in previous works, e.g., [18, 22]), and a set circuit as a circuit on polynomials, where every wire is a polynomial, and every gate performs polynomial addition or multiplication. As a result, per-gate computation time for the prover (including the time for performing the computation and the time for producing the proof) is (quasi-)linear in the degree of the polynomial (i.e., cardinality of the actual set), and not proportional to the worst-case degree of the polynomial.

Finally, as in other VC systems, verifying in TRUESET requires work proportional to the size of inputs/outputs, but not in the running time of the computation.

[1] Any function computable by Boolean circuits can be computed by a set circuit: If one encodes the empty set as 0 and a fixed singleton set $\{s\}$ as 1, a union expresses the OR gate, an intersection expresses the AND gate and a set difference from $\{s\}$ expresses the NOT gate.

```
SELECT COUNT(UNIVERSITY.id)
    FROM UNIVERSITY JOIN CS
      ON UNIVERSITY.id = CS.id
```

Figure 1: An example of a JOIN *SQL query (between tables* **UNIVERSITY** *and* **CS***) that can be efficiently supported by* TRUESET. TRUESET *will implement* JOIN *with an intersection gate and* COUNT *with a cardinality gate.*

Implementation and evaluation. We implemented TRUESET and documented its efficiency comparing it with a verifiable protocol that compiles a set circuit into an arithmetic circuit and then uses Pinocchio [23] on the produced circuit. In TRUESET the prover's running time is reduced by approximately **30x** for all set sizes of 64 elements or more. In particular, for a single intersection/union gate over 2 sets of 256 elements each, TRUESET improves the prover cost by nearly **150x**. We also show that, while other systems [23] cannot—in a reasonable amount of time—execute over larger inputs, TRUESET can scale to large sets, e.g., sets with cardinality of approximately 8000 (2^{13}), efficiently accommodating instances that are about **30x** larger than previous systems. Finally, TRUESET greatly reduces the evaluation key size, a reduction that can reach **97**% for some operations.

Applications. TRUESET is developed to serve various information retrieval applications that use set operations as a building block. For example, consider an SQL query that performs a JOIN over two tables and then computes MAX or SUM over the result of the join operation. TRUESET can model the join operation as an intersection and then use the split gate to perform the maximum or the summation/cardinality operation over the output of the join—see Figure 1. Other queries that TRUESET could model are advanced keyword search queries containing complicated filters that can be expressed as arbitrary combinations of set operations (union, intersection, difference) over an underlying data set. Finally, the computation of similarity measurements for datasets often employs set operations. One of the most popular measurements of this type, is the Jaccard index [17] which is computed for two sets, as the ratio of the *cardinalities* of their intersection and union, a computation that can be easily compiled with TRUESET.

Technical highlight. Our core technical construction is inspired by the recent *quadratic span and arithmetic programs* [14], which were used to implement VC for any

Boolean or arithmetic circuit. Since our internal representation is a polynomial circuit (as mentioned earlier), we invent *quadratic polynomial programs* (QPP). During the prover's computation, polynomials on the wires of the circuit are evaluated at a random point s—however, this takes place in the exponent of a bilinear group, in a way that the server does not learn s. Evaluating the polynomial at the point s in effect reduces the polynomial to a value—therefore one can now think of the polynomial circuit as a normal arithmetic circuit whose wires encode plain values. In this way, we can apply techniques resembling quadratic arithmetic programs. While the intuition may be summarized as above, designing the actual algebraic construction and formally proving its security is nonetheless challenging, and requires a non-trivial transformation of quadratic arithmetic programs.

1.1 Related Work

There exists a large amount of theoretical work on VC: Micali [21] presented a scheme that can accommodate proofs for any language in NP. A more efficient approach is based on *succinct non-interactive arguments of knowledge* (SNARKs) [5, 6, 7, 14]. For the case of polynomial-time computable functions, protocols based on fully-homomorphic encryption [12, 13] and attribute-based encryption [24] have also been proposed. In general, the above schemes employ heavy cryptographic primitives and therefore are not very practical.

Recent works [2, 3, 9, 23, 25, 26, 29] have made impressive progress toward implementations of some of the above schemes, showing practicality for particular functionalities. Unfortunately, the server's cost for proof computation remains too high to be considered for wide deployment in real-world applications.

The problem of verifying a circuit of set operations was first addressed in a recent work by Canetti et al. [10]. Their proofs are of size linear to the size of the circuit, without however requiring a preprocessing phase for each circuit. In comparison, our proofs are of constant size, once such a preprocessing step has been run.

Papamanthou et al. [22] presented a scheme that provides verifiability for a single set operation. However, more general set operations can be accommodated by sequentially using their approach, since all intermediate set outputs are necessary for verification. This would lead to increased communication complexity.

A related scheme appears in the work of Chung et al. [11]. As this scheme uses Turing machines for the underlying computation model, the prover has inherently high complexity. Another work that combines verifiable computation with outsourcing of storage is [1], where a protocol for streaming datasets is proposed but the supported functionalities are quadratic polynomials only.

2 Definitions

In this section we provide necessary definitions and terminology that will be useful in the rest of the paper.

Circuits of sets and polynomials. TRUESET uses the same computation abstraction as the one used in the VC scheme by Parno et al. [23]: a circuit. However, instead of field elements, the circuit wires now carry *sets*, and, instead of arithmetic multiplication and addition gates, our circuit has three types of gates: *intersection*, *union* and *difference*. For the sake of presentation, the sets we are considering are simple sets, though our construction can be extended to support multisets as well. We therefore begin by defining a set circuit:

Definition 1 (Set circuit $\mathcal{C}$) *A set circuit $\mathcal{C}$ is a circuit that has gates that implement set union, set intersection or set difference over sets that have elements in a field $\mathbb{F}$.*

A set circuit is a tool that provides a clean abstraction of the computational steps necessary to perform a set operation. This structured representation will allow us to naturally encode a set operation into a number of execution conditions that are met when it is performed correctly. We stress that it is merely a theoretical abstraction and does not affect the way in which the computation is performed; the computing party can use its choice of efficient native libraries and architectures. In comparison, previous works that use arithmetic circuits to encode more general computations, require the construction (or simulation) and evaluation of such a circuit, an approach that introduces an additional source of overhead.

As mentioned in the introduction, our main technique is based on mapping any set circuit $\mathcal{C}$ to a circuit $\mathcal{F}$ of polynomial operations, i.e., to a circuit that carries univariate polynomials on its wires and has polynomial multiplication and polynomial addition gates. We now define the polynomial circuit $\mathcal{F}$:

Definition 2 (Polynomial circuit $\mathcal{F}$) *A polynomial circuit $\mathcal{F}$ in a field $\mathbb{F}$ is a circuit that has gates that implement univariate polynomial addition and univariate polynomial multiplication over $\mathbb{F}$. We denote with d the number of multiplication gates of $\mathcal{F}$ and with N the number of input and output wires of $\mathcal{F}$. The input and output wires are indexed $1, \ldots, N$. The rest of the wires[2] are indexed $N+1, \ldots, m$.*

SNARKs. TRUESET's main building block is a primitive called *succinct non-interactive argument of knowledge* (SNARK) [14]. A SNARK allows a client to commit to

[2] These wires include free wires (which are inputs only to multiplication gates) and the outputs of the internal multiplication gates (whose outputs are not outputs of the circuit). The set of these wires is denoted with I_m and has size at most $3d$.

a computation circuit C and then have a prover provide succinct cryptographic proofs that there exists an assignment on the wires w (which is called witness) such that the input-output pair $x = (\mathcal{I}, \mathcal{O})$ is valid.

As opposed to *verifiable computation* [24], a SNARK allows a prover to specify some wires of the input $\mathcal{I}$ as part of the witness w (this is useful when proving membership in an NP language, where the prover must prove witness existence). For this reason, SNARKs are more powerful than VC and therefore for the rest of the paper, we will show how to construct a SNARK for hierarchical set operations. In the full version of our paper [20], we show how to use the SNARK construction to provide a VC scheme as well as a VC scheme for outsourced sets, where the server not only performs the computation, but also stores the sets for the client. We now give the SNARK definition, adjusted from [14].

Definition 3 (SNARK scheme) *A* SNARK *scheme consists of three probabilistic polynomial time (PPT) algorithms* (KeyGen, Prove, Verify) *defined as follows.*

1. $(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{KeyGen}(1^k, C)$. *The key generation algorithm takes as input the security parameter k and a computation circuit C; it outputs a public key* pk*, and a secret key* sk*.*

2. $\pi \leftarrow \mathsf{Prove}(\mathsf{pk}, x, w)$*: The prover algorithm takes as input the public key* pk*, an input-output pair $x = (\mathcal{I}, \mathcal{O})$, a valid witness w and it outputs a proof π.*

3. $\{0, 1\} \leftarrow \mathsf{Verify}(\mathsf{sk}, x, \pi)$*: Given the key* sk*, a statement x and a proof π, the verification algorithm outputs 0 or 1.*

We say that a SNARK is publicly-verifiable if $\mathsf{sk} = \mathsf{pk}$*. In this case, proofs can be verified by anyone with* pk*. Otherwise, we call it a secretly-verifiable SNARK, in which case only the party with* sk *can verify.*

There are various properties that a SNARK should satisfy. The most important one is *soundness*. Namely, no PPT adversary should be able to output a verifying proof π for an input-output pair $x = (\mathcal{I}, \mathcal{O})$ that is not consistent with C. All the other properties of SNARKs are described formally in Appendix 6.2.

3 A SNARK for Polynomial Circuits

In their recent seminal work, Gennaro et al. [14] showed how to compactly encode computations as quadratic programs, in order to derive very efficient SNARKs. Specifically, they show how to convert any arithmetic circuit into a comparably-sized Quadratic Arithmetic Program (QAP), and any Boolean circuit into a comparably-sized Quadratic Span Program (QSP).

In this section we describe our SNARK construction for polynomial circuits. The construction is a modification of the optimized construction for arithmetic circuits that was presented by Parno et al. [23] (Protocol 2) and which is based on the original work of Gennaro et al. [14]. Our extension accounts for univariate polynomials on the wires, instead of just arithmetic values. We therefore need to define a *quadratic polynomial program*:

Definition 4 (Quadratic Polynomial Program (QPP)) *A QPP $\mathcal{Q}$ for a polynomial circuit $\mathcal{F}$ contains three sets of polynomials $\mathcal{V} = \{v_k(x)\}, \mathcal{W} = \{w_k(x)\}, \mathcal{Y} = \{y_k(x)\}$ for $k = 1, \ldots, m$ and a target polynomial $\tau(x)$. We say that $\mathcal{Q}$ computes $\mathcal{F}$ if: $c_1(z), c_2(z), \ldots, c_N(z)$ is a valid assignment of $\mathcal{F}$'s inputs and outputs iff there exist polynomials $c_{N+1}(z), \ldots, c_m(z)$ such that $\tau(x)$ divides $p(x, z)$ where*

$$p(x,z) = \left(\sum_{k=1}^{m} c_k(z) v_k(x)\right)\left(\sum_{k=1}^{m} c_k(z) w_k(x)\right) - \left(\sum_{k=1}^{m} c_k(z) y_k(x)\right). \quad (3.1)$$

We define the degree of $\mathcal{Q}$ to equal the degree of $\tau(x)$.

The main difference of the above quadratic program with the one presented in [23] is the fact that we introduce another variable z in the polynomial $p(x, z)$ representing the program (hence we need to account for bivariate polynomials, instead of univariate), which is going to account for the polynomials on the wires of the circuit.

Constructing a QPP. We now show how to construct a QPP $\mathcal{Q}$ for a polynomial circuit. The polynomials in $\mathcal{V}, \mathcal{W}, \mathcal{Y}$ and the polynomial $\tau(x)$ are computed as follows. Let $r_1, r_2, \ldots, r_d$ be random elements in $\mathbb{F}$. First, set $\tau(x) = (x - r_1)(x - r_2)\ldots(x - r_d)$ and compute the polynomial $v_k(x)$ such that $v_k(r_i) = 1$ iff wire k is the *left input* of multiplication gate i, otherwise $v_k(r_i) = 0$. Similarly, $w_k(r_i) = 1$ iff wire k is the *right* input of multiplication gate i, otherwise $w_k(r_i) = 0$ and $y_k(r_i) = 1$ iff wire k is the *output* of multiplication gate i, otherwise $y_k(r_i) = 0$. For example, consider the circuit of Figure 2 that has five inputs and one output and its wires are numbered as shown in the figure (gates take the index of the their output wire). Then $\tau(x) = (x - r_6)(x - r_7)$. For v_k we require that $v_k(r_6) = 0$ except for $v_2(r_6) = 1$, since the second wire is the only left input for the sixth gate, and $v_k(r_7) = 0$ except for $v_1(r_7)$ and $v_6(r_7)$ which are 1, since the first and sixth wire contribute as left inputs to gate 7. Right input polynomials w_k are computed similarly and output polynomials y_k are computed such that $y_6(r_6) = y_7(r_7) = 1$; all other cases are set to 0.

To see why the above QPP computes $\mathcal{F}$, let us focus on a single multiplication gate g, with k_1 being its

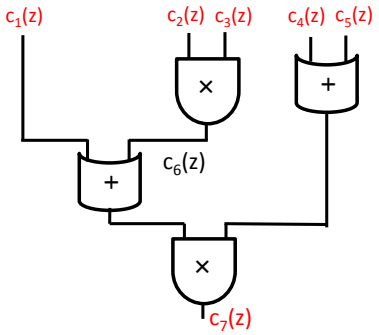

Figure 2: A sample polynomial circuit.

output wire and k_2 and k_3 be its left and right input wires respectively. Due to the divisibility requirement, it holds $p(r_i, z) = 0$ for $i = 1, \ldots, d$, hence Equation 3.1 will give $(\sum_{k=1}^{m} c_k(z)v_k(r_g))(\sum_{k=1}^{m} c_k(z)w_k(r_g)) = (\sum_{k=1}^{m} c_k(z)y_k(r_g))$. Now, from the way the polynomials v_k, w_k, y_k were defined above, most terms are 0 and what remains is $c_{k_2}(z)v_{k_2}(r_g) \cdot c_{k_3}(z)w_{k_3}(r_g) = c_{k_1}(z)y_{k_1}(r_g)$ or else $c_{k_2}(z) \cdot c_{k_3}(z) = c_{k_1}(z)$, which is the definition of a multiplication gate. More formally:

Lemma 1 *The above QPP $\mathcal{Q}$ computes $\mathcal{F}$.*

Proof: ($\Rightarrow$) Suppose $c_1(z), c_2(z), \ldots, c_N(z)$ are correct assignments of the input and output wires but there do not exist polynomials $c_{N+1}(z), \ldots, c_m(z)$ such that $\tau(x)$ divides $p(x, z)$. Then there is at least one multiplication gate r with left input x, right input y and output o, such that $p(r, z) \neq 0$. Let p be the path of multiplication gates that contains r starting from an input polynomial $c_i(z)$ to an output polynomial $c_j(z)$, where $i, j \leq N$. Since $c_i(z)$ and $c_j(z)$ are correct assignments, there must exist polynomials $c_x(z)$ and $c_y(z)$ such that $c_x(z)c_y(z) = c_o(z)$. Since r has a single left input, a single right input and a single output it holds $v_x(r) = 1$ and $v_i(r) = 0$ for all $i \neq x$. Similarly, $w_y(r) = 1$ and $w_i(r) = 0$ for all $i \neq y$ and $y_o(r) = 1$ and $y_i(r) = 0$ for all $i \neq o$. Therefore $p(r, z) \neq 0$ implies that for all polynomials $c_x(z)$, $c_y(z)$, $c_o(z)$, it is $c_x(z)c_y(z) \neq c_o(z)$, a contradiction.

($\Leftarrow$) Suppose $\tau(x)$ divides $p(x, z)$. Then $p(r, z) = 0$ for all multiplication gates r. By the definition of $v_i(x)$, $w_i(x)$, $y_i(x)$, the $c_1(z), c_2(z), \ldots, c_m(z)$ are correct assignments on the circuit wires. ■

We next give an efficient SNARK construction for polynomial circuits based on the above QPP. Recall that a polynomial circuit $\mathcal{F}$ has d multiplication gates and m wires, the wires $1, \ldots, N$ occupy inputs and outputs and set $I_m = \{N + 1, \ldots, m\}$ represents the internal wires, where $|I_m| \leq 3d$. Also, we denote with n_i the degree of polynomial on wire i and we set n to be an upper bound on the degrees of the polynomials on $\mathcal{F}$'s wires.

3.1 Intuition of Construction

The SNARK construction that we present works as follows. First, the key generation algorithm KeyGen produces a "commitment" to the polynomial circuit $\mathcal{F}$ by outputting elements that relate to the internal set of wires I_m of the QPP $\mathcal{Q} = (\mathcal{V}, \mathcal{W}, \mathcal{Y}, \tau(x))$ as the public key. These elements encode bivariate polynomials in the exponent, evaluated at randomly chosen points t and s, to accommodate for the fact that circuit $\mathcal{F}$ encodes operations over univariate polynomials and not just arithmetic values (as is the case with [14]).

As was described in the previous section, for the prover to prove that an assignment $c_1(z), c_2(z), \ldots, c_N(z)$ of polynomials on input/output wires is valid, it suffices to prove there exist polynomials $c_{N+1}(z), \ldots, c_m(z)$ corresponding to assignments on the internal wires, such that the polynomial $p(x, z)$ from Relation 3.1 has roots $r_1, r_2, \ldots, r_d$. To prove this, the prover first "solves" the circuit and computes the polynomials $c_1(z), c_2(z), \ldots, c_m(z)$ that correspond to the correct assignments on the wires. Then he uses these polynomials and the public evaluation key (i.e., the circuit "commitment") to compute the following three types of terms (which comprise the actual proof). The detailed computation of these values is described in Section 3.2.

- **Extractability terms.** These terms declare three polynomials in the exponent, namely polynomials $\sum_{k=N+1}^{m} c_k(z)v_k(x)$, $\sum_{k=N+1}^{m} c_k(z)w_k(x)$, and $\sum_{k=N+1}^{m} c_k(z)y_k(x)$. These polynomials correspond to the internal wires since the verifier can fill in the parts for the input and output wires.

  The above terms are engineered to allow extractability using a knowledge assumption. In particular, given these terms, there exists a polynomial-time extractor that can, with overwhelming probability, recover the assignment $c_{N+1}(z), \ldots, c_m(z)$ on internal wires. This proves the existence of $c_{N+1}(z), \ldots, c_m(z)$.

- **Consistency check terms.** Extraction is done separately for terms related to the three polynomials $\sum_{k=N+1}^{m} c_k(z)v_k(x)$, $\sum_{k=N+1}^{m} c_k(z)w_k(x)$, and $\sum_{k=N+1}^{m} c_k(z)y_k(x)$. We therefore require a set of consistency check terms to ensure that the extracted $c_{N+1}(z), \ldots, c_m(z)$ polynomials are consistent for the above $\mathcal{V}$, $\mathcal{W}$, and $\mathcal{Y}$ terms—otherwise, the same wire can have ambiguous assignments.

- **Divisibility check term.** Finally, the divisibility check term is to ensure that the above divisibility check corresponding to relation $p(x, z) =$

$h(x,z)\tau(x)$, holds for the polynomial

$$\left(\sum_{k=1}^{m} c_k(z)v_k(x)\right)\left(\sum_{k=1}^{m} c_k(z)w_k(x)\right) - \left(\sum_{k=1}^{m} c_k(z)y_k(x)\right)$$

declared earlier by the extractability terms.

3.2 Concrete Construction

We now give the algorithms of our SNARK construction, (following Definition 3). In comparison with the QSP and QAP constructions [14, 23], one difficulty arises in our setting when working with polynomials on wires. In essence, to express a polynomial $c_k(z)$ on a wire in our construction, we evaluate the polynomial at a committed point $z = t$. In existing QSP and QAP constructions, the prover knows the cleartext value on each wire when constructing the proof. However, in our setting, the prover does not know what t is, and hence cannot directly evaluate the polynomials $c_k(z)$'s on each wire. In fact, security would be broken if the prover knew the value of the polynomials at $z = t$.

To overcome this problem, we have to include more elements in the evaluation key which will contain exponent powers of the variable t (see the evaluation key below). In this way, the prover will be able to evaluate $c_k(t)$ in the exponent, without ever learning the value t. We now give the algorithms:

$(\mathsf{pk}, \mathsf{sk}) \leftarrow \mathsf{KeyGen}(\mathcal{F}, 1^k)$: Let $\mathcal{F}$ be a polynomial circuit. Build the corresponding QPP $\mathcal{Q} = (\mathcal{V}, \mathcal{W}, \mathcal{Y}, \tau(x))$ as above. Let e be a non-trivial bilinear map $e : \mathbb{G} \times \mathbb{G} \to \mathbb{G}_T$, and let g be a generator of $\mathbb{G}$. $\mathbb{G}$ and $\mathbb{G}_T$ have prime order p. Pick $s, t, r_v, r_w, \alpha_v, \alpha_w, \alpha_y, \beta, \gamma$ from $\mathbb{Z}_p$ and set $r_y = r_v r_w$ and $g_v = g^{r_v}$, $g_w = g^{r_w}$ and $g_y = g^{r_y}$. The public evaluation key $\mathsf{EK}_\mathcal{F}$ is

1. $\{g_v^{t^i v_k(s)}, g_w^{t^i w_k(s)}, g_y^{t^i y_k(s)}\}_{(i,k)\in[n]\times I_m}$.
2. $\{g_v^{t^i \alpha_v v_k(s)}, g_w^{t^i \alpha_w w_k(s)}, g_y^{t^i \alpha_y y_k(s)}\}_{(i,k)\in[n]\times I_m}$.
3. $\{g_v^{t^i \beta \cdot v_k(s)} g_w^{t^i \beta \cdot w_k(s)} g_y^{t^i \beta \cdot y_k(s)}\}_{(i,k)\in[n]\times I_m}$.
4. $\{g^{t^i s^j}\}_{(i,j)\in[2n]\times[d]}$.

The verification key $\mathsf{VK}_\mathcal{F}$ consists of the values

$$g, g^{\alpha_v}, g^{\alpha_w}, g^{\alpha_y}, g^{\gamma}, g^{\beta\gamma} g_y^{t(s)}$$

and the set $\{g_v^{t^i v_k(s)}, g_w^{t^i w_k(s)}, g_y^{t^i y_k(s)}\}_{(i,k)\in[n]\times[N]}$. Note $\mathsf{VK}_\mathcal{F}$ and $\mathsf{EK}_\mathcal{F}$ are the public key pk of the SNARK. Our SNARK is publicly verifiable, hence $\mathsf{sk} = \mathsf{pk}$.

$\pi \leftarrow \mathsf{Prove}(\mathsf{pk}, x, w)$: The input x contains input polynomials u and output polynomials y and the witness w (which contains assignments of polynomials on the internal wires). Let $c_k(z)$ be the polynomials on the circuit's wires such that $y = \mathcal{F}(u, w)$. Let $h(x, z)$ be the polynomial such that $p(x, z) = h(x, z) \cdot \tau(x)$. The proof is computed as follows:

1. *(Extractability terms)* $g_v^{v_m(s,t)}$, $g_w^{w_m(s,t)}$, $g_y^{y_m(s,t)}$, $g_v^{\alpha_v v_m(s,t)}$, $g_w^{\alpha_w w_m(s,t)}$, $g_y^{\alpha_y y_m(s,t)}$.
2. *(Consistency check term)* $g_v^{\beta \cdot v_m(s,t)} g_w^{\beta \cdot w_m(s,t)} g_y^{\beta \cdot y_m(s,t)}$.
3. *(Divisibility check term)* $g^{h(s,t)}$, where

(a) $v_m(x, z) = \sum_{k\in I_m} c_k(z)v_k(x)$;
(b) $w_m(x, z) = \sum_{k\in I_m} c_k(z)w_k(x)$; and
(c) $y_m(x, z) = \sum_{k\in I_m} c_k(z)y_k(x)$. Note that the term $g_v^{\beta \cdot v_m(s,t)} g_w^{\beta \cdot w_m(s,t)} g_y^{\beta \cdot y_m(s,t)}$ can be computed from public key terms $\{g_v^{t^i \beta \cdot v_k(s)} g_w^{t^i \beta \cdot v_k(s)} g_y^{t^i \beta \cdot y_k(s)}\}_{(i,k)\in[n]\times I_m}$.

$\{0, 1\} \leftarrow \mathsf{Verify}(\mathsf{pk}, x, \pi)$: Parse the proof π as

1. $\gamma_v, \gamma_w, \gamma_y, \kappa_v, \kappa_w, \kappa_y$.
2. Λ.
3. γ_h.

First, verify all three α terms: $e(\gamma_v, g^{\alpha_v}) \stackrel{?}{=} e(\kappa_v, g) \wedge e(\gamma_w, g^{\alpha_w}) \stackrel{?}{=} e(\kappa_w, g) \wedge e(\gamma_y, g^{\alpha_y}) \stackrel{?}{=} e(\kappa_y, g)$. Then verify the divisibility requirement:

$$e(\lambda_v \cdot \gamma_v, \lambda_w \cdot \gamma_w)/e(\lambda_y \cdot \gamma_y, g) \stackrel{?}{=} e(\gamma_h, g^{\tau(s)}),$$

where $\lambda_v = g^{\sum_{k\in[N]} c_k(t)v_k(s)}$, $\lambda_w = g^{\sum_{k\in[N]} c_k(t)w_k(s)}$, $\lambda_y = g^{\sum_{k\in[N]} c_k(t)y_k(s)}$. Finally verify the β term:

$$e(\gamma_v \cdot \gamma_w \cdot \gamma_y, g^{\beta\gamma}) \stackrel{?}{=} e(\Lambda, g^{\gamma}).$$

3.3 Asymptotic Complexity and Security

In this section we analyze the asymptotic complexity of our SNARK construction for polynomial circuits. We also state the security of our scheme.

KeyGen: It is easy to see that the computation time of KeyGen is $O(n|I_m| + nd + nN) = O(dn)$.

Prove: Let T be the time required to compute the polynomials $c_i(z)$ for $i = 1, \ldots, m$ and let n_i be the degree of the polynomial $c_i(z)$ for $i = 1, \ldots, m$. The computation of each $g^{c_i(z)v_i(x)}$ (similarly for $g^{c_i(z)w_i(x)}$ and $g^{c_i(z)y_i(x)}$) for $i \in I_m$ takes $O(n_i)$ time (specifically, $7 \cdot \sum n_i$ exponentiations are required to compute all the

proof), since one operation per coefficient of $c_i(z)$ is required. Then multiplication of $|I_m|$ terms is required. Therefore the total time required is

$$O\left(T + \sum_{i \in I_m} n_i + |I_m|\right) = O\left(T + d\nu\right) ,$$

where $\nu = \max_{i=1,\ldots,m}\{n_i\}$ is the maximum degree of the polynomials over the wires and since $|I_m| \leq 3d$. To compute $p(x,z)$, first the degree d polynomials $v_i(x), w_i(x), y_i(x)$ for $i = 1, ..., m$ are parsed in time $O(dm)$. Then $p(x,z)$ is computed according to Equation 1; each summation term is computed in time $O(d\nu)$ with naive bivariate polynomial multiplication and then they are summed for total complexity of $O(md\nu)$. For the division, note that $p(x,z)$ has maximum degree in z equal to 2ν and maximum degree in x equal to $2d$. To do the division, we apply "the change of variable trick". We set $z = x^{2\times(2d)+1}$ and therefore turn $p(x,z)$ into a polynomial of one variable x, namely the polynomial $p(x, x^{2\times(2d)+1})$. Therefore the dividend now has maximum degree $2\nu(4d+1)+2d$ while the divisor has still degree d. By using FFT, we can do such division in $O(d\nu \log(d\nu))$ time. Therefore the total time for Prove is $O\left(T + d\nu \log(d\nu) + md\nu\right)$.

Verify: The computation of each element $g^{c_i(z)v_i(x)}$ (resp. for $g^{c_i(z)w_i(x)}$ and $g^{c_i(z)y_i(x)}$) for $i = 1, \ldots, N$ takes $O(n_i)$ time, since one operation per coefficient of $c_i(z)$ is required. Then multiplication of N terms is required. Hence, the total time required is $O(\sum_{i\in[N]} n_i)$, proportional to the size of the input and output.

We now have the following result. The involved assumptions can be found in Appendix 6.1 and we provide its proof of security in the full version of our paper [20].

Theorem 1 (Security of the SNARK for $\mathcal{F}$) *Let $\mathcal{F}$ be a polynomial circuit with d multiplication gates. Let n be an upper bound on the degrees of the polynomials on the wires of $\mathcal{F}$ and let $q = 4d + 4$. The construction above is a SNARK under the $2(n+1)q$-PKE, the $(n+1)q$-PDH and the $2(n+1)q$-SDH assumptions.*

4 Efficient SNARKs for Set Circuits

In this section, we show how to use the SNARK construction for polynomial circuits from the previous section to build a SNARK for set circuits.

We first define a mapping from sets to polynomials (see Definition 5– such representation was also used in prior work, e.g., the work of Kissner and Song [18]). Then we express the correctness of the operations between two sets as constraints between the polynomials produced from this mapping (e.g., see Lemma 2). For a set operation to be correct, these constraints must be satisfied simultaneously. To capture that, we represent all these constraints with a circuit with loops, where a wire can participate in more than one constraint (see Figure 3).

4.1 Expressing Sets with Polynomials

We first show how to represent sets and set operations with polynomials and polynomial operations. This representation is key for achieving *input-specific* time, since we can represent a set with a polynomial evaluated at a random point (regardless of its cardinality). Given a set, we define its *characteristic polynomial*.

Definition 5 (Characteristic polynomial) *Let A be a set of elements $\{a_1, a_2, \ldots, a_n\}$ in $\mathbb{F}$. We define its characteristic polynomial as $\mathsf{A}(z) = (z + a_1) \ldots (z + a_n)$.*

We now show the relations between set operations and polynomial operations. Note that similar relations were used by Papamanthou et al. [22] in prior work.

Lemma 2 (Intersection constraints) *Let A, B and I be three sets of elements in $\mathbb{F}$. Then $\mathsf{I} = \mathsf{A} \cap \mathsf{B}$ iff there exist polynomials $\alpha(z)$, $\beta(z)$, $\gamma(z)$ and $\delta(z)$ such that*

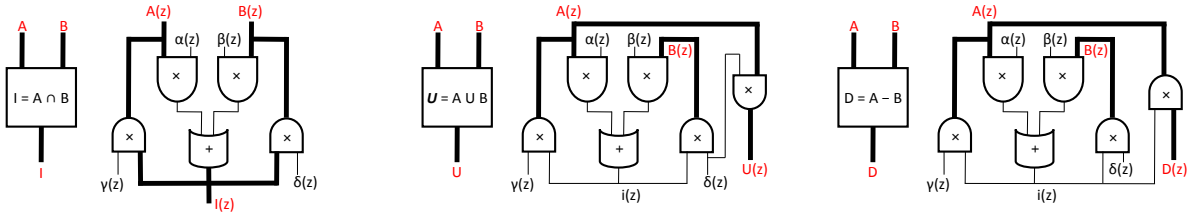
1. $\alpha(z)\mathsf{A}(z) + \beta(z)\mathsf{B}(z) = \mathsf{I}(z)$.
2. $\gamma(z)\mathsf{I}(z) = \mathsf{A}(z)$.
3. $\delta(z)\mathsf{I}(z) = \mathsf{B}(z)$.

Proof: ($\Rightarrow$) If $\mathsf{I} = \mathsf{A} \cap \mathsf{B}$, it follows that (i) the great common divisor of polynomials $\mathsf{A}(z)$ and $\mathsf{B}(z)$ is $\mathsf{I}(z)$, therefore, by Bézout's identity, there exist polynomials $\alpha(z)$ and $\beta(z)$ such that (i) $\alpha(z)\mathsf{A}(z) + \beta(z)\mathsf{B}(z) = \mathsf{I}(z)$; (ii) $\mathsf{I}(z)$ divides $\mathsf{A}(z)$ and $\mathsf{B}(z)$, therefore there exist polynomials $\gamma(z)$ and $\delta(z)$ such that $\gamma(z)\mathsf{I}(z) = \mathsf{A}(z)$ and $\delta(z)\mathsf{I}(z) = \mathsf{B}(z)$.

($\Leftarrow$) Let A, B and I be sets. Suppose there exist polynomials $\alpha(z)$, $\beta(z)$, $\gamma(z)$ and $\delta(z)$ such that (1), (2) and (3) are true. By replacing (2) and (3) into (1), we get that $\alpha(z)$ and $\beta(z)$ do not have any common factor, therefore $\mathsf{I}(z)$ is the greatest common divisor of $\mathsf{A}(z)$ and $\mathsf{B}(z)$ and therefore $\mathsf{A} \cap \mathsf{B} = \mathsf{I}$. ■

Corollary 1 (Union constraints) *Let A, B and U be three sets of elements in $\mathbb{F}$. Then $\mathsf{U} = \mathsf{A} \cup \mathsf{B}$ iff $\exists$ polynomials $i(z)$, $\alpha(z)$, $\beta(z)$, $\gamma(z)$ and $\delta(z)$ such that*

1. $\alpha(z)\mathsf{A}(z) + \beta(z)\mathsf{B}(z) = i(z)$.
2. $\gamma(z)i(z) = \mathsf{A}(z)$.
3. $\delta(z)i(z) = \mathsf{B}(z)$.
4. $\delta(z)\mathsf{A}(z) = \mathsf{U}(z)$.



(a) (b) (c)

Figure 3: Set circuits for intersection (a), union (b) and difference (c) expressed as polynomial circuits with loops using Lemma 2, Corollary 1 and Corollary 2.

Corollary 2 (Difference constraints) *Let* A, B *and* D *be three sets of elements in* $\mathbb{F}$. *Then* $\mathsf{D} = \mathsf{A} - \mathsf{B}$ *iff* $\exists$ *polynomials* $i(z)$, $\alpha(z)$, $\beta(z)$, $\gamma(z)$ *and* $\delta(z)$ *such that*

1. $\alpha(z)\mathsf{A}(z) + \beta(z)\mathsf{B}(z) = i(z)$.
2. $\mathsf{D}(z)i(z) = \mathsf{A}(z)$.
3. $\delta(z)i(z) = \mathsf{B}(z)$.

4.2 From Set to Polynomial Circuits

Polynomial circuits with loops. To compile a set circuit into a circuit on polynomials, we need to check that the constraints in Lemma 2 and Corollaries 1 and 2 simultaneously satisfy for all intersection, union, and set difference gates respectively. Doing this in a straightforward manner seems to require implementing a Boolean AND gate using polynomial algebra, which introduces an unnecessary representation overhead.

We use a simple idea to avoid this issue, by introducing polynomial circuits with *loops*. This means that the circuit's wires, following the direction of evaluation, can contain loops, as shown in Figure 3. When a circuit contains loops, we require that there exist an assignment for the wires such that every gate's inputs and output are consistent. It is not hard to see that we can build a QPP for a polynomial circuit with loops.

From set circuits to polynomial circuits. Suppose we have a set circuit $\mathcal{C}$, as in Definition 1. We can compile $\mathcal{C}$ into a polynomial circuit with loops $\mathcal{F}$ as follows:

1. Replace every intersection gate g_I with the circuit of Figure 3(a), which implements the constraints in Lemma 2. Note that 6 additional wires per intersection gate are introduced during this compilation, 4 of which are free wires. Also, for each intersection gate, 4 polynomial multiplication gates are added.
2. Replace every union gate g_U of $\mathcal{C}$ with the circuit of Figure 3(b), which implements the set of constraints in Corollary 1. Note that 7 additional wires per union gate are introduced during this compilation, 3 of which are free wires. Also, for each union gate, 5 polynomial multiplication gates are added.
3. Replace every difference gate g_D of $\mathcal{C}$ with the circuit of Figure 3(c), which implements the set of constraints in Corollary 2. Note that 7 additional wires per union gate are introduced during this compilation, 3 of which are free wires. Also, for each difference gate, 5 polynomial multiplication gates are added.

4.3 Asymptotic Complexity and Security

Let $\mathcal{C}$ be a set circuit with d gates (out of which d_1 are intersection gates and d_2 are union and difference gates) and N inputs and outputs. After compiling $\mathcal{C}$ into an polynomial circuit with loops, we end up with a circuit $\mathcal{F}$ with $4d_1 + 5d_2$ multiplication gates since each intersection introduces 4 multiplication gates and each union or difference introduces 5 multiplication gates.

Therefore, a SNARK for set circuits with $d = d_1 + d_2$ gates can be derived from a SNARK for polynomial circuits with $4d_1 + 5d_2$ multiplication gates. Note that the complexity of Prove for the SNARK for set circuits is $O(d\nu \log^2 \nu \log\log \nu)$ because the prover runs the extended Euclidean algorithm to compute the polynomials on the free wires, which takes $O(t \log^2 t \log\log t)$ time, for t-degree polynomials as inputs.

Theorem 2 (Security of the SNARK for $\mathcal{C}$) *Let* $\mathcal{C}$ *be a set circuit that has* d *total gates and* N *total inputs and outputs. Let* n *be an upper bound on the cardinalities of the sets on the wires of* $\mathcal{C}$ *and let* $q = 16d_1 + 20d_2 + 4$, *where* d_1 *is the number of intersection gates and* d_2 *is the number of union and difference gates* ($d = d_1 + d_2$). *The construction above is a SNARK for the set circuit* $\mathcal{C}$ *under the* $2(n+1)q$-PKE, *the* $(n+1)q$-PDH *and the* $2(n+1)q$-SDH *assumptions.*

We note here that there do exist known SNARK constructions for languages in NP that have excellent asymptotic behavior and are *input-specific*, e.g., the work of Bitansky et al. [6], based on recursive proof composition.

Therefore, in theory, our SNARK asymptotics are the same with the ones by Bitansky et al. [6] (when applied to the case of set operations). However, the concrete overhead of such techniques remains high; in fact, for most functionalities it is hard to deduce the involved constants. In comparison, with our approach, we can always deduce an upper bound on the number of necessary operations involved. We give a tight complexity analysis of our approach in the full version of our paper [20].

4.4 Handling More Expressive Circuits

As discussed in the introduction, by moving from QAPs to QPPs our scheme is not losing anything in expressiveness. So far we explicitly discussed the design of efficient set circuits that only consist of set gates. Ideally, we want to be able to efficiently accommodate "hybrid" circuits that consist both of set and arithmetic operations in an optimally tailored approach.

In this section we show how, by constructing a *split* gate (and a *merge* gate) that upon input a set A outputs its elements a_i, we gain some "backwards compatibility" with respect to QAPs. In particular, this allows us to compute on the set elements themselves, e.g., performing `MAX` or `COUNT`. Also, using techniques described by Parno et al. [23], one can go one step below in the representation hierarchy and represent a_i's in binary form which yields, for example, more efficient comparison operations.

Hence we produce a complete toolkit that a delegating client can use for a general purpose computation, in a way that allows it both to be more efficient for the part corresponding to set operations and at the same time perform arithmetic and bit operations optimally, choosing different levels of abstraction for different parts of the circuit.

Zero-degree assertion gate. Arithmetic values can be naturally interpreted as zero-degree polynomials. Since we want to securely accommodate both polynomials and arithmetic values in our circuit, we need to construct a gate that will constrain the values of some wires to arithmetic values. For example, we need to assure that the outputs of a split gate are indeed numbers (and not higher degree polynomials).

Lemma 3 (Zero-degree constraints) *Let $p(z)$ be a univariate polynomial in $\mathbb{F}[z]$. The degree of $p(z)$ is 0 iff $\exists$ polynomial $q(z)$ in $\mathbb{F}[z]$ such that $p(z)q(z) = 1$.*

Proof: ($\Rightarrow$) Every zero-degree polynomial $q(z) \in \mathbb{F}[z]$ also belongs in $\mathbb{F}$. Since every element in $\mathbb{F}$ has an inverse, the claim follows. ($\Leftarrow$) Assume now that $p(z)q(z) = 1$. Since polynomial 1 is of degree 0, $p(z)q(z)$ must also be of degree 0. By polynomial multiplication, we know that $p(z)q(z)$ has degree $deg(p(z)) + deg(q(z))$. Hence $deg(p(z)) = deg(q(z)) = 0$. ■

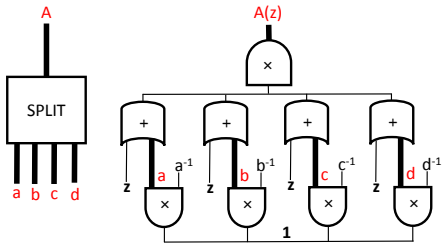


Figure 4: Implementation of a split gate for the set $\mathsf{A} = \{a, b, c, d\}$. The elements z and 1 on the wires are hard-coded in the circuit during setup. All other polynomials on the wires are computed by the prover.

This simple gate consists of a multiplication gate between polynomial $p(z)$ and an auxiliary input $q(z)$ computed by the server and the output is set to the (hard-coded) polynomial 1. If the input is indeed a zero-degree polynomial, by the above Lemma, $q(z)$ is easily computable by the server (an inverse computation in $\mathbb{F}$).

Split gate. A split gate, depicted in Figure 4, operates as follows. On input a wire with value $\mathsf{A}(z)$, it outputs n wires with the individual elements a_i. First, each of the wires carrying a_i is connected to a degree-zero assertion gate. This will make sure that these wires carry arithmetic values. Second, each of these wires is used as an input to an addition gate, with the other input being the degree-one polynomial z. Then the outputs of all the addition gates are multiplied together and the output of the multiplication is connected to the wire carrying $\mathsf{A}(z)$.

Split gate with variable number of outputs. In the above we assumed that the split gate has a fixed number of outputs, n. However, the number of outputs can vary. To accommodate this, we assume that n is an upper bound on the number of outputs of a split gate. Now, for each of the n output wires, we introduce an indicator variable ν_i (picked by the prover) such that if $\nu_i = 1$, this output wire is occupied and carries an arithmetic value, otherwise $\nu_i = 0$. Then, in the split gate of Figure 4, instead of $\prod_{i=1}^{n}(z + a_i)$ we compute $\prod_{i=1}^{n}[\nu_i(z + a_i) + (1 - \nu_i)]$. Note here that an additional restriction we need to impose is that $\nu_i \in \{0, 1\}$. Fortunately this can be checked very easily by adding one self-multiplication gate and a loop wire for each value that enforces the condition $\nu_i \cdot \nu_i = \nu_i$ that clearly holds iff $\nu_i = 0$ or 1.

Cardinality gate. One immediate side-effect of our construction for split gates with variable number of outputs, is that it indicates a way to construct another very important type of gate, namely a *cardinality* gate. Imagine for example a computation where the requested output is not a set but only its cardinality (e.g., a `COUNT` SQL-query or the Jaccard similarity index). A cardinality gate is implemented exactly like a split gate, however it only has a

single output wire that is computed as $\sum_i \nu_i$, using $n-1$ addition gates over the ν_i wires.

Merge gate. Finally, the *merge* gate upon input n wires carrying numerical values a_i, outputs a single wire that carries them as a set (i.e., its characteristic polynomial). The construction is similar to that of the split gate, only in reverse order. First input wires are tested to verify they are of degree 0, with n zero-degree assertion gates. Then, these wires are used as input for union gates, taken in pairs, in an iterative manner (imagine a binary tree of unions with n leaves and the output set at the root).

5 Evaluation

We now present the evaluation of TRUESET comparing its performance with Pinocchio [23], which is the state-of-the-art general VC scheme (already reducing computation time by orders-of-magnitude when compared with previous implementations). We also considered alternative candidates for comparison such as Pantry [9] which is specialized for stateful computations. Pantry is theoretically more efficient than Pinocchio, as it can support a RAM-based $O(n)$-time algorithm for computing set intersection (i.e., when the input sets are sorted), instead of the circuit-based $O(n \log^2 n)$ or $O(n^2)$ algorithms that Pinocchio supports. However, evaluation showed that Pantry requires considerable proof construction time, even for simple memory-based operations (e.g., 92 seconds for a single verifiable *put* operation in a memory of 8192 addresses), hence we chose to compare only with Pinocchio.

In our experiments, we analyze the performance of TRUESET both for the case of a single set operation and multiple set operations. We begin by presenting the details of our implementation and the evaluation environment and then we present the performance results.

5.1 Implementation

We built TRUESET by extending Pinocchio's C++ implementation so that it can handle set circuits, with the special set gates that we propose. However, since the original implementation of Pinocchio used efficient libraries for pairing-based cryptography and field manipulation that are not available for public use (internal to Microsoft), the first step was to replace those libraries with available free libraries that have similar characteristics. In particular, we used the Number Theory Library (NTL) [27] along with the GNU Multi-Precision (GMP) library [15] for polynomial arithmetic, in addition to an efficient free library for ate-pairing over Barreto-Naehrig curves [4], in which the underlying BN curve is $y^2 = x^3 + 2$ over a 254-bit prime field $\mathbb{F}_p$ that maintains a 126 bit-level of security. As in Pinocchio, the size of the cryptographic proof produced by our implementation is typically equal to 288 bytes in all experiments regardless of the input or circuit sizes.

TRUESET's executable receives an input file describing a set circuit that contains one or more of the set gates described earlier. The executable compiles the circuit to a QPP in two stages. In the first stage, the set gates are transformed into their equivalent representation using polynomial multiplication and addition gates, as in Figures 3 and 4, and then the QPP is formed directly in the second stage by generating the roots, and calculating the V, W and Y polynomials.

Optimizations. For a fair comparison, we employ the same optimizations used for reducing the exponentiation overhead in Pinocchio's implementation. Concerning polynomial arithmetic, Pinocchio's implementation uses an FFT approach to reduce the polynomial multiplication costs. In our implementation, we use the NTL library, which already provides an efficient solution for polynomial arithmetic based on FFT [28].

In addition to the above, the following optimizations were found to be very useful when the number of set gates is high, or when the set split gate is being used.
1) For key generation, we reduce the generated key size by considering the maximum polynomial degree that can appear on each wire, instead of assuming a global upper bound on the polynomial degree for all wires (as described in previous sections). This can be calculated by assuming a maximum cardinality of the sets on the input wires, and then iterating over the circuit wires to set the maximum degree per wire in the worst case, e.g. the sum of the worst case cardinalities of the input sets for the output of a union gate, and the smaller for intersections.
2) The NTL library does not provide direct support for bivariate polynomial operations, needed to calculate $h(x,z)$ through division of $p(x,z)$ by $\tau(x)$. Hence, instead of doing a naive $O(n^2)$ polynomial division, we apply the change-of-variable trick discussed in Section 3.3 to transform bivariate polynomials into univariate ones that can be handled efficiently with NTL FFT operations.
3) Finally, calculation of the coefficients of the characteristic polynomial corresponding to the output is done by the prover and not by the verifier. The verifier then verifies that the set elements of the output (i.e., the roots of the characteristic polynomials) match the polynomial (expressed in coefficients) returned by the server. This can be efficiently done through a randomized check—see algorithm certify() from [22]. We specify that this slightly increases the communication bandwidth (the server effectively sends the output set twice, in two different encodings) but we consider this an acceptable overhead (This can be avoided by having the client perform the interpolation himself, increasing the verification time). It can also be noted that the input polynomial coefficients computa-

tion can be outsourced similarly to the server side, if the client does not have them computed already.

5.2 Experiments Setup

We now provide a comparison between TRUESET's approach and Pinocchio's approach based for set operations. For a fair comparison, we considered two different ways to construct the arithmetic circuits used by Pinocchio to verify the set operations:

- Pairwise comparison-based, which is the naive approach for performing set operations. This requires $O(n^2)$ equality comparisons.
- Sorting network-based, in which the input sets are merged and sorted first using and odd-even merge-sort network [19]. Then a check for duplicate consecutive elements is applied to include/remove repeated elements, according to the query being executed. This requires $O(n \log^2 n)$ comparator gates, and $O(n)$ equality gates.

Although the second approach is asymptotically more efficient, when translated to Pinocchio's circuits it results in numerous multiplication gates. This is due to the k-bits split gates needed to perform comparison operations, resulting into great overhead in the key generation and proof computation stages. For a k-bit possible input value, this split gate needs k multiplication constraints to constrain each bit wire to be either 0 or 1. (It should be noted that these gates translate a wire into its bit-level representation and they should not be confused with the split gates we introduce in this paper, which output the elements of a set as separate arithmetical values). On the other hand, the pairwise approach uses zero-equality gates to check for equality of elements. Each equality gate translates into only two multiplication gates, requiring only two roots.

For fairness purposes, different Pinocchio circuits were produced for each different input set cardinality we experiment with, as each wire in Pinocchio's circuits represents a single element. On the other hand, TRUESET can use the same circuit for different input cardinalities.

We consider two Pinocchio circuit implementations:

- MS Pinocchio: This is the executable built using efficient Microsoft internal libraries.
- NTL-ZM Pinocchio: This is a Pinocchio version built using exactly the same free libraries we used for our TRUESET implementation. This will help ensure having a fair comparison.

The experiments were conducted on a Lenovo IdeaPad Y580 Laptop. The executable used a single core of a 2.3 GHz Intel Core i7 with 8 GB of RAM. For the input sets, disjoint sets containing elements in $\mathbb{F}$ were assumed. For running time statistics, ten runs were collected for each data point, and the 95% confidence interval was calculated. Due to the scale of the figures, the confidence interval of the execution times (i.e., error bars) was too low to be visualized.

5.3 Single-Gate Circuit

In this subsection, we compare TRUESET and Pinocchio's protocols based on the verification of a single union operation that accepts two input sets of equal cardinalities. We study both the time overhead and the key sizes with respect to different input set cardinalities. Note that, experiments for higher input cardinalities in Pinocchio's case incur great memory overhead due to the large circuit size, therefore we were unable to even perform Pinocchio's for large input sizes.

Figure 5 shows the comparison between TRUESET's approach and Pinocchio's pairwise and sorting network approaches, versus the cardinality of each input set. The results show clearly that TRUESET outperforms both approaches in the key generation and proof computation stages by orders of magnitude, while maintaining the same verification time. Specifically, TRUESET outperforms Pinocchio in the prover's running time by *150x* when the input set cardinality is 2^8. This saving happens in both polynomial computations and exponentiation operations, as shown in Figure 5 (c). We also note that Pinocchio's pairwise comparison approach outperforms the sorting network approach due to the expensive split gates needed for comparisons in the sorting-network circuits, as discussed above, which results into a large constant affecting the performance at small cardinalities.

Considering evaluation and verification key sizes, Figure 5 also shows a comparison between TRUESET and Pinocchio under both the pairwise and sorting networks approaches. The figures demonstrate that TRUESET yields much smaller evaluation keys due to the more compact wire representation it employs (a single wire for a set as opposed to a wire per element), e.g., at an input set cardinality of 2^8, the saving is about 98%. It can also be noticed that the keys generated in Pinocchio using sorting networks are much larger than the ones generated in pairwise circuits, due to the use of the split gates. On the other hand, TRUESET and Pinocchio almost maintain the same verification key sizes, as the verification key mainly depends on the number of input elements in addition to the number of output elements in the worst case. (The verification key in TRUESET is *negligibly* more than the verification key of Pinocchio, due to an additional value that is needed to be verified per each input or output set. This is because an n-element set is represented by an n-degree polynomial which requires $n + 1$ coefficients.)

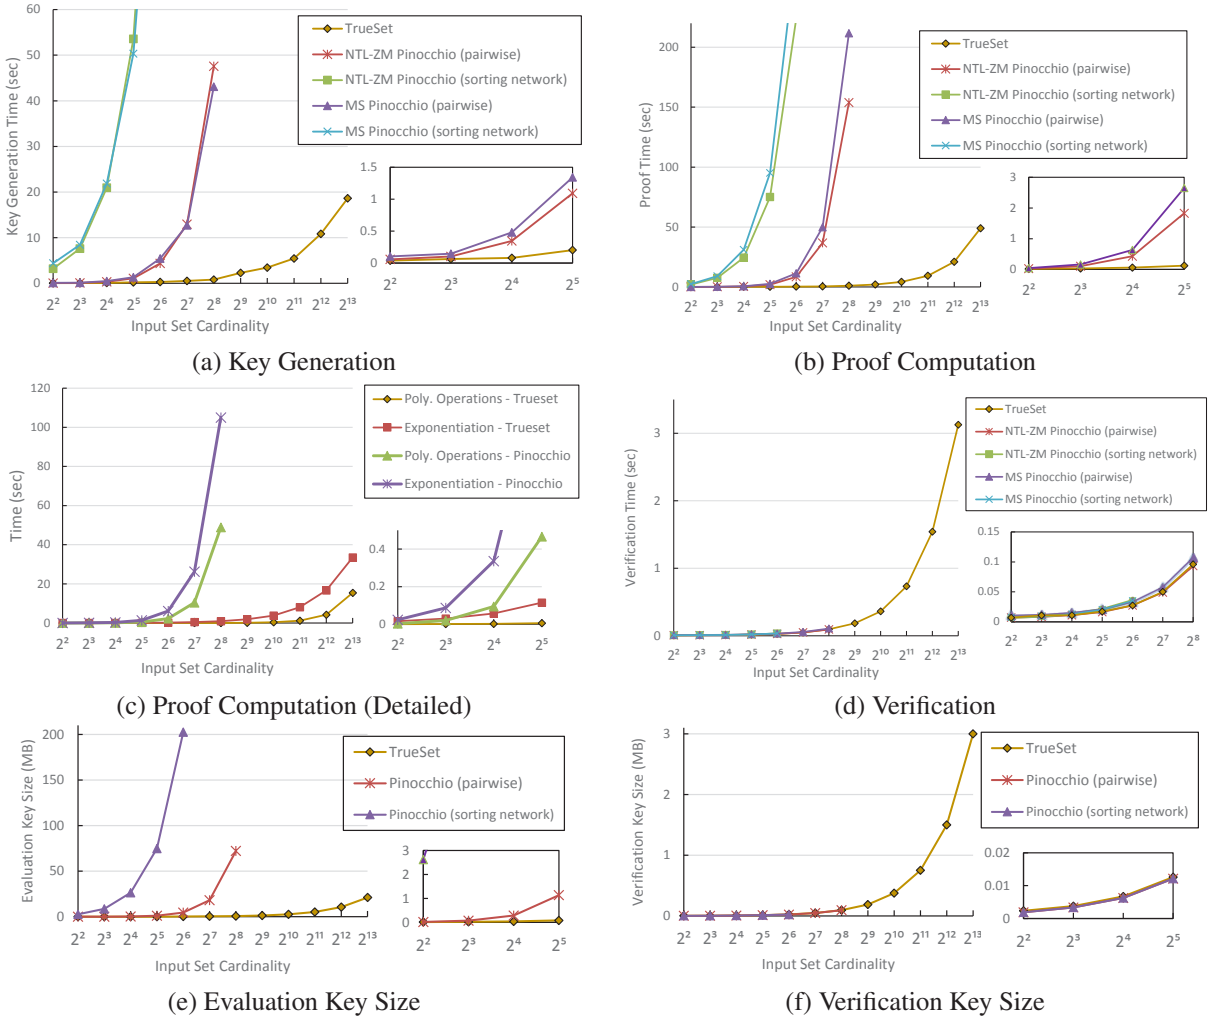

Figure 5: Comparison between TRUESET *and Pinocchio for the case of a single union gate. In the horizontal axis, we show the cardinality of* each *input set in logarithmic scale. (Note: Each time data point is the average of ten runs. The error bars were too small to be visualized). Subfigures (a), (b) and (d) show the comparison in terms of the key generation, proof computation and verification times, while (c) shows* TRUESET*'s prover's time in more detail compared to Pinocchio's prover in the case of pairwise comparison. Subfigures (e) and (f) show the compressed evaluation and verification key sizes (The cryptographic proof for all instances is 288 bytes).*

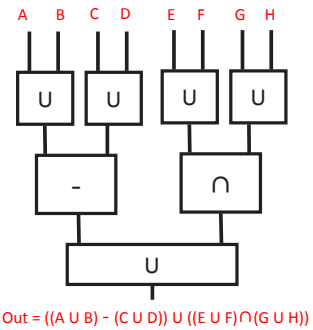

Figure 6: The multiple-gate circuit used for evaluation.

5.4 Multiple-Gate Circuit

We now compare TRUESET and Pinocchio's performance for a complex set circuit consisting of multiple set operations, illustrated in Figure 6. The circuit takes eight input sets of equal cardinalities, and outputs one set. We compare both the prover's overhead and the key sizes with respect to different input set cardinalities, but this time we consider only Pinocchio circuits based on pairwise comparisons, as the sorting network approach has much larger overhead for computation times and key sizes as shown in the previous subsection.

Figure 7 shows a comparison between TRUESET's approach and Pinocchio's approach. The results again

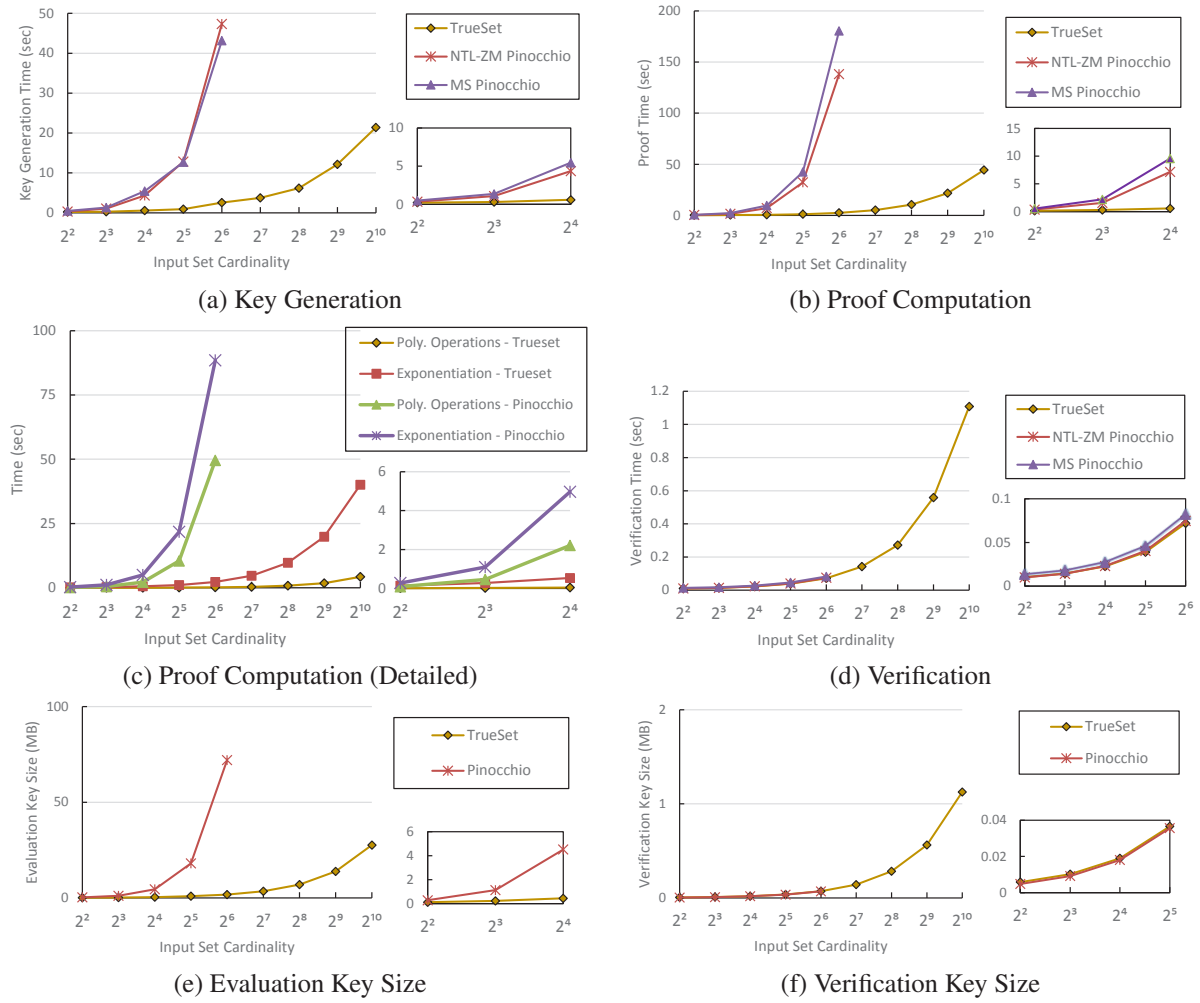

Figure 7: Comparison between TRUESET *and Pinocchio in the case of the multiple-gate circuit shown in Fig. 6, assuming the pair-wise comparison circuit for Pinocchio. In the horizontal axis, we show the cardinality of* each *input set in logarithmic scale. Subfigures (a), (b) and (d) show the comparison in terms of the key generation, proof computation and verification time, while (c) shows* TRUESET*'s prover's time in more detail compared to Pinocchio's prover time. Subfigures (e) and (f) show the compressed evaluation and verification key sizes (The cryptographic proof for all instances is 288 bytes).*

confirm that TRUESET greatly outperforms Pinocchio's elapsed time for key generation and proof computation, while maintaining the same verification time. In particular, for input set cardinality of 2^6, TRUESET's prover has a speedup of more than **50x**. In terms of key sizes, the figure confirms the observation that the evaluation key used by TRUESET is tiny compared to that of Pinocchio, e.g., 97% smaller when the input cardinality is 2^6.

5.5 Cardinality and Sum of Set Elements

Here, we evaluate TRUESET when a split gate is used to calculate the cardinality and sum for the output set of Figure 6. We compare that with Pinocchio's performance for the same functions. One important parameter that has to be defined for the split gate first is the maximum cardinality of the set it can support. This is needed for translating the split gate to the appropriate number of multiplication gates needed for verification. For example, a split gate added to the output of the circuit in Figure 6, will have to account for $4n$ set elements in the worst case, if n is the upper bound on the input set cardinalities.

Table 1 presents a comparison between TRUESET and Pinocchio in terms of the elapsed times in the three stages and the evaluation/verification key sizes, when the input set cardinality is 64. As the table shows, TRUESET can provide better performance in terms of the key generation and proof computation times (4x better proof computation time), in addition to a much smaller public evaluation key. It can be noted that, while there definitely exists a large improvement over Pinocchio, it is not as large as the one

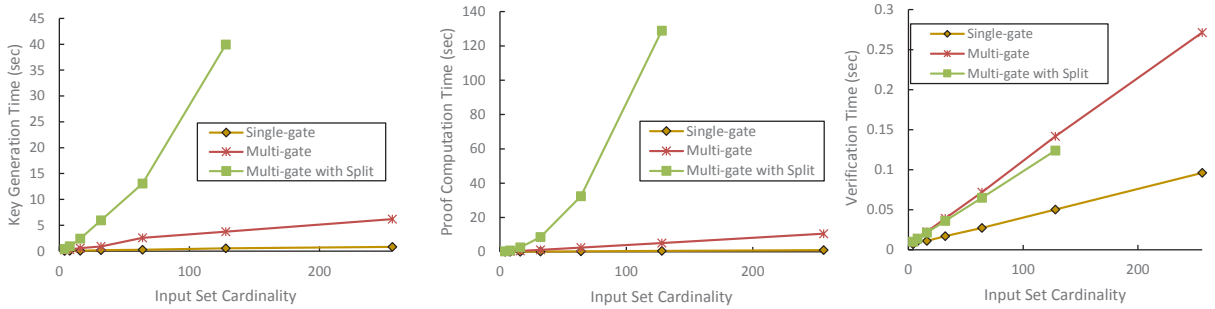

Figure 8: Summary of TRUESET *performance under all circuits in linear scale.*

	TRUESET	MS Pinocchio	NTL-ZM Pinocchio
Key Generation (sec)	13.07	43.03	47.39
Proof Computation (sec)	32.45	174.99	137.79
Verification (sec)	0.065	0.074	0.066
Evaluation Key (MB)	12.7	72.45	72.45
Verification Key (KB)	49.65	48.6	48.6

Table 1: Comparison between TRUESET *and Pinocchio on a circuit that computes* ***the cardinality and the sum*** *of the output set in the circuit in Figure 6, at input set cardinality of 64.*

exhibited for the previous single-gate and multiple-gate circuits. Overall, we found the split gate to be costlier than set gates since the multiplication gates introduced by the split gate increase proportionally with the number of the set elements it can support, whereas set gates are "oblivious" to the number of elements.

5.6 Discussion of Results

The evaluation of TRUESET for single-gate and multiple-gate circuits showed huge improvement for both key generation and proof computation time over Pinocchio. For example, for the single union case with 2^8-element input sets, a speed-up of 150x was obtained for the prover's time, while providing more than 98% saving in the evaluation key size. For a multiple-gate circuit comprised of seven set gates with eight input sets, each of 2^6 elements, a prover speed-up of more than 50x, and key size reduction of 97% were obtained.

As can be qualitatively inferred by our plots, these improvements in performance allow us to accommodate problem instances that are several times larger than what was considered achievable by previous works. TRUESET achieves the performance behavior that Pinocchio exhibits for sets of a few dozen elements, for sets that scale up to approximately 8000 elements, handling circuits with nearly 30x larger I/O size. Figure 8 summarizes the behavior of TRUESET for all circuits we experimented with, illustrating its performance for the three stages in linear scale. In all cases, the running time increases approximately linearly in the input size. The cost increases more abruptly when a split gate is introduced due to the added complexity discussed above. Improving the performance of the split gate is one possible direction for future work.

Remarks. We discuss here a few points related to the performance of our scheme.

Performance on Arithmetic Circuits. The presented evaluation covered the case of set circuits only, in which our construction outperformed arithmetic circuits verified using Pinocchio. Our construction can support typical arithmetic circuits as well, by assuming that the maximum polynomial degree on each wire is 0. In this case, our construction will reduce to Pinocchio's, however due to the bivariate polynomial operations, there will be more overhead in accommodating arithmetic circuits. For example, for an arithmetic circuit handling the multiplication of two 50x50 32-bit element matrices, the prover's time with TRUESET increased by 10% compared to Pinocchio.

Outsourced Sets. In the above, we assumed that the client possesses the input sets. However, it is common practice in cloud computing, to not only delegate computations but storage as well. In this case, the client initially outsources the sets to the server and then proceeds to issue set operation queries over them. This introduces the need for an additional mechanism to ensure the authenticity of the set elements used by the server. The full version of our paper [20] describes a modified protocol that handles this case using Merkle tree proofs.

Supporting multisets. Finally, it should be noted that the comparisons with Pinocchio above assumed proper sets only. In a setting that accommodates multiset operations (i.e., sets that allow repetition in elements), we expect TRUESET's performance to be much better, as it can naturally handle multiset cases without adding any modifications. On the other hand, Pinocchio multiset circuits are going to become more complex due to the added complexity of taking repetitions into account. For example, in intersection gates, it will not be enough to only check that two element are equal, but it will also be necessary to make sure that the matched element was not encountered before, introducing additional overhead.

Acknowledgments

We would like to thank David Evans and the anonymous reviewers for their invaluable comments and feedback.

6 Appendix

6.1 Computational Assumptions

Assumption 1 (q-PDH assumption [16]) *The q-power Diffie-Hellman (q-PDH) assumption holds for $\mathcal{G}$ if for all PPT $\mathcal{A}$ the following probability is negligible in k:*

$$\Pr\left[\begin{array}{l}(p,\mathbb{G},\mathbb{G}_T,e,g)\leftarrow\mathcal{G}(1^k);s\leftarrow\mathbb{Z}_p^*;\\ \mathbf{G}\leftarrow\left[g,g^s,\ldots,g^{s^q},g^{s^{q+2}},\ldots,g^{s^{2q}}\right];\\ \sigma\leftarrow(p,\mathbb{G},\mathbb{G}_T,e,\mathbf{G});\\ y\leftarrow\mathcal{A}(\sigma):y=g^{s^{q+1}}\end{array}\right].$$

Assumption 2 (q-PKE assumption [16]) *The q-power knowledge of exponent assumption holds for $\mathcal{G}$ if for all PPT $\mathcal{A}$ there exists a non-uniform PPT extractor $\chi_{\mathcal{A}}$ such that the following probability is negligible in k:*

$$\Pr\left[\begin{array}{l}(p,\mathbb{G},\mathbb{G}_T,e,g)\leftarrow\mathcal{G}(1^k);\{\alpha,s\}\leftarrow\mathbb{Z}_p^*;\\ \mathbf{G}\leftarrow\left[g,g^s,\ldots,g^{s^q},g^{\alpha},g^{\alpha s},\ldots,g^{\alpha s^q}\right];\\ \sigma\leftarrow(p,\mathbb{G},\mathbb{G}_T,e,\mathbf{G});\\ (c,\hat{c};a_0,a_1,\ldots,a_q)\leftarrow(\mathcal{A}||\chi_{\mathcal{A}})(\sigma,z):\\ \hat{c}=c^{\alpha}\wedge c\neq g^{\prod_{i=0}^{q}a_is^i}\end{array}\right],$$

for any auxiliary information $z\in\{0,1\}^{\mathsf{poly}(k)}$ that is generated independently of α. Note that $(y;z)\leftarrow(\mathcal{A}||\chi_{\mathcal{A}})(x)$ signifies that on input x, $\mathcal{A}$ outputs y, and that $\chi_{\mathcal{A}}$, given the same input x and $\mathcal{A}$'s random tape, produces z.

Assumption 3 (q-SDH assumption [8]) *The q-strong Diffie-Hellman (q-SDH) assumption holds for $\mathcal{G}$ if for all PPT $\mathcal{A}$ the following probability is negligible in k:*

$$\Pr\left[\begin{array}{l}(p,\mathbb{G},\mathbb{G}_T,e,g)\leftarrow\mathcal{G}(1^k);\{s\}\leftarrow\mathbb{Z}_p^*;\\ \sigma\leftarrow(p,\mathbb{G},\mathbb{G}_T,e,\mathbf{G}=\left[g,g^s,\ldots,g^{s^q}\right]);\\ (y,c)\leftarrow\mathcal{A}(\sigma):y=e(g,g)^{\frac{1}{s+c}}.\end{array}\right].$$

6.2 Succinct Non-Interactive Arguments of Knowledge (SNARKs)

Definition 6 (SNARK) *Algorithms* $(\mathsf{KeyGen},\mathsf{Prove},\mathsf{Verify})$ *give a* succinct non-interactive argument of knowledge (SNARK) *for an NP language L with corresponding NP relation R_L if:*

Completeness: *For all $x\in L$ with witness $w\in R_L(x)$, the following probability is negligible in k:*

$$\Pr\left[\mathsf{Verify}(\mathsf{sk},x,\pi)=0\;\middle|\;\begin{array}{c}(\mathsf{pk},\mathsf{sk})\leftarrow\mathsf{KeyGen}(1^k),\\ \pi\leftarrow\mathsf{Prove}(\mathsf{pk},x,w)\end{array}\right]$$

Adaptive soundness: *For any PPT algorithm $\mathcal{A}$, the following probability is negligible in k:*

$$\Pr\left[\begin{array}{c}\mathsf{Verify}(\mathsf{sk},x,\pi)=1\\ \wedge\,(x\notin L)\end{array}\;\middle|\;\begin{array}{c}(\mathsf{pk},\mathsf{sk})\leftarrow\mathsf{KeyGen}(1^k),\\ (x,\pi)\leftarrow\mathcal{A}(1^k,\mathsf{pk})\end{array}\right]$$

Succinctness: *The length of a proof is given by $|\pi|=\mathsf{poly}(k)\mathsf{poly}\log(|x|+|w|)$.*

$$\Pr\left[\begin{array}{c}(\mathsf{pk},\mathsf{sk})\leftarrow\mathsf{KeyGen}(1^k)\\ \pi\leftarrow\mathsf{Prv}(\mathsf{pk},x,\mu)\\ \mathsf{Verify}(\mathsf{sk},x,\pi)=1\\ \wedge\\ w\leftarrow\mathsf{Extract}(\mathsf{pk},\mathsf{sk},x,\pi)\\ w\notin R_L(x)\end{array}\right]=\mathsf{negl}(k).$$

Zero-knowledge: *There exists a simulator* Sim*, such that for any PPT adversary $\mathcal{A}$, the following holds:*

$$\Pr\left[\begin{array}{c}\mathsf{pk}\leftarrow\mathsf{KeyGen}(1^k);(x,w)\leftarrow\mathcal{A}(\mathsf{pk});\\ \pi\leftarrow\mathsf{Prove}(\mathsf{pk},x,w):(x,w)\in R_L\\ \textit{and}\;\mathcal{A}(\pi)=1\end{array}\right]$$

$$\simeq$$

$$\Pr\left[\begin{array}{c}(\mathsf{pk},\mathsf{state})\leftarrow\mathsf{Sim}(1^k);(x,w)\leftarrow\mathcal{A}(\mathsf{pk});\\ \pi\leftarrow\mathsf{Sim}(\mathsf{pk},x,\mathsf{state}):(x,w)\in R_L\\ \textit{and}\;\mathcal{A}(\pi)=1.\end{array}\right]$$

We say that a SNARK is *publicly verifiable* if $\mathsf{sk}=\mathsf{pk}$. In this case, proofs can be verified by anyone with pk. Otherwise, we call it a *secretly-verifiable* SNARK, in which case only the party with sk can verify.

Succinct Non-Interactive Zero Knowledge for a von Neumann Architecture

Eli Ben-Sasson, *Technion*
Alessandro Chiesa, *MIT*
Eran Tromer, *Tel Aviv University*
Madars Virza, *MIT*

Abstract

We build a system that provides succinct non-interactive zero-knowledge proofs (*zk-SNARK*s) for program executions on a von Neumann RISC architecture. The system has two components: a cryptographic proof system for verifying satisfiability of arithmetic circuits, and a circuit generator to translate program executions to such circuits. Our design of both components improves in functionality and efficiency over prior work, as follows.

Our circuit generator is the first to be *universal*: it does not need to know the program, but only a bound on its running time. Moreover, the size of the output circuit depends *additively* (rather than multiplicatively) on program size, allowing verification of larger programs.

The cryptographic proof system improves proving and verification times, by leveraging new algorithms and a pairing library tailored to the protocol.

We evaluated our system for programs with up to 10,000 instructions, running for up to 32,000 machine steps, each of which can arbitrarily access random-access memory; and also demonstrated it executing programs that use *just-in-time compilation*. Our proofs are 230 bytes long at 80 bits of security, or 288 bytes long at 128 bits of security. Typical verification time is 5 ms, regardless of the original program's running time.

1 Introduction

1.1 Goal

Consider the setting where a client owns a public input x, a server owns a private input w, and the client wishes to learn $z := F(x,w)$ for a program F known to both parties. For instance, x may be a query, w a confidential database, and F the program that executes the query on the database.

Security. The client is concerned about *integrity* of computation: how can he ascertain that the server reports the correct output z? In contrast, the server is concerned about *confidentiality* of his own input: how can he prevent the client from learning information about w?

Cryptography offers a powerful tool to address these security concerns: *zero-knowledge proofs* [43]. The server, acting as the prover, attempts to convince the client, acting as the verifier, that the following NP statement is true: "there exists w such that $z = F(x,w)$". Indeed:

- The *soundness* property of the proof system guarantees that, if the NP statement is false, the prover cannot convince the verifier (with high probability). Thus, soundness addresses the client's integrity concern.
- The *zero-knowledge* property of the proof system guarantees that, if the NP statement is true, the prover can convince the verifier without leaking any information about w (beyond was is leaked by the output z). Thus, zero knowledge addresses the server's confidentiality.

Moreover, the client sometimes not only seeks soundness but also *proof of knowledge* [43, 11], which guarantees that, whenever he is convinced, not only can he deduce that a witness w exists, but also that the server *knows* one such witness. This stronger property is often necessary to security if F encodes cryptographic computations, and is satisfied by most zero-knowledge proof systems.

Efficiency. Besides the aforementioned security desiderata, many settings also call for *efficiency* desiderata. The client may be either unable or unwilling to engage in lengthy interactions with the server, or to perform large computations beyond the "bare minimum" of sending the input x and receiving the output z. For instance, the client may be a computationally-weak device with intermittent connectivity (e.g., a smartphone).

Thus, it is desirable for the proof to be *non-interactive* [25, 55, 23]: the server just send the claimed output $\tilde{z}$, along with a non-interactive proof string π that attests that $\tilde{z}$ is the correct output. Moreover, it is also desirable for the proof to be *succinct*: π has size $O_\lambda(1)$ and can be verified in time $O_\lambda(|F|+|x|+|z|)$, where $O_\lambda(\cdot)$ is some polynomial in a security parameter λ; in other words, π is very short and easy to verify (i.e., verification time does *not* depend on $|w|$, nor F's running time).

zk-SNARKs. A proof system achieving the above security and efficiency desiderata is called a (publicly-verifiable) *zero-knowledge Succinct Non-interactive ARgument of Knowledge* (zk-SNARK). zk-SNARK constructions can be applied to a wide range of security applications, provided these constructions deliver good enough *efficiency*, and support rich enough *functionality* (i.e., the class of programs F that is supported).

Remark 1.1. In the zero-knowledge setting above, the client does not have the server's input, and so cannot conduct the computation on his own. Hence, it is *not meaningful* to compare "efficiency of outsourced computation at the server" and "efficiency of native execution at the client", because the latter was never an option. Non-interactive zero-knowledge proofs (and zk-SNARKs) are useful regardless of *cross-over points*.

Our goal in this paper is to construct

a zk-SNARK implementation supporting executions on a universal von Neumann RISC machine.

1.2 Prior work

zk-SNARKs. Many works have obtained zk-SNARK constructions [45, 51, 38, 22, 56, 16, 52, 27]. Three of these [56, 16, 27] provide implementations, and thus we briefly recall them. Parno et al. [56] present two main contributions.

- A zk-SNARK, with essentially-optimal asymptotics, for arithmetic circuit satisfiability, based on *quadratic arithmetic programs* (QAPs) [38]. They accompany their construction with an implementation.
- A compiler that maps C programs with fixed memory accesses and bounded control flow (e.g., array accesses and loop iteration bounds are compile-time constants) into corresponding arithmetic circuits.

Ben-Sasson et al. [16] present three main contributions.

- Also a QAP-based zk-SNARK with essentially-optimal asymptotics for arithmetic circuit satisfiability, and a corresponding implementation. Their construction follows the linear-interactive proofs of [22].
- A simple RISC architecture, TinyRAM, along with a circuit generator for generating arithmetic circuits that verify correct execution of TinyRAM programs.
- A compiler that, given a C program, produces a corresponding TinyRAM program.

Finally, Braun et al. [27] re-implemented the protocol of [56] and combined it with a circuit generator that incorporates memory-checking techniques [24] to support random-access memory [14].

Outsourcing computation to powerful servers. Numerous works [63, 65, 66, 64, 32, 68, 71, 67, 27] seek to verifiably outsource computation to untrusted powerful servers, e.g., in order to make use of cheaper cycles or storage. (See Appendix A for a summary.) We stress that verifiable outsourcing of computations *is not our goal*. Rather, as mentioned, we study functionality and efficiency aspects of *non-interactive zero-knowledge proofs*, which are useful even when applied to relatively-small computations, and even with high overheads.

Compared to most protocols to outsource computations, known zk-SNARKs use "heavyweight" techniques, such as *probabilistically-checkable proofs* [6] and expensive pairing-based cryptography. The optimal choice of protocol, and whether it actually pays off compared to local *native execution*, are complex, computation-dependent questions [71], and we leave to future work the question of whether zk-SNARKs are useful for the goal of outsourcing computations.

1.3 Limitations of prior work

Recent work has made tremendous progress in taking zk-SNARKs from asymptotic theory into concrete implementations. Yet, known implementations suffer from several limitations.

Per-program key generation. As in any non-interactive zero-knowledge proof, a zk-SNARK requires a one-time trusted setup of public parameters: a *key generator* samples a proving key (used to generate proofs) and a verification key (used to check proofs). However, current zk-SNARK implementations [56, 16] require the setup phase to depend on the program F, which is *hard-coded* in the keys. Key generation is costly (quasilinear in F's runtime) and is thus difficult to amortize if conducted anew for each program. More importantly, per-program key generation requires, *for each new choice of program*, a trusted party's help.

Limited support for high-level languages. Known circuit generators have limited functionality or efficiency: (i) [56]'s circuit generator only supports programs without data dependencies, since memory accesses and loop iteration bounds cannot depend on a program's input; (ii) [27]'s circuit generator allows data-dependent memory accesses, but each such access requires expensive hashing to verify Merkle-tree authentication paths; (iii) [16]'s circuit generator supports arbitrary programs but its circuit size scales inefficiently with program size (namely, it has size $\Omega(\ell T)$ for ℓ-instruction T-step TinyRAM programs). Moreover, while there are techniques that mitigate some of the above limitations [72], these only apply in special cases, and not do address general data dependencies, a common occurrence in many programs.

Generic sub-algorithms. The aforementioned zk-SNARKs use several sub-algorithms, and in particular elliptic curves and pairings. Protocol-specific optimizations are a key ingredient in fast implementations of

pairing-based protocols [59], yet prior implementations only utilize off-the-shelf cryptographic libraries, and miss key optimization opportunities.

1.4 Results

We present two main contributions: a new circuit generator and a new zk-SNARK for circuits. These can be used independently, or combined to obtain an overall system.

1.4.1 A new circuit generator

We design and build a new circuit generator that incorporates the following two main improvements.

(1) Our circuit generator is *universal*: when given input bounds ℓ, n, T, it produces a circuit that can verify the execution of *any* program with $\leq \ell$ instructions, on *any* input of size $\leq n$, for $\leq T$ steps. Instead, all prior circuit generators [66, 64, 56, 16, 27] hardcoded the program in the circuit. Combined with a zk-SNARK for circuits (or any NP proof system for circuits), we achieve a notable conceptual advance: *once-and-for-all key generation* that allows verifying all programs up to a given size. This removes major issues in all prior systems: expensive per-program key generation, and the thorny issue of conducting it anew in a trusted way for every program.

Our circuit generator supports a universal machine that, like modern computers, follows the *von Neumann paradigm* (program and data lie in the same read/write address space). Concretely, it supports a von Neumann RISC architecture called vnTinyRAM, a modification of TinyRAM [17]. Thus, we also support programs leveraging techniques such as *just-in-time compilation* or *self-modifying code* [36, 58].

To compile C programs to the vnTinyRAM machine language, we ported the GCC compiler to this architecture, building on the work of [16].

See Figure 1 for a functionality comparison with prior circuit generators (for details, see [27, §2]).

Supported functionality	[66, 64, 56]	[16]	[27]	**this work**
side-effect free comp.	✓	✓	✓	✓
data-dep. mem. accesses	×	✓	✓	✓
data-dep. contr. flow	×	✓	×	✓
self-modifying code	×	×	×	✓
universality	×	×	×	✓

Figure 1: Functionality comparison among circuit generators.

(2) Our circuit generator efficiently handles *larger* arbitrary programs: the size of the generated circuit $C_{\ell,n,T}$ is $O\big((\ell+n+T)\cdot\log(\ell+n+T)\big)$ gates. Thus, the dependence on program size is *additive*, instead of multiplicative as in [16], where the generated (non-universal) circuit has size $\Theta\big((n+T)\cdot(\log(n+T)+\ell)\big)$. As Figure 2 shows, our efficiency improvement compared to [16] is not merely asymptotic but yields sizable concrete savings: as program size ℓ increases, our amortized per-cycle gate count is essentially unchanged, while that of [16] grows without bound, becoming orders of magnitudes more expensive.

$n = 10^2$	$\lvert C_{\ell,n,T}\rvert / T$		improvement
$T = 2^{20}$	[16]	**this work**	
$\ell = 10^3$	1,872	1,368	1.4×
$\ell = 10^4$	10,872	1,371	7.9×
$\ell = 10^5$	100,872	1,400	72.1×
$\ell = 10^6$	1,000,872	1,694	590.8×

Figure 2: Per-cycle gate count improvements over [16].

An efficiency comparison with other non-universal circuit generators [66, 64, 56, 27] is not well-defined. First, they support more restricted classes of programs, so a programmer must "write around" the limited functionality. Second, their efficiency is not easily specified, since the output circuit is ad hoc for the given program, and the only way to know its size is to actually run the circuit generator. We expect, and find, that such circuit generators perform better than ours for programs that are already "close to a circuit", and worse for programs rich in data-dependent memory accesses and control flow.

1.4.2 A new zk-SNARK for circuits

Our third contribution is a high-performance implementation of a zk-SNARK for arithmetic circuits.

(3) We improve upon and implement the protocol of Parno et al. [56]. Unlike previous zk-SNARK implementations [56, 16, 27], we do not use off-the-shelf cryptographic libraries. Rather, we create a tailored implementation of the requisite components: the underlying finite-field arithmetic, elliptic-curve group arithmetic, pairing-based checks, and so on.

To facilitate comparison with prior work, we instantiate our techniques for two specific algebraic setups: we provide an instantiation based on Edwards curves [33] at 80 bits of security (as in [16]), and an instantiation based on Barreto–Naehrig curves [9] at 128 bits of security (as in [56, 27]).

On our reference platform (a typical desktop), proof verification is fast: at 80-bit security, for an n-byte input to the circuit, verification takes $4.7 + 0.0004 \cdot n$ milliseconds, *regardless of circuit size*; at 128-bit security, it takes $4.8 + 0.0005 \cdot n$. The constant term dominates for small inputs, and corresponds to the verifier's pairing-based checks; in both cases, it is *less than half* the time for separately evaluating the 12 requisite pairings of the checks. We achieve this saving by merging parts of the pairings' computation in a protocol-dependent way — another reason for a custom implementation of the underlying math.

Key generation and proof generation entail a per-gate cost. For example, for a circuit with 16 million gates: at 80 bits of security, key generation takes 81 μs per gate and proving takes 109 μs per gate; at 128 bits of security, these per-gate costs mildly increase to 100 μs and 144 μs.

As in previous zk-SNARK implementations, proofs have constant size (independent of the circuit or input size); for us, they are 230 bytes at 80 bits of security, and 288 bytes at 128 bits of security.

Compared to previous implementations of zk-SNARKs for circuits [56, 16, 27], our implementation improves both proving and verification times, e.g., see Figure 3.

	80 bits of security			128 bits of security		
	[16]	**this**	impr.	[56]	**this**	impr.
Key gen.	306 s	97 s	3.2×	123 s	117 s	1.1×
Prover	351 s	115 s	3.1×	784 s	147 s	5.3×
Verifier	66.1 ms	4.9 ms	13.5×	9.2 ms	5.1 ms	1.8×
Proof	322 B	230 B	1.4×	288 B	288 B	(same)

Figure 3: Comparison with prior zk-SNARKs for a 1-million-gate arithmetic circuit and a 1000-bit input, running on our benchmarking machine, using software provided by the respective authors. Since [27] is a re-implementation of [56], we only include the latter's performance. ($N = 5$ and std $< 2\%$)

1.4.3 Two components: independent or combined

Our new circuit generator and our new zk-SNARK for circuits can be used independently. For instance, the circuit generator can (up to interface matching) replace the circuit generators in [66, 64, 56, 16, 27], thus granting these systems universality. Similarly, our zk-SNARK for circuits can replace the underlying zk-SNARKs in [56, 16, 27], or be used directly in applications where a suitable circuit is already specified.

Combining these two components, we obtain a full system: a *zk-SNARK for proving/verifying correctness of* vnTinyRAM *computations*; see Figure 4 and Figure 5 for diagrams of this system. We evaluated this overall system for programs with up to 10,000 instructions, running for up to 32,000 steps. Verification time is, again, only few milliseconds, independent of the running time of the vnTinyRAM program, even when program size and input size are kilobytes. Proofs, as mentioned, have a small constant size. Key generation and proof generation entail a per-cycle cost, with a dependence on program size that "tapers off" as computation length increases. For instance, at 128-bit security and vnTinyRAM with a word size of 32 bits, key generation takes 210 ms per cycle and proving takes 100 ms per cycle, for 8K-instruction programs.

JIT case study: efficient `memcpy`. Besides evaluating individual components, we give an example demonstrating the rich functionality supported by the integrated system. We wrote a vnTinyRAM implementation of `memcpy` that leverages *just-in-time compilation* (in particular, *dynamic loop unrolling*) to require fewer cycles. (See Section B.)

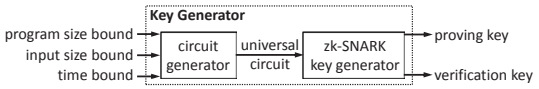

Figure 4: **Offline phase (once).** The key generator outputs a proving key and verification key, for proving and verifying correctness of any program execution meeting the given bounds.

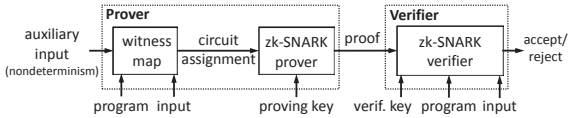

Figure 5: **Online phase (any number of times).** The prover sends a short and easy-to-verify proof to a verifier. This can be repeated any number of times, each time for a different program and input.

2 Preliminaries

$\mathbb{F}[z]$ denotes the ring of univariate polynomials over $\mathbb{F}$, and by $\mathbb{F}^{\leq d}[z]$ the subring of polynomials of degree $\leq d$. Concatenation of vectors/scalars is denoted by $\circ$.

2.1 Arithmetic circuits

Given a finite field $\mathbb{F}$, an $\mathbb{F}$-*arithmetic circuit* takes inputs that are elements in $\mathbb{F}$, and its gates output elements in $\mathbb{F}$. The circuits we consider only have *bilinear gates*.[1]

Definition 2.1. *Let n,h,l respectively denote the input, witness, and output size. The* **circuit satisfaction problem** *of a circuit $C\colon \mathbb{F}^n \times \mathbb{F}^h \to \mathbb{F}^l$ with bilinear gates is defined by the relation $\mathscr{R}_C = \{(\vec{x},\vec{a}) \in \mathbb{F}^n \times \mathbb{F}^h : C(\vec{x},\vec{a}) = 0^l\}$ and language $\mathscr{L}_C = \{\vec{x} \in \mathbb{F}^n : \exists \vec{a} \in \mathbb{F}^h,\ C(\vec{x},\vec{a}) = 0^l\}$.*

All the arithmetic circuits we consider are over prime fields $\mathbb{F}_p$. In this case, when passing boolean strings as inputs to arithmetic circuits, we *pack* the string's bits into as few field elements as possible: given $s \in \{0,1\}^m$, we use $[\![s]\!]_p^m$ to denote the vector $\vec{x} \in \mathbb{F}_p^{|m|_p}$, where $|m|_p := \lceil m / \lfloor \log p \rfloor \rceil$, such that the binary representation of $x_i \in \mathbb{F}_p$ is the i-th block of $\lceil \log p \rceil$ bits in s (padded with 0's if needed). We extend the notation $[\![s]\!]_p^m$ to binary strings $s \in \{0,1\}^n$ with $n < m$ bits via padding: $[\![s]\!]_p^m := [\![s0^{m-n}]\!]_p^m$.

2.2 Quadratic arithmetic programs

Our zk-SNARK leverages *quadratic arithmetic programs* (QAPs), introduced by Gennaro et al. [38].

Definition 2.2. *A* **quadratic arithmetic program** *of size m and degree d over $\mathbb{F}$ is a tuple $(\vec{A},\vec{B},\vec{C},Z)$, where $\vec{A},\vec{B},\vec{C}$ are three vectors, each of $m+1$ polynomials in $\mathbb{F}^{\leq d-1}[z]$, and $Z \in \mathbb{F}[z]$ has degree exactly d.*

[1] A gate with inputs $x_1,\ldots,x_m \in \mathbb{F}$ is *bilinear* if the output is $\langle \vec{a},(1,x_1,\ldots,x_m)\rangle \cdot \langle \vec{b},(1,x_1,\ldots,x_m)\rangle$ for some $\vec{a},\vec{b} \in \mathbb{F}^{m+1}$. In particular, these include addition, multiplication, and constant gates.

Like a circuit, a QAP induces a satisfaction problem:

Definition 2.3. *The* **satisfaction problem** *of a size-m QAP* $(\vec{A},\vec{B},\vec{C},Z)$ *is the relation* $\mathscr{R}_{(\vec{A},\vec{B},\vec{C},Z)}$ *of pairs* $(\vec{x},\vec{s})$ *such that (i)* $\vec{x}\in\mathbb{F}^n$, $\vec{s}\in\mathbb{F}^m$, *and* $n\leq m$; *(ii)* $x_i=s_i$ *for* $i\in[n]$ *(i.e.,* $\vec{s}$ *extends* $\vec{x}$*); and (iii) the polynomial* $Z(z)$ *divides the following one:*

$$(A_0(z)+\textstyle\sum_{i=1}^m s_iA_i(z))\cdot(B_0(z)+\sum_{i=1}^m s_iB_i(z)) \\ -(C_0(z)+\textstyle\sum_{i=1}^m s_iC_i(z))\ .$$

We denote by $\mathscr{L}_{(\vec{A},\vec{B},\vec{C},Z)}$ *the language of* $\mathscr{R}_{(\vec{A},\vec{B},\vec{C},Z)}$.

Gennaro et al. [38] showed that circuit satisfiability can be efficiently reduced to QAP satisfiability (which can then be proved and verified using zk-SNARKs):

Lemma 2.4. *There exist two polynomial-time algorithms* $\mathsf{QAPinst},\mathsf{QAPwit}$ *that work as follows. For any circuit* $C\colon\mathbb{F}^n\times\mathbb{F}^h\to\mathbb{F}^l$ *with a wires and b gates,* $(\vec{A},\vec{B},\vec{C},Z):=\mathsf{QAPinst}(C)$ *is a QAP of size m and degree d over* $\mathbb{F}$ *that satisfies the following three properties.*

- EFFICIENCY. *It holds that* $m=a$ *and* $d=b+l+1$.
- COMPLETENESS. *For any* $(\vec{x},\vec{a})\in\mathscr{R}_C$, *it holds that* $(\vec{x},\vec{s})\in\mathscr{R}_{(\vec{A},\vec{B},\vec{C},Z)}$, *where* $\vec{s}:=\mathsf{QAPwit}(C,\vec{x},\vec{a})$.
- PROOF OF KNOWLEDGE. *For any* $(\vec{x},\vec{s})\in\mathscr{R}_{(\vec{A},\vec{B},\vec{C},Z)}$, *it holds that* $(\vec{x},\vec{a})\in\mathscr{R}_C$, *where* $\vec{a}$ *is a prefix of* $\vec{s}$.
- NON-DEGENERACY. *The polynomials* $A_0,\ldots,A_n$ *are nonzero and distinct.*

2.3 Pairings

Let $\mathbb{G}_1$ and $\mathbb{G}_2$ be two cyclic groups of order r. We denote elements of $\mathbb{G}_1,\mathbb{G}_2$ via calligraphic letters such as $\mathscr{P},\mathscr{Q}$. We write $\mathbb{G}_1$ and $\mathbb{G}_2$ in additive notation. Let $\mathscr{P}_1$ be a generator of $\mathbb{G}_1$, i.e., $\mathbb{G}_1=\{\alpha\mathscr{P}_1\}_{\alpha\in\mathbb{F}_r}$ (α is also viewed as an integer, hence $\alpha\mathscr{P}_1$ is well-defined); let $\mathscr{P}_2$ be a generator for $\mathbb{G}_2$. A *pairing* is an efficient map $e\colon\mathbb{G}_1\times\mathbb{G}_2\to\mathbb{G}_T$, where $\mathbb{G}_T$ is also a cyclic group of order r (which we write in multiplicative notation), satisfying the following properties: (i) *bilinearity*: for every nonzero elements $\alpha,\beta\in\mathbb{F}_r$, it holds that $e(\alpha\mathscr{P}_1,\beta\mathscr{P}_2)=e(\mathscr{P}_1,\mathscr{P}_2)^{\alpha\beta}$; (ii) *non-degeneracy*: $e(\mathscr{P}_1,\mathscr{P}_2)$ is not the identity in $\mathbb{G}_T$.

2.4 zk-SNARKs for arithmetic circuits

A (preprocessing) **zk-SNARK** for $\mathbb{F}$-arithmetic circuit satisfiability (see, e.g., [22]) is a triple of polynomial-time algorithms (G,P,V), called *key generator*, *prover*, and *verifier*. The key generator G, given a security parameter λ and an $\mathbb{F}$-arithmetic circuit $C\colon\mathbb{F}^n\times\mathbb{F}^h\to\mathbb{F}^l$, samples a *proving key* pk and a *verification key* vk; these are the proof system's public parameters, which need to be generated only once per circuit. After that, anyone can use pk to generate non-interactive proofs for the language $\mathscr{L}_C$, and anyone can use the vk to check these proofs. Namely, given pk and any $(\vec{x},\vec{a})\in\mathscr{R}_C$, the honest prover $P(\mathsf{pk},\vec{x},\vec{a})$ produces a proof π attesting that $\vec{x}\in\mathscr{L}_C$; the verifier $V(\mathsf{vk},\vec{x},\pi)$ checks that π is a valid proof for $\vec{x}\in\mathscr{L}_C$. A proof π is both a proof of knowledge, and a (statistical) zero-knowledge proof. The succinctness property requires that π has length $O_\lambda(1)$ and V runs in time $O_\lambda(|\vec{x}|)$, where O_λ hides a (fixed) polynomial in λ.

Constructions. Several zk-SNARK constructions are known [45, 51, 38, 22, 56, 16, 52]. The most efficient ones are based on *quadratic span programs* (QSPs) [38, 52] or *quadratic arithmetic programs* (QAPs) [38, 22, 56, 16]. We focused on QAP-based constructions, because QAPs allow for tighter reductions from *arithmetic* circuits (see Lemma 2.4). Concretely, we build on the QAP-based zk-SNARK protocol of Parno et al. [56] (see Section 4).

Remark 2.5 (full succinctness)**.** The key generator G takes C as input, and so its complexity is linear in $|C|$. One could require G to *not* take C as input, and have its output keys work for *all* (polynomial-size) circuits C; then, G's running time would be independent of C. A zk-SNARK satisfying this stronger property is *fully succinct*. Theoretical constructions of such zk-SNARKs are known, based on various cryptographic assumptions [54, 69, 21]. Despite achieving essentially-optimal asymptotics [6, 18, 15, 14, 21] no implementations of them have been reported to date.

2.5 A von Neumann RISC architecture

Ben-Sasson et al. [16] introduced TinyRAM, a Harvard RISC architecture with word-addressable memory. We modify TinyRAM to obtain vnTinyRAM, which differs from it in two main ways. First, vnTinyRAM follows the *von Neumann paradigm*, whereby program and data are stored in the same read-write address space; programs may use runtime code generation. Second, vnTinyRAM has byte-addressable memory, along with instructions to load/store bytes or words.[2]

Besides the above main differences, vnTinyRAM is very similar to TinyRAM. Namely, it is parametrized by the *word size*, denoted W, and the *number of registers*, denoted K. The *CPU state* of the machine consists of (i) a W-bit *program counter*; (ii) K general-purpose W-bit *registers*; (iii) a 1-bit *condition flag*. The full state of the machine also includes *memory*, which is a linear array of 2^W bytes, and two *tapes*, each with a string of W-bit words, and read-only in one direction. One tape is for a *primary input* $\mathbb{x}$ and the other for an *auxiliary input* $\mathbb{w}$ (treated as nondeterministic, untrusted advice).

[2] Byte-addressing is common in programs performing array or string operations (and is a deeply-ingrained assumption in the GCC and LLVM compilers), while word-addressing in programs performing arithmetic.

In memory, an instruction is represented as a double word (one word for an immediate, and another for opcode, etc.). Thus, a *program* $\mathbb{P}$ is a list of address/double-word pairs specifying the initial contents of memory; all other memory locations assume the initial value of 0.

We define the language of accepting computations:

Definition 2.6. *Fix bounds ℓ, n, T. The language $\mathscr{L}_{\ell,n,T}$ consists of pairs $(\mathbb{P}, \mathbb{x})$ such that: (i) $\mathbb{P}$ is a program with $\leq \ell$ instructions, (ii) $\mathbb{x}$ is a primary input with $\leq n$ words, (iii) there exists an auxiliary input $\mathbb{w}$ s.t. $\mathbb{P}(\mathbb{x}, \mathbb{w})$ accepts in $\leq T$ steps. We denote by $\mathscr{R}_{\ell,n,T}$ the relation corresponding to $\mathscr{L}_{\ell,n,T}$.*

3 Our circuit generator

A circuit generator translates the correctness of suitably-bounded program executions into circuit satisfiability: given input bounds ℓ, n, T, it produces a circuit that can verify the execution of *any* program with $\leq \ell$ instructions, on *any* input of size $\leq n$, for $\leq T$ steps. More precisely, using the notations $[\![s]\!]_p$ (for packing the binary string s into field elements) and $|s|_p$ (for computing the number of field elements required to pack s) introduced in Section 2.1, we define a (universal) circuit generator for vnTinyRAM as follows.

Definition 3.1. *A* **(universal) circuit generator** *of efficiency $f(\cdot)$ over a prime field $\mathbb{F}_p$ is a polynomial-time algorithm* circ*, together with an efficient* witness map wit*, working as follows. For any program size bound ℓ, time bound T, and primary-input size bound n, $C := \mathsf{circ}(\ell, n, T)$ is an $\mathbb{F}_p$-arithmetic circuit $C\colon \mathbb{F}_p^m \times \mathbb{F}_p^h \to \mathbb{F}_p^l$, for $m := |\ell 2W|_p + |nW|_p$ and some h, l, where W is the word size (cf. Section 2.5).*

- EFFICIENCY. *The circuit C has $f(\ell, n, T)$ gates.*
- COMPLETENESS. *Given any program $\mathbb{P}$, primary input $\mathbb{x}$, and witness $\mathbb{w}$ such that $\big((\mathbb{P}, \mathbb{x}), \mathbb{w}\big) \in \mathscr{R}_{\ell,n,T}$, it holds that $(\vec{x}, \vec{a}) \in \mathscr{R}_C$, where $\vec{x} := [\![\mathbb{P}]\!]_p^{\ell 2W} \circ [\![\mathbb{x}]\!]_p^{nW}$ and $\vec{a} := \mathsf{wit}(\ell, n, T, \mathbb{P}, \mathbb{x}, \mathbb{w})$.*
- PROOF OF KNOWLEDGE. *There is a polynomial-time algorithm such that, given any $(\vec{x}, \vec{a}) \in \mathscr{R}_C$, outputs a witness $\mathbb{w}$ for $(\mathbb{P}, \mathbb{x}) \in \mathscr{L}_{\ell,n,T}$.*

The circuit C output by circ is *universal* because it does not depend on the program $\mathbb{P}$ or primary input $\mathbb{x}$, but only on their respective size bounds ℓ and n (as well as the time bound T). When combined with any proof system for circuit satisfiability (e.g., our zk-SNARK), this fact enables the generation of the proof systems' parameters to be universal as well. Namely, it is possible to generate keys for all bound choices (e.g., in powers of 2) up to some constant, *once and for all*; afterwards, one can pick the keys corresponding to bounds fitting a given computation. This avoids expensive per-program key generation and, more importantly, the need for a trusted party to conduct key generation anew for every program.

We construct a universal circuit generator with the following efficiency:

Theorem 3.2. *There is a circuit generator of efficiency $f(\ell, n, T) = O\big((\ell + n + T) \cdot \log(\ell + n + T)\big)$ over any prime field $\mathbb{F}_p$ of size $p > 2^{2W}$, where W is the word size (cf. Section 2.5).*

(In our case, the condition $p > 2^{2W}$ is always fulfilled.)

3.1 Past techniques

Most of the difficulties that arise when designing a circuit generator have to do with *data dependencies*. A circuit's topology does not depend on its inputs but, in contrast, program flow and memory accesses depend on the choice of program and the program's inputs. Thus, a circuit tasked with verifying program executions must be "ready" to support a multitude of program flows and memory accesses, despite the fact that its topology has already been fixed. Various techniques have been applied to the design of circuit generators.

Program analysis. In the extreme, if both the program $\mathbb{P}$ and its inputs $(\mathbb{x}, \mathbb{w})$ are known in advance, designing a circuit generator is simple: construct a circuit that evaluates $\mathbb{P}$ on $(\mathbb{x}, \mathbb{w})$ by preparing the circuit's topology to match the pre-determined program flow and memory accesses. But now suppose that only $\mathbb{P}$ is known in advance, but not its inputs $(\mathbb{x}, \mathbb{w})$. In this case, by analyzing $\mathbb{P}$ piece by piece (e.g., separately examine the various loops, branches, and so on), one could try to design a circuit $C_{\mathbb{P}}$ that can handle different choices of inputs. Most prior circuit generators [66, 64, 56, 27] take this approach.

However, this approach suffers from several limitations. First, the class of supported programs $\mathbb{P}$ is not rich, because support for data dependencies is limited. E.g., [56] requires array accesses and loop iteration bounds to be compile-time constants; also, while [27] supports data-dependent memory accesses, most program flow is also restricted to be known (or bounded) at compile-time; mitigations are possible, but only in special cases [72]. Second, and more importantly, this approach does not seem to allow for designing universal circuit generators, because the program $\mathbb{P}$ is *not known in advance* and thus there is no program to analyze.

Multiplex every access. Computers are universal random-access machines (RAMs), so one approach of designing a universal circuit is to mimic a computer's execution, building a layered circuit as follows. The i-th layer contains the entire state of the machine (CPU state and random-access memory) at time step i, and layer $i+1$ is computed from it by evaluating the transition function

of the machine, handling any accesses to memory via multiplexing. While this approach supports arbitrary program flow, memory accesses are inefficiently supported; indeed, if memory has S addresses, the resulting circuit is huge: it has size $\Omega(TS)$.

Nondeterministic routing. Ben-Sasson et al. [14] suggested using *nondeterministic routing* on a Beneš network to support memory accesses efficiently; Our circuit generator builds on the techniques of [14, 16], so we briefly review the main idea behind nondeterministic routing.

Following [14], Ben-Sasson et al. [16] introduced a simple computer architecture, called TinyRAM, and constructed a routing-based circuit generator for TinyRAM. They define the following notions. A *CPU state*, denoted S, is the CPU's contents (e.g., program counter, registers, flags) at a given time step. An *execution trace* for a program $\mathbb{P}$, time bound T, and primary input $\mathtt{x}$ is a sequence $\mathsf{tr} = (S_1, \ldots, S_T)$ of CPU states. An execution trace tr is *valid* if there is an auxiliary input $\mathtt{w}$ such that the execution trace induced by $\mathbb{P}$ running on inputs $(\mathtt{x}, \mathtt{w})$ is tr.

We seek an arithmetic circuit C for verifying that tr is valid. We break this down by splitting validity into three sub-properties: (i) *validity of instruction fetch* (for each time step, the correct instruction is fetched); (ii) *validity of instruction execution* (for each time step, the fetched instruction is correctly executed); and (iii) *validity of memory accesses* (each load from an address retrieves the value of the last store to that address).

The first two properties are verified as follows. Construct a circuit $C_{\mathbb{P}}$ so that, for any two CPU states S and S', $C_{\mathbb{P}}(S, S', g)$ is satisfied for some "guess" g if and only if S' can be reached from S (by fetching from $\mathbb{P}$ the instruction indicated by the program counter in S and then executing it), for *some* state of memory. Then, properties (i) and (ii) hold if $C_{\mathbb{P}}(S_i, S_{i+1}, \cdot)$ is satisfiable for $i = 1, \ldots, T-1$. Thus, C contains $T-1$ copies of $C_{\mathbb{P}}$, each wired to a pair of adjacent states in tr.

The third property is verified via nondeterministic routing. Assume that C also gets as input $\mathsf{MemSort}(\mathsf{tr})$, which equals to the sorting of tr by accessed memory addresses (breaking ties via timestamps), and write a circuit C_{mem} so that validity of memory accesses holds if C_{mem} is satisfied by each pair of adjacent states in $\mathsf{MemSort}(\mathsf{tr})$. (Roughly, C_{mem} checks consistency of "load-after-load", "load-after-store", and so on.) However, C merely gets some auxiliary input tr^*, which *purports* to be $\mathsf{MemSort}(\mathsf{tr})$. So C works as follows: (a) C has $T-1$ copies of C_{mem}, each wired to a pair of adjacent states in tr^*; (b) C separately verifies that $\mathsf{tr}^* = \mathsf{MemSort}(\mathsf{tr})$ by routing on a $O(T \log T)$-node Beneš network. The switches of the routing network are set according to non-deterministic guesses (i.e., additional values in the auxiliary input), and the routing network merely *verifies* that the switch settings induce a permutation; this allows for a very tight reduction. (Known constructions that *compute* the correct permutation hide large constants in big-oh notation [1].)

Past inefficiencies. After filling in additional details, the construction of [16] reviewed above gives a circuit of size $\Theta\big((n+T)\cdot(\log(n+T)+\ell)\big) = \Omega(\ell \cdot T)$. The $\Omega(\ell \cdot T)$ arises from the fact that all of the ℓ instructions in $\mathbb{P}$ are *hardcoded* into each of the $T-1$ copies of $C_{\mathbb{P}}$. Thus, besides being non-universal, the circuit scales inefficiently as ℓ grows (e.g., for $\ell = 10^4$, $C_{\mathbb{P}}$'s size is already dominated by $\mathbb{P}$'s size).

3.2 Our construction

In comparison to [16], our circuit generator is universal and, moreover, its size only grows with $\ell + T$ (additive dependence on program size) instead of with $\ell \cdot T$ (multiplicative dependence). As our evaluation demonstrates (see Section 5.1), the size improvement actually translates into significant savings in practice.

Instead of hardcoding the program $\mathbb{P}$ into each copy of the circuit $C_{\mathbb{P}}$, we follow the von Neumann paradigm, where the program $\mathbb{P}$ lies in the same read/write memory space as data. We ensure that $\mathbb{P}$ is loaded into the initial state of memory, using a dedicated circuit; we then verify instruction fetch via the *same* routing network that is used for checking data loads/stores. While the idea is intuitive, realizing it involves numerous technical difficulties, some of which are described below.

Routing instructions and data. We extend an execution trace to not only include CPU states but also instructions: $\mathsf{tr} = (S_1, I_1, \ldots, S_T, I_T)$ where S_i is the i-th CPU state, and I_i is the i-th executed instruction. We seek an arithmetic circuit C that checks tr, in this "extended" format, for the same three properties as above: (i) *validity of instruction fetch*; (ii) *validity of instruction execution*; (iii) *validity of memory accesses*.

As in [16], checking that tr satisfies property (ii) is quite straightforward. Construct a circuit C_{exe} so that, given two CPU states S, S' and an instruction I, $C_{\mathsf{exe}}(S, S', I, g)$ is satisfied, for some guess g, if and only if S' can be reached from S, by executing I, for some state of memory. Then, C contains $T-1$ copies of C_{exe}, each wired to adjacent CPU states and an instruction, i.e., the i-th copy is $C_{\mathsf{exe}}(S_i, S_{i+1}, I_i, g_i)$.

Unlike [16], though, we verify properties (i) and (iii) jointly, via the same routing network. The auxiliary input now contains $\mathsf{tr}^* = (A_1, \ldots, A_{2T})$, purportedly equal to the memory-sorted list of *both* instructions fetches and CPU states. (Since the program $\mathbb{P}$ lies in the same read-write memory as data, an instruction fetch from $\mathbb{P}$ is merely a special type of memory load.) Thus, to check that tr satisfies properties (i) and (iii), we design C to (a) verify that $\mathsf{tr}^* = \mathsf{MemSort}(\mathsf{tr})$ via nondeterministic routing, and

(b) verify validity of all (i.e., instruction and data) memory accesses, via a new circuit C'_{mem} applied to each pair of adjacent items A_i, A_{i+1} in $\mathtt{tr}^*$. Thus, in this approach, $\mathbb{P}$ is never replicated T times; rather, the fetching of its instructions is verified together with all other memory accesses, one instruction fetch at a time.

Multiple memory-access types. Each copy of C'_{mem} inspects a pair of items in $\mathtt{tr}^*$ and (assuming $\mathtt{tr}^* = \mathsf{MemSort}(\mathtt{tr})$) must ensure consistency of "load-after-load", "load-after-store", and so on. However, unlike in [16], the byte-addressable memory of vnTinyRAM is accessed in *different-sized* blocks: instruction-size blocks for instruction fetch; word-size blocks when loading/storing words; and byte-size blocks when loading/storing bytes. The consistency checks in C'_{mem} must handle "aliasing", i.e., accesses to the same point in memory via different addresses and block sizes.

We tackle this difficulty as follows. Double-word blocks are the largest blocks in which memory is accessed (as instructions are encoded as double words; cf. Section 2.5). We thus let each item in $\mathtt{tr}^*$ always specify a double-word, even if the item's memory access was with respect to a smaller-sized block (e.g., word or byte). With this modification, we can let C'_{mem} perform consistency checks "at the double-word level", and handling word/byte accesses by mapping them to double-word accesses with suitable shifting and masking.

Booting the machine. We have so far assumed that the program $\mathbb{P}$, given as input to C, *already* appears in memory. However, the circuit C sketched so far only verifies the validity of $\mathtt{tr}$ with respect to a machine whose memory is initialized to *some* state, corresponding to the execution of *some* program. But C must verify correct execution of, specifically, $\mathbb{P}$, and so it must also verify that memory is initialized to contain $\mathbb{P}$. Since C does not explicitly maintain memory (not even the initial one) and only implicitly reasons about memory via the routing network, it is not clear how C can perform this check.

We tackle this difficulty as follows. We further modify the the execution trace $\mathtt{tr}$, by extending it with an initial *boot* section, preceding the beginning of the computation, during which the input program $\mathbb{P}$ is stored into memory, one instruction $\mathbb{P}_i$ at a time. This extends the length of both $\mathtt{tr}$ and $\mathtt{tr}^*$ from $2T$ to $\ell + 2T$, for ℓ-instruction programs, and introduces a new type of item, "boot input store", in $\mathtt{tr}^*$. Similarly, the routing network is now responsible for routing $\ell + 2T$, rather than $2T$, packets.

Further optimizations. The above construction sketch (depicted in Figure 6) is only intuitive, and does not discuss other optimizations that ultimately yield the performance that we report in Section 5.1.

For example, while [16] rely on Beneš networks, we rely on *arbitrary-size Waksman networks* [10], which only require $N(\log N - 0.91)$ switches to route N packets, instead of $2^{\lceil \log N \rceil}(\lceil \log N \rceil - 0.5)$. Besides being closer to the information-theoretic lower bound of $N(\log N - 1.443)$, such networks eliminate costly rounding effects in [16], where the size of the network is *doubled* if N is just above a power of 2.

Compiling to vnTinyRAM. To enable verification of higher-level programs, written in C, we ported the GCC compiler to the vnTinyRAM architecture, by modifying the Harvard-architecture, word-addressible TinyRAM C compiler of [16]. Given a C program, written in the same subset of C as in [16], the compiler produces the initial memory map representing a program $\mathbb{P}$. This also served to validate the vnTinyRAM architectural choices (e.g., the move to byte-addressing significantly, and added instructions, improved efficiency for many programs).

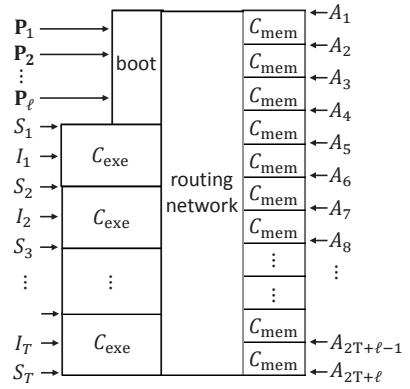

Figure 6: Outline of our universal circuit construction with the extended trace $\mathtt{tr}$ on the left and (allegedly) its memory sort $\mathtt{tr}^*$ on the right.

4 Our zk-SNARK for circuits

We discuss our second main contribution: a high-performance implementation of a zk-SNARK for arithmetic circuit satisfiability. Our approach is to *tailor* the requisite mathematical algorithms to the *specific* zk-SNARK protocol at hand. While our techniques can be instantiated in many algebraic setups and security levels, we demonstrate them in two specific settings, to facilitate comparison with prior work.

See Section 2.4 for an informal definition of a zk-SNARK for arithmetic circuit satisfiability. We improve upon and implement the zk-SNARK of Parno et al. [56]. For completeness the "PGHR protocol" is summarized in the full version of this paper, which provides pseudocode for its key generator G, prover P, and verifier V. The construction is based on QAPs, introduced in Section 2.2.

Like most other zk-SNARKs, the PGHR protocol relies on a *pairing*, which is specified by a prime $r \in \mathbb{N}$, three

cyclic groups $\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T$ of order r, and a bilinear map $e\colon \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{G}_T$. (See Section 2.3.)

A pairing is typically instantiated via a *pairing-friendly elliptic curve*. Concretely, suppose that one uses a curve E defined over $\mathbb{F}_q$, with embedding degree k with respect to r, to instantiate the pairing. Then $\mathbb{G}_T$ is set to μ_r, the subgroup of r-th roots of unity in $\mathbb{F}^*_{q^k}$. The instantiation of $\mathbb{G}_1$ and $\mathbb{G}_2$ depends on the choice of e; typically, $\mathbb{G}_1$ is instantiated as an order-r subgroup of $E(\mathbb{F}_q)$, while, for efficiency reasons [7, 8], $\mathbb{G}_2$ as an order-r subgroup of $E'(\mathbb{F}_{k/d})$ where E' is a *d-th twist* of E. Finally, the pairing e is typically a two-stage function $e(\mathscr{P}, \mathscr{Q}) := \mathsf{FE}(\mathsf{ML}(\mathscr{P}, \mathscr{Q}))$, where $\mathsf{ML}\colon \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{F}_q^k$ is known as *Miller loop*, and $\mathsf{FE}\colon \mathbb{F}_q^k \to \mathbb{F}_q^k$ is known as *final exponentiation* and maps α to $\mathsf{FE}(\alpha) := \alpha^{(q^k-1)/r}$.

As mentioned, we instantiate our techniques based on two different curves: an Edwards curve for the 80-bit security level (as in [16]) and a Barreto–Naehrig curve for the 128-bits security level (as in [56, 27]). We selected both the Edwards curve and Barreto–Naehrig curve so that $r-1$ has high *2-adic order* (i.e., $r-1$ is divisible by a large power of 2), because this was shown to improve the efficiency of the key generator and the prover [16].

4.1 An optimized verifier

The verifier V takes as input a verification key vk, input $\vec{x} \in \mathbb{F}_r^n$, and proof π, and checks if π is a valid proof for the statement "$\vec{x} \in \mathscr{L}_C$". The computation of V consists of two parts. First, use $\mathsf{vk}_{\mathsf{IC},0}, \ldots, \mathsf{vk}_{\mathsf{IC},n} \in \mathbb{G}_1$ (part of vk) and input $\vec{x}$ to compute $\mathsf{vk}_{\vec{x}} := \mathsf{vk}_{\mathsf{IC},0} + \sum_{i=1}^{n} x_i \mathsf{vk}_{\mathsf{IC},i}$. Second, use vk, $\mathsf{vk}_{\vec{x}}$, and π, to compute 12 pairings and perform the required checks. In other words, V performs $O(n)$ scalar multiplications in $\mathbb{G}_1$, followed by $O(1)$ pairing evaluations.

With regard to V's first part, variable-base multi-scalar multiplication techniques can be used to reduce the number of $\mathbb{G}_1$ operations needed to compute $\mathsf{vk}_{\vec{x}}$ [16, 56]. With regard to V's second part, even if the pairing evaluations take constant time (independent of the input size n), these evaluations are very expensive and *dominate for small n*. Our focus here is to minimize the cost of these pairing evaluations.

When only making "black-box" use of a pairing, the verifier must evaluate 12 pairings, amounting to 12 Miller loops plus 12 final exponentiations. The straightforward approach is to compute these using a generic high-performance pairing library. We proceed differently: we obtain high-performance implementations of *subcomponents* of a pairing, and then tailor their use specifically to V's protocol.

Namely, first, we obtain state-of-the-art implementations of a Miller loop and final exponentiation. We utilize *optimal pairings* [70] to minimize the number of loop iterations in each Miller loop, and, to efficiently evaluate each Miller loop, rely on the formulas of [3] (for Edwards curves) and [20] (for BN curves). As for final exponentiation, we use multiple techniques to speed it up: [62, 44, 35, 50].

Next, building on the above foundation, we incorporate in V the following optimizations.

(1) Sharing Miller loops and final exponentiations. The verifier V computes two products of two pairings. We leverage the fact that a product of pairings can be evaluated faster than evaluating each pairing separately and then multiplying the results [60]. Concretely, in a product of m pairings, the Miller loop iterations for evaluating each factor can be carried out in "lock-step" so to share a single *Miller accumulator variable*, using one $\mathbb{F}_{q^k}$ squaring per loop instead of m.

In a similar vein, one can perform a single final exponentiation on the product of the outputs of the m Miller loops, instead of m final exponentiations and then multiplying the results. In fact, since the output of the pairing can be inverted for free (as the element is *unitary* so that inverting equals conjugating [61]), the idea of "sharing" final exponentiations extends to a ratio of pairing products. Thus, in the verifier we only need to perform 5, instead of 12, final exponentiations.

Our implementation incorporates both of the above techniques. For example, at the 80-bit security level, separately computing 12 optimal pairings costs 13.6 ms, but the above techniques reduce the time to only 8.1 ms. We decrease this further as discussed next.

(2) Precomputation by processing the verification key. Of the 12 pairings the verifier needs to evaluate, only one is such that both of its inputs come from the proof π. The other 11 pairings have one fixed input, either a generator of $\mathbb{G}_1$ or $\mathbb{G}_2$, or coming from the verification key vk.

When one input to a pairing is fixed, precomputation techniques apply [60], especially in the case when the fixed input is the *base point* in Miller's algorithm. In V, this holds for 9 out of the 11 pairing evaluations. We thus split the verifier's computation into an *offline phase*, which consists of a one-time precomputation that *only* depends on vk, and a many-time *online phase*, which depends on the precomputed values, input $\vec{x}$, and proof π. The result of the offline phase is a *processed verification key* vk^*. While vk^* is longer than vk, it allows the online phase to be faster.

E.g., at the 80-bit security level, vk^* decreases the total cost of pairing checks from 8.1 ms to 4.7 ms.

4.2 An optimized prover

The prover P takes as input a proving key pk (which includes the circuit $C\colon \mathbb{F}_r^n \times \mathbb{F}_r^h \to \mathbb{F}_r^l$), input $\vec{x} \in \mathbb{F}_r^n$, and witness $\vec{a} \in \mathbb{F}_r$. The prover P is tasked to produce a proof

π, attesting that $\vec{x} \in \mathscr{L}_C$. The computation of P consists of two main parts. First, compute the coefficients $\vec{h}$ of the polynomial $H(z) := \frac{A(z)B(z)-C(z)}{Z(z)}$, where $A,B,C \in \mathbb{F}_r[z]$ are derived from the QAP instance $(\vec{A},\vec{B},\vec{C},Z) := \mathsf{QAPinst}(C)$ and QAP witness $\vec{s} := \mathsf{QAPwit}(C,\vec{x},\vec{a})$. Second, use the coefficients $\vec{h}$, QAP witness $\vec{s}$, and public key pk to compute π.

With regard to the first part of P, the coefficients $\vec{h}$ can be efficiently computed via FFT techniques [16, 56]; our implementation follows [16], and leverages the high 2-adic order of $r-1$ for both of the elliptic curves we use. With regard to P's second part, computing π requires solving large instances of the following problem: given elements $\mathscr{Q}_1,\ldots,\mathscr{Q}_n$ all in $\mathbb{G}_1$ (or all in $\mathbb{G}_2$) and scalars $\alpha_1,\ldots,\alpha_n \in \mathbb{F}_r$, compute $\langle \vec{\alpha},\vec{\mathscr{Q}}\rangle := \alpha_1\mathscr{Q}_1 + \cdots + \alpha_n\mathscr{Q}_n$. Previous work [56, 16] has leveraged generic multi-scalar multiplication to compute π. We observe that these algorithms can be tailored to the specific scalar distributions arising in P. In P, the vector $\vec{\alpha}$ is one of two types: (i) $\vec{\alpha} \in \mathbb{F}_r^{d+1}$ and represents the coefficients of the degree-d polynomial H; or (ii) $\vec{\alpha} = (1 \circ \vec{s} \circ \delta_1 \circ \delta_2 \circ \delta_3) \in \mathbb{F}_r^{4+m}$, for random $\delta_1,\delta_2,\delta_3 \in \mathbb{F}_r$.

In case i, the entries in of $\vec{\alpha}$ are random-looking. We use the Bos–Coster algorithm [26] due to its lesser memory requirements (as compared to, e.g., [57]). We follow [19]'s suggestions and achieve an assembly-optimized heap to implement the Bos–Coster algorithm.

In case ii, the entries in $\vec{s}$ depend on the input $(C,\vec{x},\vec{a})$ to QAPwit; in turn, $(C,\vec{x},\vec{a})$ depends on our circuit generator (Section 3). Using the above algorithm "as is" is inefficient: the algorithm works well when all the scalars have roughly the same bit complexity, but the entries in $\vec{c}$ have very different bit complexity. Indeed, $\vec{\alpha}$ equals to $\vec{s}$ augmented with a few entries; and $\vec{s}$, the QAP witness, can be thought of as the list of wire values in C when computing on $(\vec{x},\vec{a})$; the bit complexity of a wire value depends on whether it is storing a boolean value, a word value, and so on. We observe that there are only a few "types" of values, so that the entries of $\vec{\alpha}$ can be clustered into few groups of scalars with approximately the same bit complexity; we then apply the algorithm of [26] to each such group.

4.3 An optimized key generator

The key generator G takes as input a circuit $C\colon \mathbb{F}_r^n \times \mathbb{F}_r^h \to \mathbb{F}_r^l$, and is tasked to compute a proving key pk and a verification key vk. The computation of G consists of two main parts. First, evaluate each A_i,B_i,C_i at a random element τ, where $(\vec{A},\vec{B},\vec{C},Z) := \mathsf{QAPinst}(C)$ is the QAP instance. Second, use these evaluations to compute pk and vk.

With regard to G's first part, we follow [16] and again leverage the fact that $\mathbb{F}_r$ has a primitive root of unity of large order. With regard to G's second part, it is dominated by the cost of computing pk, which requires solving large instances of the following problem: given an element $\mathscr{P}$ in $\mathbb{G}_1$ or $\mathbb{G}_2$ and scalars $\alpha_1,\ldots,\alpha_n \in \mathbb{F}_r$, compute $\alpha_1\mathscr{P},\ldots,\alpha_n\mathscr{P}$. Previous work [56, 16], used fixed-base windowing [28] to efficiently compute such fixed-base multi-scalar multiplications.

In our implementation, we achieve additional efficiency, in space rather than in time. Specifically, we leverage a structural property of QAPs derived from arithmetic circuits, in order to reduce the size of the proving key pk, as we now explain. Lemma 2.4 states that an $\mathbb{F}$-arithmetic circuit $C\colon \mathbb{F}^n \times \mathbb{F}^h \to \mathbb{F}^l$, with α wires and β gates, can be converted into a corresponding QAP of size $m = \alpha$ and degree $d \approx \beta$ over $\mathbb{F}$. Roughly, this is achieved in two steps. First, construct three matrices $\mathbf{A},\mathbf{B},\mathbf{C} \in \mathbb{F}^{(m+1)\times d}$ that encode C's topology: for each $j \in [d]$, the j-th column of $\mathbf{A},\mathbf{B}$ respectively encodes the "left" and "right" coefficients of the j-th bilinear gate in C, while the j-th column of $\mathbf{C}$ encodes the coefficients of the gate's output. Second, letting $S \subset \mathbb{F}$ be a set of size d, define $Z(z) := \prod_{\omega\in S}(z-\omega)$ and, for $i \in \{0,\ldots,m\}$, let A_i be the low-degree extension of the i-th row of $\mathbf{A}$; similarly define each B_i and C_i. All prior QAP-based zk-SNARK implementations exploit the fact that *columns* in the matrices $\mathbf{A},\mathbf{B},\mathbf{C}$ are very sparse.

In contrast, we also leverage a *different* kind of sparsity: we observe that it is common for *entire rows* of $\mathbf{A},\mathbf{B},\mathbf{C}$ to be all zeroes, causing the corresponding low-degree extensions to be zero polynomials.[3] For instance, our circuit generator typically outputs a circuit for which the percentage of non-zero polynomials in $\vec{A},\vec{B},\vec{C}$ is only about $52\%, 15\%, 71\%$ respectively. The fact that many polynomials in $\vec{A},\vec{B},\vec{C}$ evaluate to zero can be used towards reducing the size of pk, by switching from a dense representation to a sparse one.

In fact, we have *engineered* our circuit generator to reduce the number of non-zero polynomials in $\vec{B}$ as much as possible, because computations associated to evaluations of $\vec{B}$ are conducted with respect to more expensive $\mathbb{G}_2$ arithmetic, which we want to avoid as much as possible.

5 Evaluation

We evaluated our system on a desktop computer with a 3.40 GHz Intel Core i7-4770 CPU (with Turbo Boost disabled) and 32 GB of RAM. All experiments, except the largest in Figure 8 and 9, used a small fraction of the RAM. For the two largest experiments in Figure 9 we added a Crucial M4 solid state disk for swap space. (While our code supports multi-threading, our experiments are in single-thread mode, for comparison with prior work.)

[3] E.g., if the i-th wire never appears with a non-zero coefficient as the "left" input of a bilinear gate, then the i-th row of $\mathbf{A}$ is zero.

5.1 Performance of our circuit generator

In Section 3 we described our universal circuit generator; we now benchmark its performance.

Parameters. The circuit supports vnTinyRAM, which is parametrized by two quantities: the *word size* W and the *number of registers* K (see Section 2.5). We report performance for a machine with $K = 16$ registers, and two choices of word size: $W = 16$ and $W = 32$.

Methodology. Theorem 3.2 provides an asymptotic efficiency guarantee: it states that our circuit generator has efficiency $f(\ell,n,T) = O\big((\ell+n+T)\cdot\log(\ell+n+T)\big)$. To understand concrete efficiency, we "uncover" the constants hidden in the *big-oh* notation. By studying the number of gates in various subcircuits of the generated circuit $C := \mathsf{circ}(\ell,n,T)$, we computed the following (quite tight) upper bound on C's size:

$$(12+2W)\cdot\ell+(12+W)\cdot n+|C_{\mathsf{exe}}|\cdot T+(|C_{\mathsf{mem}}|+ 4\log H-1.82)\cdot H$$

where $H := (\ell+n+2T)$ is the "height" of the routing network, and

- for $(W,K) = (16,16)$: $|C_{\mathsf{exe}}| = 777$ and $|C_{\mathsf{mem}}| = 211$;
- for $(W,K) = (32,16)$: $|C_{\mathsf{exe}}| = 1114$ and $|C_{\mathsf{mem}}| = 355$.

In Figure 7, we give per-cycle gate counts (i.e., $|C|/|T|$) for various choices of (ℓ,n,T); we also give sub-counts divided among program/input boot, CPU execution, memory checking, and routing. (See the full version of this paper for an extended table with additional data.)

Discussion. We first go through the size expression, to understand it: The first two terms, $(12+2W)\cdot\ell+(12+W)\cdot n$, correspond to the pre-execution boot phase, during which an ℓ-instruction program and an n-word primary input are loaded into the machine. The term $|C_{\mathsf{exe}}|\cdot T$ corresponds to the T copies of C_{exe} used to verify each CPU transition, given the fetched instruction and two CPU states. The term $|C_{\mathsf{mem}}|\cdot H$ corresponds to the H copies of C_{mem} used to verify consistency on the memory-sorted trace. Finally, the term $(4\log H-1.82)\cdot H$ corresponds to the routing network for routing H packets (two gates for each of $(2\log H-0.91)\cdot H$ binary switches). Note that $H = (\ell+n+2T)$ because boot needs $\ell+n$ memory stores (one for each program instruction and primary input word) and execution needs $2T$ memory accesses (1 instruction fetch and 1 data store/load per execution cycle).

The gate counts in Figure 7 demonstrate the additive (instead of multiplicative) dependence on program size of our universal circuit pays off. For example, for $(W,K) = (32,16)$, a 100-fold increase in program size, from $\ell = 10^3$ to $\ell = 10^5$, barely impacts the per-cycle gate count: for $T = 2^{20}$, it increases from 1,992.5 to only 2,041.5. Indeed, the cost of program size is incurred, once and for all, during the machine boot; Figure 7 shows that the per-cycle cost of machine boot diminishes as T grows.

Second, *less than half* of C's gates are dedicated to verifying accesses to random-access memory, while the majority of gates are dedicated to verifying execution of the CPU; indeed, almost always, $|C_{\mathsf{exe}}|T > \frac{1}{2}|C|$. Put otherwise, C, which verifies an automaton with random-access memory (vnTinyRAM), has size that is less than twice that for verifying an automaton with the same CPU but no random-access memory at all. Moreover, note that the size of C_{exe} appears quite tight: for example, with $(W,K) = (32,16)$, it has size 1114, not much larger than the size of the CPU state (545 bits).

5.2 Performance of our zk-SNARK for circuit satisfiability

In Section 4 we described our zk-SNARK implementation; we now benchmark its performance.

Methodology. We provide performance characteristics for each of the zk-SNARK algorithms, G, P and V, at the 80-bit and 128-bit security levels.

(1) The key generator G takes as input an arithmetic circuit C: $\mathbb{F}_r^n \times \mathbb{F}_r^h \to \mathbb{F}_r^l$. Its efficiency mostly depends on the number of gates and wires in C, because these affect the size and degree of the corresponding QAP (see Lemma 2.4). Thus, we evaluate G on a circuit with 2^i gates and 2^i wires for $i \in \{10,12,\ldots,24\}$ (and fixed $n = h = l = 100$). In Figure 8 we report the resulting running times and key sizes, as *per-gate costs*.

(2) The prover P takes as input a proving key pk, input $\vec{x} \in \mathbb{F}_r^n$, and witness $\vec{a} \in \mathbb{F}_r^h$. Its efficiency mostly depends on the number of gates and wires in C (the circuit used to generate pk); we thus evaluate P on the proving keys output by G, for the same circuits as above. In Figure 8 we report the times, as per-gate costs, and proof sizes.

(3) The verifier V takes as input a verification key vk, input $\vec{x} \in \mathbb{F}_r^n$, and proof π. Its efficiency depends only on $\vec{x}$ (since the size of $\vec{x}$ determines that of vk). Thus, we evaluate V on a random input $\vec{x} \in \mathbb{F}_r^n$ of 2^i bytes for $i \in \{2,4,\ldots,20\}$. In Figure 8 we report the resulting running times, along with corresponding key sizes.

Discussion. The data demonstrates that our zk-SNARK implementation works and scales as expected, as long as sufficient memory is available (e.g., on a desktop computer with 32GB of DRAM: up to 16 million gates). Key generation takes about 10 ms per gate of C; the size of a proving key is about 300 B per gate, and the size of a verification key is about 1 B per byte of input to C. Running the prover takes 11 ms to 14 ms per gate. For an n-byte input, proof verification time is $c_1 n + c_0$, where c_0 is a few milliseconds and c_1 is a few tenths of microseconds.

5.3 Performance of the combined system

As discussed, our circuit generator (Section 3) and zk-SNARK for circuits (Section 4) can be used in-

dependently, or combined to obtain a zk-SNARK for vnTinyRAM. For completeness, the paper's full version we spell out how these two components can be combined. Here we report measured performance of this combined system, at the 128-bit security level, and for a word size $W = 32$ and number of registers $K = 16$.

Methodology. A zk-SNARK for vnTinyRAM is a triple of algorithms $(\mathsf{KeyGen},\mathsf{Prove},\mathsf{Verify})$. Given bounds ℓ,n,T (for program size, input size, and time), the efficiency of KeyGen and Prove depends on ℓ,n,T, while that of Verify essentially depends only on ℓ,n. Thus, we benchmark the system as follows. We evaluate KeyGen and Prove for various choices of ℓ and T, while keeping $n = 100$. Instead, since the efficiency of Verify does not depend on T, we evaluate Verify, for various choices of ℓ and n, on random ℓ-instruction programs and n-word inputs. In Figure 9, we report the following measurements: KeyGen's running time, the sizes of the keys pk and vk, Prove's runtime, the (constant) proof size, and Verify's running time. For quantities growing with T, we divide by T and report the per-cycle cost.

Discussion. The measurements demonstrate that, on a desktop computer, our zk-SNARK for vnTinyRAM scales up to computations of 32,000 machine cycles, for programs with up to 10,000 instructions. Key generation takes about 200 ms per cycle; the size of a proving key is 500 KB to 650 KB per cycle, and the size of a verification key is a few kilobytes. Running the prover takes 100 ms to 200 ms per cycle. Verification times remain a few ms , even for inputs and programs of several kilobytes.

Program-specific vk**.** The time complexity of Verify is $O(\ell+n)$, so verification time grows with program size. This is inevitable, because Verify must *read* a program $\mathbb{P}$ (of at most ℓ instructions) and input $\mathbb{x}$ (of at most n words) in order to check, via the given proof π, if $(\mathbb{P},\mathbb{x}) \in \mathscr{L}_{\ell,n,T}$ (cf. Definition 2.6). However, this is inconvenient, e.g., when one has to verify many proofs relative to different inputs to the *same* program $\mathbb{P}$. In our zk-SNARK it is possible to amortize this cost as follows. Given vk and $\mathbb{P}$, one can derive, in time $O(\ell)$, a *program-specific* verification key $\mathsf{vk}_{\mathbb{P}}$, which can be used to verify proofs relative to any input to $\mathbb{P}$. Subsequently, the time complexity of Verify for any input $\mathbb{x}$ (to $\mathbb{P}$) is $O(n)$, *independent* of ℓ.

5.4 Comparison with prior work

5.4.1 Comparison with prior circuit generators

Universality is the main innovative feature of our circuit generator. *No* previous circuit generator achieves univer-

sality. (See Figure 1 and Section 3.)

Putting universality aside and focusing on efficiency instead, a comparison with previous circuit generators is a multi-faceted problem. On one hand, due to a shared core of techniques, a comparison with [16]'s circuit generator is straightforward, and shows significant improvements in circuit size, especially as program size grows. See Section 1.4.1 and Figure 2 (the figure is for $W, K = 16$).

Instead, a comparison with other circuit generators [66, 64, 56, 27] is complex. First, they support a smaller class of programs (see Figure 1), so a programmer must "write around" the limited functionality, somehow. And second, their efficiency is not easily specified: due to the program-analysis techniques (see Section 3.1) the output circuit is ad hoc for the given program, and the only way to know its size is to actually run the circuit generator.

Compared to [66, 64, 56, 27], our circuit generator performs better for programs that are rich in memory accesses and control flow, and worse for programs that are more "circuit like".

Comparison with [66, 64, 56]. The circuit generators in [66, 64, 56] restrict loop iteration bounds and memory accesses to be known at compile time; if a program does not respect these restrictions, it must be first somehow mapped to another one that does. For simplicity, we take [56]'s circuit generator (the latest one) as representative and, to illustrate the differences between [56]'s and our circuit generator, we consider two "extremes".

On one extreme, we wrote a simple C program multiplying two 10×10 matrices of 16-bit integers. The circuit generator in [56] produces a circuit with 1100 gates; instead, our circuit generator (when given the corresponding vnTinyRAM assembly) produces a much larger circuit: one with $\approx 10^7$ gates.

On the other extreme, we consider a program making many random accesses to memory: pointer-chasing. Given a permutation π of $[N]$, start position $i \in [N]$, and an integer k, the program outputs $\pi^k(i)$, the element obtained by starting from i and following "pointers" for k times. Since no information about π is known at compile time, the only way of obtaining $\pi(j)$, the pointer to follow, in [56] is via a *linear scan*. On a simple C program that does one linear scan of π to obtain each new pointer, [56]'s generator outputs a circuit with $2Nk+1$ gates (each of the k array accesses costs $2N$ gates).

In vnTinyRAM, the corresponding program $\mathbb{P}$ consists of 9 instructions, and the input $\mathtt{x}$ to it is $N+3$ words. Booting vnTinyRAM with $\mathbb{P}$ and $\mathtt{x}$ requires $9+N+3$ "boot stores" (see Section 3.2), and takes $5+4k$ cycles to execute (independent of N). Say that we fix $k = 10$; then, in our circuit generator (with $W = 32$ and $K = 16$), each cycle costs about 2000 gates, and can perform a random access to memory. Thus, pointer chasing in our case is cheaper than in [56] already for $N > 5000$, and the multiplicative saving, which is about $\frac{20N}{2000 \cdot (5+40)} = \frac{N}{4500}$, grows unbounded as N increases.

Comparison with [27]. The circuit generator of [27] is also based on program analysis, but provides an additional feature that allows data-dependent memory accesses: a program may access memory by guessing the value and verifying its validity via a subcircuit that checks Merkle-tree authentication paths. In [27], memory consists of 2^{30} cells, and each access costs many gates: 140K for a load, and 280K for a store. In comparison, in our circuit generator for vnTinyRAM (with word size $W = 32$ so that memory has 2^{32} cells), each memory store/load costs less than 1000 gates out of about 2000 per cycle (see Section 5.1). Besides the aforementioned feature, [27] rely on program analysis, and (as in [66, 64, 56]) only support bounded control flow. Thus, [27] performs better than our circuit generator for programs with bounded control flow and few data-dependent accesses to memory.

5.4.2 Comparison with prior zk-SNARKs

Addressing the other component of our system, the zk-SNARK for circuits: Figure 3 compares our implementation with prior ones, on a 1-million-gate circuit with a 1000-byte input. As shown, we mildly improve the key generation time and, more importantly, significantly improve the "online" costs of proving and verification.

6 Conclusion

We have presented two main contributions: (i) a circuit generator for a von Neumann RISC architecture that is *universal* and scales *additively* with program size; and (ii) a high-performance zk-SNARK for arithmetic circuit satisfiability. These two components can be used independently to the benefit of other systems, or combined into a zk-SNARK that can prove/verify correctness of computations on this architecture.

The benefits of universality. Universality attains the conceptual advance of *once-and-for-all key generation*, allowing verifying all programs up to a given size. This removes major issues in prior systems: expensive per-program key generation and the thorny issue of conducting it anew in a trusted way for every program.

The price of universality. The price of universality is still very high. Going forward, and aiming for widespread use in security applications, more work is required to slash costs of key generation and proving so to scale up to larger computations: e.g., billion-gate circuits, or millions of vnTinyRAM cycles, and beyond. An interesting open problem is whether the "program analysis" techniques underlying most prior circuit generators [66, 64, 56, 27], typically more efficient for restricted classes of programs, can be used to construct universal circuits.

Beyond vnTinyRAM. Finally, going beyond the foundation of a von Neumann RISC architecture, more work lies ahead towards a richer architecture (e.g., efficient support for floating-point arithmetic and cryptographic acceleration), code libraries, and tighter compilers.

A Other prior work

Prior work most relevant to us is about zk-SNARKs, and is discussed in Section 1.2. There are also numerous works studying variations or relaxations of the goal we consider; here, we summarize some of them.

Interactive proofs for low-depth circuits. Goldwasser et al. [42] obtained an interactive proof for outsourcing computations of *low-depth circuits*. A set of works [32, 68, 67] has optimized and implemented the protocol of [42]. The protocol of [42] can also be reduced to a two-message argument system [48, 47]. Canetti et al. [30] showed how to extend the techniques in [42] to also handle non-uniform circuits.

Batching arguments. Ishai et al. [46] constructed a *batching argument* for NP, where, to simultaneously verify that N circuits of size S are satisfiable, the verifier runs in time $\max\{S^2, N\}$.

A set of works [63, 65, 66, 64] has improved, optimized, and implemented the batching argument of Ishai et al. [46] for the purpose of outsourcing computation. In particular, by relying on quadratic arithmetic programs of [38], Setty et al. [64] have improved the running time of the verifier and prover to $\max\{S,N\} \cdot \text{poly}(\lambda)$ and $\tilde{O}(S) \cdot \text{poly}(\lambda)$ respectively. Vu et al. [71] provide a system that incorporates both the batching arguments of [63, 65, 66, 64] as well as the interactive proofs of [32, 68, 67]. The system decides which of the two approaches is more efficient to use for outsourcing a given computation.

Braun et al. [27] apply batching techniques (as well as zk-SNARKs) to verify MapReduce computations, by relying on various verifiable data structures.

Arguments with competing provers. Canetti et al. [29] use collision-resistant hashes to get a protocol for outsourcing deterministic computations in a model where a verifier interacts with two computationally-bounded provers at least one of which is honest [34]. The protocol in [29] works *directly* for random-access machines, and therefore does not require reducing random-access machines to any "lower-level" representation (such as circuits). Canetti et al. implement their protocol for deterministic x86 programs.

Previous circuit generators. Some prior work addresses the problem of translating high-level languages into low-level languages such as circuits. Most prior work only supports restricted classes of programs: [66, 64] present a circuit generator based on Fairplay [53, 12], whose SFDL language does not support important primitives and has inefficient support for others; [56] present a circuit generator for programs without data dependencies (pointers and array indices must be known at compile time, and so do loop iteration bounds).

Other works support more general functionality: [16] rely on nondeterministic routing to support random-access machine computations [14]; [27] rely on online memory checking [24, 14] to support accessing untrusted storage from a circuit. See [27, Section 2] for a more detailed overview of some of the above techniques.

Other cryptographic tools. *Fully-homomorphic encryption* (FHE) [39] and *probabilistically-checkable proofs* [5, 4] are powerful tools that are often used in protocols for outsourcing computations (with integrity or confidentiality guarantees, or both) [49, 54, 2, 37, 31, 47, 41]. However, such constructions have so far not been explored in practice. Another powerful tool is *secure multi-party computation* [40, 13], but most work in this area does not consider the goal of succinctness.

B Case study: `memcpy`

The function `memcpy` is a standard C function that works as follows: given as input two array pointers and a length, `memcpy` copies the contents of one array to the other. Of course, with no data dependencies, copying data in a circuit is trivial: you just connect the appropriate wires. However, when the array addresses and their lengths are unknown, and `memcpy` is invoked as a subroutine in a larger program, the trivial solution *does not work*, and an efficient implementation is needed.

A naive implementation of `memcpy` iterates, via a loop, over each array position i and copies the i-th value from one array to the other. In vnTinyRAM each such loop iteration costs 6 instructions; 2 of these are to increase the iteration counter and jump back to the start of the loop. Thus, for m-long arrays, copying takes $6m$ instructions (discounting loop initialization). But, in vnTinyRAM, one can do better: loop unrolling can be used to avoid paying for the 2 "control" instructions. Asymptotically, the optimal number of unrollings *depends* on the array length: it is $\Theta(\sqrt{m})$. Thus, optimal unrolling requires dynamic code generation on a von Neumann architecture. We wrote a 54-instruction vnTinyRAM program for `memcpy` that uses dynamic loop unrolling to achieve an efficiency of $\approx 4m + 11.5\sqrt{m}$ cycles for m-long arrays. For $m \geq 600$, we get $1.25\times$ speed-up over the naive implementation, and $1.4\times$ speed-up for $m \geq 3000$.

Faster Private Set Intersection based on OT Extension

Benny Pinkas
Bar-Ilan University, Israel

Thomas Schneider

Michael Zohner
TU Darmstadt, Germany

Abstract

Private set intersection (PSI) allows two parties to compute the intersection of their sets without revealing any information about items that are not in the intersection. It is one of the best studied applications of secure computation and many PSI protocols have been proposed. However, the variety of existing PSI protocols makes it difficult to identify the solution that performs best in a respective scenario, especially since they were not all implemented and compared in the same setting.

In this work, we give an overview on existing PSI protocols that are secure against semi-honest adversaries. We take advantage of the most recent efficiency improvements in OT extension to propose significant optimizations to previous PSI protocols and to suggest a new PSI protocol whose runtime is superior to that of existing protocols. We compare the performance of the protocols both theoretically and experimentally, by implementing all protocols on the same platform, and give recommendations on which protocol to use in a particular setting.

1 Introduction

Private set intersection (PSI) allows two parties P_1 and P_2 holding sets X and Y, respectively, to identify the intersection $X \cap Y$ without revealing any information about elements that are not in the intersection. The basic PSI functionality can be used in applications where two parties want to perform JOIN operations over database tables that they must keep private, e.g., private lists of preferences, properties, or personal records of clients or patients. PSI is used for privacy-preserving computation of functionalities such as relationship path discovery in social networks [37], botnet detection [40], testing of fully-sequenced human genomes [3], proximity testing [43], or cheater detection in online games [10]. Another use case is measurement of the performance of web ad campaigns, by comparing purchases by users who were shown a specific ad to purchases of users who were not shown the ad. This is essentially a variant of PSI where the input of the web advertising party is the identities of the users who were shown the ad, and the input of the merchant, or of an agency that operates on its behalf, is the identities of the buyers. It was published that Facebook and Datalogix, a consumer data collection company, perform this type of measurements.[1] (The article indicates that they seem to be using the insecure hash-based solution described in §1.1, but instead they can use a properly secure PSI protocol while still being reasonably efficient.)

PSI has been a very active research field, and there have been many suggestions for PSI protocols. The large number of proposed protocols makes it non-trivial to perform comprehensive cross-evaluations. This is further complicated by the fact that many protocol designs have not been implemented and evaluated, were analyzed under different assumptions and observations, and were often optimized w.r.t. overall runtime while neglecting other relevant factors such as communication.

In this paper, we give an overview on existing efficient PSI protocols, optimize the recently proposed PSI protocols of [27] and [17], based on garbled circuits and Bloom filters, respectively, and describe a new PSI protocol based on recent results in the area of efficient OT extensions [1, 35]. We compare both the theoretical and empirical performance of all protocols on the same platform and conclude with remarks on the protocols and their suitability for different scenarios.

1.1 Classification of PSI Protocols

A naive solution When confronted with the PSI problem, most novices come up with a solution where both parties apply a cryptographic hash function to their inputs and then compare the resulting hashes. Although this protocol is very efficient, it is insecure if the input domain is not large or does not have high entropy, since one party could easily run a brute force attack that applies the hash function to all items that are likely to be in the input set and compare the results to the received hashes. (When inputs to PSI have a high entropy, a protocol that compares hashes of the inputs can be used [41].)

[1] https://www.eff.org/deeplinks/2012/09/deep-dive-facebook-and-datalogix-whats-actually-getting-shared-and-how-you-can-opt

PSI is one of the best studied problems in secure computation. Since its introduction, several techniques have been used to realize PSI protocols. While the first PSI protocols were special-purpose solutions based on public-key primitives, other solutions were based on circuit-based generic techniques of secure computation, that are mostly based on symmetric cryptography. A recent development are PSI protocols that are based on oblivious transfer (OT) alone, and combine the efficiency of symmetric cryptographic primitives with special purpose optimizations. Finally, we describe PSI protocols that utilize a third party to achieve even better efficiency.

Public-Key-Based PSI A PSI protocol based on the Diffie-Hellmann (DH) key agreement scheme was presented in [29] (related ideas were presented earlier in [36]). This protocol is based on the commutative properties of the DH function and was used for private preference matching, which allows two parties to verify if their preferences match to some degree.

Freedman et al. [21] introduced PSI protocols secure against semi-honest and malicious adversaries in the standard model (rather than in the random oracle model assumed in the DH-based protocol). This protocol was based on polynomial interpolation, and was extended in [19], which presents protocols with simulation-based security against malicious adversaries, and evaluates the practical efficiency of the proposed hashing schemes. We discuss the proposed hashing schemes in §6. A similar approach that uses oblivious pseudo-random functions to perform PSI was presented in [20]. A protocol that uses polynomial interpolation and differentiation for finding intersections between multi-sets was presented in [34].

Another PSI protocol that uses public-key cryptography (more specifically, blind-RSA operations) and scales linearly in the number of elements was presented in [14] and efficiently implemented and benchmarked in [15].

A PSI protocol based on additively homomorphic encryption was described in [11], but is excluded from this evaluation since it scales quadratically in the number of elements and is hence slower than related solutions.

Circuit-Based PSI Generic secure computation protocols have been subject to huge efficiency improvements in the last decade. They allow the secure evaluation of arbitrary functions, expressed as Arithmetic or Boolean circuits. Several Boolean circuits for PSI were proposed in [27] and evaluated using the Yao's garbled circuits framework of [28]. The authors showed that their Java implementation scales very well with increasing security parameter and outperforms the blind-RSA protocol of [14] for larger security parameter.[2] We reflect on and present new optimizations for circuit-based PSI in §3.

OT-Based PSI A recent PSI protocol of [17] uses Bloom filters [9] and OT extension [30] to obtain very efficient PSI protocols with security against semi-honest and malicious adversaries. We describe this protocol and our optimization using random OT extension [1] in §4.

Third Party-Based PSI Several PSI protocols have been proposed that utilize additional parties, e.g., [4]. In [25], a trusted hardware token is used to evaluate an oblivious pseudo-random function. This approach was extended to multiple untrusted hardware tokens in [18]. Several efficient server-aided protocol for PSI were presented and benchmarked in [32]. For their PSI protocol with a semi-honest server, the authors report a runtime of 1.7 s for server-aided PSI on one million elements using 20 threads between cloud instances in the US east - and west coast and 10 MB of communicated data. In comparison, our fastest PSI protocol without a server requires 4.9 s for 2^{18} elements using four threads and sends 78 MB (cf. Tab. 1 and Tab. 8). Note that this comparison is sketchy and is only meant to demonstrate that using a third party can increase performance. In our work we focus on PSI protocols without a third party.

1.2 Our Contributions

We describe in detail the PSI protocols based on generic secure computation and on Bloom filters, and suggest how to improve their performance using carefully analyzed features of OT extension. We then introduce a new OT-based PSI protocol, and perform a detailed experimental comparison of all the PSI protocols that we described. In the following, we detail our contributions.

Optimizations of Existing Protocols We improve the circuit- and Bloom-filter-based PSI protocols using recent optimizations for OT extension [1]. In particular, in §3 we evaluate the circuit-based solution of [27] on a secure evaluation of the GMW protocol, and utilize features of random OT (cf. §2.2) to optimize the performance of multiplexer gates (which form about two thirds of the circuit). In §4.3 we redesign the Bloom filter-based protocol of [17] to benefit from using random OT and to support multi-core environments.

[2] Subsequent work of [15] claimed that the blind-RSA protocol of [14] runs faster than the circuit-based protocol of [27] even for larger security parameter. Their implementation is in C++ instead of Java.

A Novel OT-Based PSI Protocol We present a new PSI protocol that is directly based on OT (§5) and directly benefits from recent improvements in efficient OT extensions [1, 35]. The basic version of the protocol can efficiently compare one element with many elements, but for PSI on n elements it requires $O(n^2 \log n)$ communication. In §6 we use carefully analyzed hashing techniques in order to achieve $O(n \log n)$ communication. The resulting protocol has very low computation complexity since it mostly requires symmetric key operations and has even less communication than some public-key-based PSI protocols.

A Detailed Comparison of PSI Protocols We implement the most promising candidate PSI protocols using state-of-the-art cryptographic techniques and compare their performance on the same platform. As far as we know, this is the first time that such a wide comparison has been made, since previous comparisons were either theoretical, compared implementations on different platforms or programming languages, or used implementations without state-of-the-art optimizations. Our implementations and experiments are described in detail in §7. Certain experimental results were unexpected. We give a partial summary of our results in Tab. 1: the values in parenthesis give the overhead of the original protocols and highlight the gains achieved by our optimizations.

PSI Protocol	DH ECC [29]	Circuit [27] optimized GMW §3.2 (original GMW [1])	Bloom Filter optimized §4.3 (original [17])	OT §5+§6
Runtime (s)	416	762 (1,304)	68 (154)	14
Comm. (MB)	24	14,040 (23,400)	740 (1,393)	78

Table 1: Runtime and transferred data for private set intersection protocols on sets with 2^{18} 32-bit elements and 128-bit security with a single thread over Gigabit LAN.

We highlight here the conclusions of our results:

- The Diffie-Hellman-based protocol [29], which was the first PSI protocol, is actually the most efficient w.r.t. communication (when implemented using elliptic-curve crypto). Therefore it is suitable for settings with distant parties which have strong computation capabilities but limited connectivity.
- Generic circuit-based protocols [27] are less efficient than the newer, OT-based constructions, but they are more flexible and can easily be adapted for computing variants of the set intersection functionality (e.g., computing whether the size of the intersection exceeds some threshold). Our experiments also support the claim of [27] that circuit-based PSI protocols are faster than the blind-RSA-based PSI protocol of [14] for larger security parameters and given sufficient bandwidth.
- While for larger security parameter previously proposed circuit- and OT-based protocols can be faster than the public-key-based protocols on a Gigabit LAN, the DH-based protocol of [29] outperforms *all* of them in an Internet network setting. Our new OT-based protocol (§5+§6) is the only protocol that maintains its performance advantage in this setting and even outperforms public-key-based PSI protocols for a mobile network setting.

2 Preliminaries

We give our notation and security definitions in §2.1 and review recent relevant work on oblivious transfer in §2.2.

2.1 Notation and Security Definitions

We denote the parties as P_1 and P_2, and their respective input sets as X and Y with $|X| = n_1$ and $|Y| = n_2$. When the two input sets are of equal size, we use $n = n_1 = n_2$. We refer to elements from X as x and elements from Y as y and each element has bit-length σ (we detail the relation between n and σ in the full version [47]).

We write $b[i]$ for the i-th element of a list b, denote the bitwise-AND between two bit strings a and b of equal length as $a \wedge b$ and the bitwise-XOR as $a \oplus b$.

We refer to a correlation resistant one-way function as CRF, and to a pseudo-random generator as PRG.

We write $\binom{N}{1}$-OT_ℓ^m for m parallel 1-out-of-N oblivious transfers on ℓ-bit strings, and write OT_ℓ^m for $\binom{2}{1}$-OT_ℓ^m.

Security parameters We denote the symmetric security parameter as κ, the asymmetric security parameter as ρ, the statistical security parameter as λ, and use the recommended key sizes of the NIST guideline [45], summarized in Tab. 2. We denote the bit size of elliptic curve points with φ, i.e., $\varphi = 284$ for Koblitz curve K-283 when using point compression.

Security	SYM (κ)	FFC and IFC (ρ)	ECC (φ)	Hash
80-bit	80	1,024	K-163	SHA-1
128-bit	128	3,072	K-283	SHA-256

Table 2: NIST recommended key sizes for symmetric cryptography (SYM), finite field cryptography (FFC), integer factorization cryptography (IFC), elliptic curve cryptography (ECC) and hash functions.

Adversary definition The secure computation literature considers two types of adversaries with different strengths: A *semi-honest adversary* tries to learn as much information as possible from a given protocol execution but is not able to deviate from the protocol steps. The semi-honest adversary model is appropriate for scenarios where software attestation is enforced or where an untrusted third party is able obtain the transcript of the protocol after its execution, either by stealing it or by legally enforcing its disclosure. The stronger, *malicious adversary* extends the semi-honest adversary by being able to deviate arbitrarily from the protocol steps.

Most protocols for private set intersection, as well as this work, focus on solutions that are secure against semi-honest adversaries. PSI protocols for the malicious setting exist, but they are considerably less efficient than protocols for the semi-honest setting (see, e.g., [13, 16, 19, 21, 26, 31]).

The random oracle model As most previous works on efficient PSI, we use the random oracle model to achieve more efficient implementations [8]. We provide details and argue about the use of random oracles in the full version [47].

2.2 Oblivious Transfer

Oblivious transfer (OT) is a major building block for secure computation. When executing m invocations of 1-out-of-2 OT on ℓ-bit strings (denoted $\binom{2}{1}$-OT_ℓ^m), the sender S holds m message pairs (x_0^i, x_1^i) with $x_0^i, x_1^i \in \{0,1\}^\ell$, while the receiver R holds an m-bit choice vector b. At the end of the protocol, R receives $x_{b[i]}^i$ but learns nothing about $x_{1-b[i]}^i$, and S learns nothing about b. Many OT protocols have been proposed, most notably (for the semi-honest model) the Naor-Pinkas OT [42], which uses public-key operations and has amortized complexity of $3m$ public-key operations when performing m OTs.

OT extension [6, 30] reduces the number of expensive public-key operations for OT_ℓ^m to that of only $\mathrm{OT}_\kappa^\kappa$, and computes the rest of the protocol using more efficient symmetric cryptographic operations which are orders of magnitude faster. The security parameter κ is essentially independent of the number of OTs m, and can be as small as 80 or 128. Thereby, the computational complexity for performing OT is reduced to such an extent, that the network bandwidth becomes the main bottleneck [1].

Recently, the efficiency of OT extension protocols has gained a lot of attention. In [35], an efficient 1-out-of-N OT extension protocol was shown, that has sub-linear communication in κ for short messages. Another protocol improvement is outlined in [1, 35], which decreases the communication from R to S by half. Additionally, several works [1, 44] improve the efficiency of OT by using an OT variant, called **random OT**. In random OT, (x_0^i, x_1^i) are chosen uniformly and randomly within the OT and are output to S, thereby removing the final message from S to R. Random OT is useful for many applications, and we show how it can reduce the overhead of PSI. We elaborate on these OT extension protocols in the full version [47].

3 Circuit-Based PSI

Unlike special purpose private set intersection protocols, the protocols that we describe in this section are based on a *generic* secure computation protocol that can be used for computing arbitrary functionalities. State-of-the-art for computing the PSI functionality is the sort-compare-shuffle (SCS) circuit of [27], which has size $\mathcal{O}(n \log n)$ (cf. full version [47]for details.) We discuss these protocols by reflecting on the generic secure computation protocol of Goldreich-Micali-Wigderson (GMW) [23] (§3.1) and outlining major optimizations for evaluating the SCS circuit for PSI using GMW (§3.2).

The usage of generic protocols holds the advantage that the functionality of the protocol can easily be extended, without having to change the protocol or the security of the resulting protocol. For example, it is straightforward to change the protocol to compute the size of the intersection, or a function that outputs 1 iff the intersection is greater than some threshold, or compute a summation of values (e.g., revenues) associated with the items that are in the intersection. Computing these variants using other PSI protocols is non-trivial.

3.1 The GMW Protocol

We focus on the GMW protocol [23] for generic secure computation, which was implemented in the semi-honest model for multiple parties in [12], optimized for two parties in [49], and extended to the malicious model in [44].

The GMW protocol represents the function to be computed as a Boolean circuit and uses an XOR-based secret-sharing and OT to evaluate the circuit. A circuit with input bit u from P_1 and v from P_2 is evaluated as follows. First, P_1 and P_2 secret-share their input bit $u = u_1 \oplus u_2$ and $v = v_1 \oplus v_2$ and P_i obtains the shares labeled with i. The parties then evaluate the Boolean circuit gate-by-gate, as detailed next. To evaluate an XOR gate with input wires u and v and output wire w, P_1 locally computes $w_1 = u_1 \oplus v_1$ while P_2 locally computes $w_2 = u_2 \oplus v_2$.

Evaluating AND gates using multiplication triples An AND gate with input wire u and v and output wire w

requires an interaction between both parties using a *multiplication triple* [5]. A multiplication triple is a set of shares $\alpha_1, \alpha_2, \beta_1, \beta_2, \gamma_1, \gamma_2 \in \{0,1\}$ with $(\alpha_1 \oplus \alpha_2) \wedge (\beta_1 \oplus \beta_2) = \gamma_1 \oplus \gamma_2$. Given a multiplication triple, to evaluate an AND gate implementing u AND v, the parties compute $d_i = \alpha_i \oplus u_i$ and $e_i = \beta_i \oplus v_i$, exchange d_i, e_i, reconstruct $d = d_1 \oplus d_2$ and $e = e_1 \oplus e_2$, and compute the shares of the gate output wire as $w_1 = (d \wedge e) \oplus (d \wedge \beta_1) \oplus (e \wedge \alpha_1) \oplus \gamma_1$ and $w_2 = (d \wedge \beta_2) \oplus (e \wedge \alpha_2) \oplus \gamma_2$. These are all extremely efficient operations and therefore the efficiency of the evaluation depends on the efficiency of generating multiplication triples.

As described in [1], multiplication triples can be generated using two random OTs on one-bit strings as follows: both parties choose $\alpha_i \in_R \{0,1\}$ and run two random OTs, where in the first OT P_1 acts as sender and P_2 as receiver with choice bit α_2, and in the second OT P_2 acts as sender and P_1 as receiver with choice bit α_1. From each OT, the sender obtains (x_0^i, x_1^i) and sets $\beta_i = x_0^i \oplus x_1^i$ and the receiver obtains $x_{\alpha_i}^i$. To compute valid γ_0, γ_1 values for the triple, note that $(\alpha_1 \oplus \alpha_2) \wedge (\beta_1 \oplus \beta_2) = (\alpha_1 \wedge \beta_1) \oplus (\alpha_1 \wedge \beta_2) \oplus (\alpha_2 \wedge \beta_1) \oplus (\alpha_2 \wedge \beta_2) = \gamma_0 \oplus \gamma_1$. P_i locally computes $\alpha_i \wedge \beta_i$. Values $\alpha_1 \wedge \beta_2$ and $\alpha_2 \wedge \beta_1$ are computed using the output of the random OT as $\alpha_1 \wedge \beta_2 = x_{\alpha_1}^2 \oplus x_0^2$ and $\alpha_2 \wedge \beta_1 = x_{\alpha_2}^1 \oplus x_0^1$. Finally, P_1 sets $\gamma_1 = (\alpha_1 \wedge \beta_1) \oplus x_0^1 \oplus x_{a_1}^2$ and P_2 sets $\gamma_2 = (\alpha_2 \wedge \beta_2) \oplus x_0^2 \oplus x_{\alpha_2}^1$. These computations can be done in a preprocessing step before the input is known, are independent of circuit's structure, and highly parallelizable.

3.2 Optimized Circuit-Based PSI

We describe in this section an optimization which greatly reduces the overhead of circuit based PSI for GMW (as is detailed in Tab. 5 in §7, the reduction in the runtime for inputs of size 2^{18} is about 40%). The optimization is based on a protocol proposed in [39].

Approximately $2/3$ of the AND gates in the SCS circuit are due to multiplexers (cf. full version [47] for details). In each multiplexer operation with σ-bit inputs x and y and a choice bit s, we compute $z[j] = s \wedge (x[j] \oplus y[j]) \oplus x[j]$ for each $1 \leq j \leq \sigma$ using σ AND gates in total. The evaluation of this multiplexer circuit in the GMW protocol requires random $\mathrm{OT}_1^{2\sigma}$, namely 2σ random OTs of single-bit inputs. We observe that the same wire s is input to multiple AND gates which allows for the following optimization.

Consider an input wire u that is the input to multiple AND gates of the form $w[1] = (u \text{ AND } v[1]), \ldots, w[\sigma] = (u \text{ AND } v[\sigma])$. Similar to the evaluation of a single AND gate described in §3.1, these gates can be evaluated using a multiplication triple generalized to vectors, which we call a *vector multiplication triple*.

A vector multiplication triple has the following form: $\alpha_1, \alpha_2 \in \{0,1\}$; $\beta_1, \beta_2, \gamma_1, \gamma_2 \in \{0,1\}^\sigma$, where P_i holds the shares labeled with i that satisfy the condition $(\alpha_1 \oplus \alpha_2) \wedge (\beta_1[j] \oplus \beta_2[j]) = \gamma_1[j] \oplus \gamma_2[j]$. To evaluate the AND gates, both parties compute $d_i = \alpha_i \oplus u_i$ and $e_i[j] = \beta_i[j] \oplus v_i[j]$, exchange $d_i, e_i[j]$, set $d = d_1 \oplus d_2$, $e[j] = e_1[j] \oplus e_2[j]$, and $w_i[j] = (d \wedge e[j]) \oplus (d \wedge \beta_i[j]) \oplus (e[j] \wedge \alpha_i) \oplus \gamma_i[j]$. The vector multiplication triple can be pre-computed analogously to the regular multiplication triples described in §3.1, but using random OT_σ^2, namely only two random OTs applied to σ-bit strings: The parties each choose $\alpha_1, \alpha_2 \in_R \{0,1\}$ and perform a random OT_σ^1 with P_1 acting as sender and P_2 acting as receiver with choice bit α_2, and a second random OT_σ^1 with P_2 acting as sender and P_1 acting as receiver with choice bit α_1. From these random OTs, P_i obtains $\beta_i \in \{0,1\}^\sigma = x_0^i \oplus x_1^i$ and, analogously to the regular multiplication triple generation, a valid $\gamma_i \in \{0,1\}^\sigma$.

Efficiency Overall, evaluating σ AND gates with a vector multiplication triple requires to send $2\sigma + 2$ bits (instead of 4σ bits with σ regular multiplication triples). Generating a vector multiplication triple requires 2 random OTs on σ-bit strings (instead of 2σ random OTs with σ regular multiplication triples); as the communication of random OT is independent of the input length, this improves communication by factor σ.

In the SCS circuit we have $2n\log_2 n + n + 1$ multiplexers, each of which can be evaluated using a single vector multiplication triple. This reduces the number of random OTs from $2\sigma(2n\log_2 n + n + 1)$ to $2(2n\log_2 n + n + 1)$.

Further applications of vector multiplication triples As a side note, we comment that our vector multiplication triples can be used in every circuit where wires are used as input in two or more AND gates. As such, another beneficial application is multiplication. When computing a multiplication between two σ-bit numbers x and y using the school method multiplication circuit [49], each bit x_i is multiplied with every bit of y: $\forall_{1 \leq i \leq \sigma} \forall_{1 \leq j \leq \sigma} (x_i \wedge y_j)$. Here, using vector multiplication triples allows to reduce the total number of random OTs by a factor two, from $4\sigma^2 - 2\sigma$ OTs to $2\sigma^2$.

4 Bloom Filter-Based PSI

The recent PSI protocol of [17] uses Bloom Filters (BF) and OT to compute set intersection. We summarize Bloom filters in §4.1 and the PSI protocol of [17] in §4.2. We then present a redesigned optimized version of the protocol in §4.3. This optimization reduces the runtime for inputs of size 2^{18} by $55\% - 60\%$ (cf. §7, Tab. 5).

4.1 The Bloom Filter

A BF that represents a set of n elements consists of an m-bit string F and k independent uniform hash functions $h_1,...,h_k$ with $h_i : \{0,1\}^* \mapsto [1,m]$, for $1 \leq i \leq k$. Initially, all bits in F are set to zero. An element x is inserted into the BF by setting $F[h_i(x)] = 1$ for all i. To query if the BF contains an item y, one checks all bits $F[h_i(y)]$. If there is at least one j such that $BF[h_j(y)] = 0$, then y is not in the BF. If, on the other hand, all bits $BF[h_i(y)]$ are set to one, then y is in the BF except for a false positive probability ε. An upper bound on ε can be computed as $\varepsilon = p^k(1+O(\frac{k}{p}\sqrt{\frac{\ln m - k\ln p}{m}}))$, where $p = 1-(1-\frac{1}{m})^{kn}$. The authors of [17] propose to choose the number of hash functions as $k = 1/\varepsilon$ and the size of the BF as $m = kn/\ln 2 \approx 1.44kn$. In their experiments, they set $\varepsilon = 2^{-\kappa}$, resulting in $k = \kappa$ and a filter of size $m \approx 1.44\kappa n$.

4.2 Garbled Bloom Filter-Based PSI

For BF-based PSI, one cannot simply compute the bitwise AND of the BFs that represent each set, as this leaks information (see [17] for details). Instead, the authors of [17] introduced a variant of the BF, called Garbled Bloom Filter (GBF). Like a BF, a GBF G uses κ hash functions $h_1,...,h_\kappa$, but instead of single bits, it holds shares of length ℓ at each position $G[i]$, for $1 \leq i \leq m$. These shares are chosen uniformly at random, subject to the constraint that for every element x contained in the filter G it holds that $\bigoplus_{j=1}^{\kappa} G[h_j(x)] = x$.

To represent a set X using a GBF G, all positions of G are initially marked as unoccupied. Each element $x \in X$ is then inserted as follows. First, the insertion algorithm tries to find a hash function $t \in [1...\kappa]$ such that $G[h_t(x)]$ is unoccupied (the probability of not finding such a function is equal to the probability of a false positive in the BF, which is negligible due to the choice of parameters). All other unoccupied positions $G[h_j(x)]$ are set to random ℓ-bit shares. Finally, $G[h_t(x)]$ is set to $G[h_t(x)] = x \oplus \left(\bigoplus_{j=1, j\neq t}^{\kappa} G[h_j(x)]\right)$ to obtain a valid sharing of x. We emphasize that because existing shares need to be re-used, the generation of the GBF cannot be fully parallelized. (We describe below in §4.3 how the protocol can be modified to enable a parallel execution.)

In the semi-honest secure PSI protocol of [17], P_1 generates a m-bit GBF G_X from its set X and P_2 generates a m-bit BF F_Y from its set Y. P_1 and P_2 then perform OT_ℓ^m, where for the i-th OT P_1 acts as a sender with input $(0, G_X[i])$ and P_2 acts as a receiver with choice bit $F_Y[i]$. Thereby, P_2 obtains an intersection GBF $G_{(X\wedge Y)}$, for which $G_{(X\wedge Y)}[i] = 0$ if $F_Y[i] = 0$ and $G_{(X\wedge Y)}[i] = G_X[i]$ if $F_Y[i] = 1$. P_2 can check whether an element y is in the intersection by checking whether $\bigoplus_{i=1}^{k} G_{(X\wedge Y)}[h_i(y)] \stackrel{?}{=} y$. (Note that P_2 cannot perform this check for any value which is not in its input set, since the probability that it learns all GBF locations associated with that value is equal to the probability of a false positive, which is negligible due to the choice of parameters.) The bit-length of the shares in the GBF can be set to $\ell = \lambda$.

4.3 Random GBF-Based PSI

We introduce an optimization of the GBF-based PSI protocol of [17], which we call the *random Garbled Bloom Filter* protocol. The core idea is to have parties collaboratively generate a *random* GBF. This is in contrast to the original protocol where the GBF had to be of a specific structure (i.e., have the XOR of the entries of $x \in X$ be x). The modified protocol can be based on random OT extension (in fact, on a version of the protocol which is even more efficient than the original random OT extension). For each position in the filter, each party learns a random value if the corresponding bit in its BF is 1. P_1 then sends to P_2 the XOR of the GBF values corresponding to each of its inputs, and P_2 compares these values to the XOR of the GBF values of its own inputs.

We denote the primitive that enables this solution an oblivious pseudo-random generator (OPRG), which takes as inputs bits b_1, b_2 from each party, respectively, generates a random string s, and outputs to P_t s if $b_t = 1$ and nothing otherwise, for $t \in \{0,1\}$. Additionally, we require that the parties remain oblivious to whether the other party obtained s. A protocol for computing this functionality is obtained by modifying the existing random OT extension protocol of [1] as follows.

Recall that in random OT extension, S has no input in the i-th OT and outputs two values (x_0^i, x_1^i), while R inputs a choice bit vector b and outputs $x_{b[i]}^i$. Computation of each of these values involves one evaluation of a hash function H (cf. §2.2; the detailed random OT extension protocol is summarized in the full version [47]). The new functionality is obtained by having S ignore the x_0^i output that it receives, and ignore also the x_1^i output if $b_1 = 0$. Similarly, R ignores its output if $b_2 = 0$. The random OT extension protocol thus becomes more efficient, since the parties can ignore parts of the computation.

Our resulting Bloom filter-based protocol works as follows. First, P_1 and P_2 each generate a BF, F_X and F_Y respectively. They evaluate the OPRG with P_1 being the sender and P_2 being the receiver, using the bits of F_X and F_Y as inputs, to obtain random GBFs G_X and G_Y with entries in $\{0,1\}^\ell$. For each element x_j in its set X, P_1 then computes $m_{P_1}[j] = \bigoplus_{i=1}^{\kappa} G_X[h_i(x_j)]$, with $1 \leq j \leq n_1$. Finally, P_1 sends all m_{P_1} values in random order to P_2, which identifies whether an element y in its set is in the intersection by checking whether a j exists such that $m_{P_1}[j] = \bigoplus_{i=1}^{\kappa} G_Y[h_i(y)]$.

Correctness For each item in the intersection, P_2 gets from P_1 the same XOR value that it computed from its own GBF, and therefore identifies that the item is in the intersection. For any item which is not in the intersection, it holds with overwhelming probability that the XOR value computed by P_2 is independent of the n_1 values received from P_1. The probability of a false positive identification for that value is therefore $n_1 \cdot 2^{-\ell}$. The probability of a false positive identification for any of the values is $n_1 n_2 \cdot 2^{-\ell}$. To achieve correctness with probability 1-$2^{-\lambda}$, we therefore set $\ell = \lambda + \log_2 n_1 + \log_2 n_2$.

Security The security of each party can be easily proved using a simulation argument. P_2's security is obvious, since the only information that P_1 learns are the random outputs of the random OT protocol, which are independent of P_2's input and can be easily simulated by P_1. P_1's security is apparent from observing that the information that P_2 receives from P_1 is composed of

- The XOR values that P_2 computed for each item in the intersection.
- The XOR values that P_1 computed for its $n_1 - |X \cap Y|$ items that are not in the intersection. These values are independent of P_2's BF unless one of these items is a false-positive identification in the filter, which happens with negligible probability ε.

Therefore, the information received from P_1 can be easily simulated by P_2 given its legitimate output, i.e., $X \cap Y$.

Efficiency As shown in Tab. 3, our resulting random GBF-based PSI protocol has less computation and communication complexity than the original GBF protocol in [17]. In terms of communication, in our new protocol, P_1 has to send the $n_1\ell$-bit vector m_{P_1} and P_2 has to send $m\kappa$ bits in the random OTs. (This is compared to $2m\lambda$ bits and $2m\kappa$ bits sent in the original protocol. Later in our experiments in §7 we show that the communication is reduced by a factor between 1.9 and 3, cf. Tab. 6.)

The computation complexity of our protocol is $\mathrm{HW}(F_X)$ hash function evaluations for P_1 and $\mathrm{HW}(F_Y)$ hash function evaluations for P_2, where $\mathrm{HW}(\cdot)$ denotes the Hamming weight. When the number of hash functions k and the size of the BF m are chosen optimally, we can approximate the average Hamming weight in a BF using the probability that a single bit is set to 1, which is $1-(1-(\frac{1}{m}))^{kn} \approx \frac{1}{2}$. Thus, $\mathrm{HW}(F) \approx \frac{m}{2}$.

A main advantage of our protocol is that it allows to parallelize *all* operations: BFs can be generated in parallel (bits in the BF are changed only from 0 to 1) and, most importantly, the random GBF can also be constructed in parallel, in contrast to the original GBF-based protocol.

Optimization	Party	# Bits Sent	# calls to H
Original GBF-based PSI [17]	P_1	$2m\lambda$	$2m$
	P_2	$2m\kappa$	m
Random GBF-based PSI (§4.3)	P_1	$n_1\ell$	$m/2$
	P_2	$m\kappa$	$m/2$

Table 3: Communication and computation complexities for Bloom-filter-based PSI of [17] and our optimization. (λ: statistical security parameter, κ: symmetric security parameter, n_i: number of elements of party P_i, $m \approx 1.44\kappa\max(n_1,n_2)$, $\ell = \lambda + \log_2 n_1 + \log_2 n_2$).

5 Private Set Intersection via OT

We propose a new private set intersection protocol that is based on the most efficient OT extension techniques, in particular the random OT functionality [1, 44] and the efficient 1-out-of-N OT of [35]. This PSI protocol scales very efficiently with an increasing set size.

We first describe the protocol for a private equality test (PEQT) between two elements x and y (§5.1) and then describe how to efficiently extend it for comparing y to a set $X = \{x_1, ..., x_n\}$ (§5.2). The resulting protocol can then be simply extended to perform PSI between sets X and Y by applying the parallel comparison protocol for each element $y \in Y$ (§5.3). The overhead of the protocol can be greatly improved using hashing (§6).

5.1 The Basic PEQT Protocol

In the most basic private equality test (PEQT) protocol, P_1 and P_2 check whether their σ-bit elements x and y are equal by engaging in random $\binom{2}{1}$ $\mathrm{OT}^{\sigma}_{\ell}$, where P_2 uses the bits of y as its choice vector. From each random OT, P_1 obtains two uniformly distributed and random ℓ-bit strings (s^i_0, s^i_1), and P_2 obtains $s^i_{y[i]}$. P_1 then computes $m_{P_1} = \bigoplus_{i=1}^{\sigma} s^i_{x[i]}$ (the XOR of the strings corresponding to the binary representation of x) and sends it to P_2. P_2 compares this value to $m_{P_2} = \bigoplus_{i=1}^{\sigma} s^i_{y[i]}$ and decides that $x = y$ iff $m_{P_1} = m_{P_2}$.

The basic private equality test can be improved by using a base-N representation of the inputs and a $\binom{N}{1}$ OT in the protocol. Specifically, let $N = 2^{\eta}$. P_1 and P_2 check whether their σ-bit elements x and y are equal by representing them using $t = \sigma/\eta$ letters from an alphabet of size N, and then engaging in random $\binom{N}{1}$-OT^t_{ℓ}.

For this, P_2 cuts its σ-bit element y into t blocks $y[i]$ of bitlength η each: $y = y[1]||\ldots||y[t]$; similarly, P_1 interprets $x = x[1]||\ldots||x[t]$. In the i-th random $\binom{N}{1}$-OT, P_2 inputs $y[i]$ as choice bits and P_1 obtains N random and uniformly distributed ℓ-bit strings $(s^i_0, ..., s^i_{N-1})$; P_2 obtains $s^i_{y[i]}$. P_1 sends $m_{P_1} = \bigoplus_{i=1}^{t} s^i_{x[i]}$ to P_2 who compares it to $m_{P_2} = \bigoplus_{i=1}^{t} s^i_{y[i]}$ and decides that $x = y$ iff $m_{P_1} = m_{P_2}$.

Correctness If $x = y$ then the choices that both parties make for their sums are equal, i.e., $m_{P_1} = \bigoplus_{i=1}^{t} s^i_{x[i]} = \bigoplus_{i=1}^{t} s^i_{y[i]} = m_{P_2}$, and P_2 successfully identifies equality.

If $x \neq y$ then the probability that $m_{P_1} = m_{P_2}$ is $2^{-\ell}$. To see that this is true, assume w.l.o.g. that the inputs differ in their last sub-string, i.e., $x[t] \neq y[t]$. Equality only holds if the last element received by P_2, namely $s^t_{y[t]}$, is equal to $\bigoplus_{i=1}^{t} s^i_{x[i]} \oplus \bigoplus_{i=1}^{t-1} s^i_{y[i]}$. The value of $s^t_{y[t]}$ is independent of the other values, and therefore this equality happens with probability $2^{-\ell}$ and thus we can set ℓ to be equal to the statistical security parameter λ.

Security P_2's security is obvious, since the only information that P_1 learns are the random values chosen in the random OT, which are independent of P_2's input.

As for P_1's security, note that P_2's view in the protocol consists of its t outputs in the random $\binom{N}{1}$-OT protocols, and of the value m_{P_1} sent by P_1. If $x = y$ then m_{P_1} is equal to the XOR of the first t values. Otherwise, all $t+1$ values are uniformly distributed. In both cases, the view of P_2 can be easily simulated given the output of the protocol (i.e., knowledge whether $x = y$). The protocol is therefore secure according to the common security definitions of secure computation [22].

Efficiency Since in the i-th random OT P_1 needs only the output $s^i_{x[i]}$, it suffices to evaluate one hash function per random OT. When using the random $\binom{2}{1}$-OT extension protocol[3] of [1] and $\ell = \lambda$, the parties perform random $\text{OT}^{\sigma}_{\lambda}$, send $\sigma\kappa + \lambda$ bits, and do σ hash function evaluations each. In comparison, when using the random $\binom{N}{1}$-OT extension protocol of [35], the parties perform only σ/η OTs and send 2κ bits per OT; in total, they have to send $2\sigma\kappa/\eta + \lambda$ bits and do σ/η hash function evaluations each. In the full version [47] we provide an analysis which shows that setting $\eta = 8$ results in optimal performance for our PSI protocols.

5.2 Private Set Inclusion Protocol

In a private set inclusion protocol, P_1 and P_2 check whether y equals any of the values in $X = \{x_1, ..., x_{n_1}\}$. The set inclusion protocol is similar to the basic PEQT protocol, but in order to perform multiple comparisons in parallel, the OTs are computed over longer strings, essentially transferring (in parallel) a random string for each element in the set X.

In more detail, both parties run a random $\binom{N}{1}$-$\text{OT}^t_{n_1\ell}$, where P_2 uses the bits of y as choice bits. Each received string is of length $n_1\ell$ bits. That is, in the i-th random OT, P_1 obtains N random strings $(s^i_0, ..., s^i_{N-1}) \in \{0,1\}^{n_1\ell}$, and P_2 obtains one random string $s^i_{y[i]}$. The strings are parsed as a list of n_1 sub-strings of length ℓ bits each. We refer to the j-th sub-string in these lists as $s^i_w[j]$, for $1 \leq j \leq n_1$ and $0 \leq w < N$. Using these sub-strings, P_1 and P_2 can then compute the XOR of the strings corresponding to their respective inputs, compare the results and decide on equality, as was described in the basic PEQT protocol in §5.1. In more detail, P_1 computes $m_{P_1}[j] = \bigoplus_{i=1}^{t} s^i_{x_j[i]}[j]$ and sends the $n_1\ell$-bit string m_{P_1} to P_2. P_2 decides whether y matches any of the elements in X by computing $m_{P_2} = \bigoplus_{i=1}^{t} s^i_{y[i]}$ and checking whether a j exists with $m_{P_1}[j] = m_{P_2}$.

Correctness and security follow from the properties of the protocol of §5.1. However, now we require that the value m_{P_2} and *all* the n_1 values $m_{P_1}[j]$ are distinct, which happens with probability $n_1 2^{-\ell}$. Thus, to achieve correctness with probability 1-$2^{-\lambda}$, we must increase the bit-length of the OTs to $\ell = \lambda + \log_2 n_1$. Also, note that P_2 learns the position j at which the match is found, which can be avoided by randomly permuting the inputs.

Efficiency The set inclusion protocol that compares y to *many* values has the same number of random OTs as the basic comparison protocol comparing y to a *single* value, but it requires the transferred strings to be of length $n_1(\lambda + \log_2(n_1))$ bits instead of λ bits. Note, however, that since we use random OTs there is no need to send these strings in the OT protocol. Instead, all strings corresponding to the same value of the same input bit can be generated from a single seed using a pseudo-random generator. Therefore, the amount of data transferred in the OTs is the same as for the single comparison PEQT protocol.

The only additional data that is sent is the $n_1(\lambda + \log_2 n_1)$-bit string m_{P_1}, which P_1 sends to P_2. Hence, the total amount of communication is $2\sigma\kappa/\eta + n_1(\lambda + \log_2 n_1)$ bits.

In addition, the PRG which is used to generate the output string from the OT must be evaluated multiple times to generate the $n_1(\lambda + \log_2 n_1)$ bits. Therefore, the set inclusion protocol, which compares y to n_1 elements, is less efficient than a single run of the PEQT protocol, but is definitely more efficient than n_1 invocations of the PEQT protocol.

5.3 The OT-Based PSI Protocol

To obtain the final PSI protocol that computes $X \cap Y$, P_2 simply invokes the private set inclusion protocol of §5.2 for each $y \in Y$. Correctness and security follow from the properties of the private set inclusion protocol.

[3] Note that for $\sigma < \kappa$ we can perform σ base-OTs instead of using OT extension. However, here we analyze the costs when using OT extension for simplicity and consistency reasons.

Efficiency Overall, to compute the intersection between sets X and Y of σ-bit elements, the protocol requires $n_2\sigma/\eta$ random $\binom{N}{1}$-OTs of $n_1(\lambda+\log_2 n_1)$ bit-strings and additionally $n_1 n_2(\lambda+\log_2 n_1)$ bits to be sent. Using the random $\binom{N}{1}$-OT of [35], the total amount of communication is $2n_2\sigma\kappa/\eta + n_1 n_2(\lambda+\log_2 n_1)$ bits. For large n_1 and n_2, this amount of communication grows too large for an efficient solution. In order to cope with large sets, one can use a hashing scheme, as shown in §6.

6 Hashing Schemes and PSI

Several private set intersection protocols are based on running many invocations of pairwise private equality tests (PEQT). These protocols include [11, 21, 27] or our set inclusion protocol in §5. A straightforward implementation of these protocols requires n^2 invocations of PEQT for sets of size n, and therefore does not scale well. In [19, 21] it was proposed to use hashing schemes to reduce the number of comparisons that have to be computed. The idea is to have each party use a publicly known random hashing scheme to map its input elements to a set of bins. If an input element is in the intersection, both parties map it to the same bin. Therefore, the protocol can check for intersections only between items that were mapped to the same bin by both parties.

Naively, if n items are mapped to n bins then the average number of items in a bin is $O(1)$, checking for an intersection in a bin takes $O(1)$ work, and the total overhead is $O(n)$. However, privacy requires that the parties hide from each other how many of their inputs were mapped to each bin.[4] As a result, we must calculate in advance the number of items that will be mapped to the *most populated* bin (w.h.p.), and then set all bins to be of that size. (This can be done by storing dummy items in bins which are not fully occupied.) This change hides the bin sizes but also increases the overhead of the protocol, since the number of comparisons per bin now depends on the size of the most populated bin rather than on the actual number of items in the bin. However, while the parties need to pretend externally that all their items are real, they do not need to apply all their internal computations to their dummy items (since they know that these items are not in the intersection). A careful implementation of this observation, which takes into account timing attacks, can further optimize the computation complexity of the underlying protocols.

The work of [19, 21] gave asymptotic values for the bin sizes that are used with this technique, and of the resulting overhead. They left the task of setting appropriate parameters for the hashing schemes to future work. We revisit the hashing schemes that were outlined in [19, 21], namely, simple hashing, balanced allocations, and Cuckoo hashing (§6.1). We evaluate the performance when using hashing schemes for PSI (§6.2), and describe an analysis of the involved parameters (§6.3). We conclude that Cuckoo hashing yields the best performance (for parameters which we find to be most reasonable).

6.1 Hashing Schemes

Simple Hashing In the simplest hashing scheme the hash table consists of b bins $B_1 ... B_b$. Hashing is done by mapping each input element e to a bin $B_{h(e)}$ using a hash function $h : \{0,1\}^\sigma \mapsto [1,b]$ that was chosen uniformly at random and independently of the input elements. An element is always added to the bin to which it is mapped, regardless of whether other elements are already stored in that bin. Estimating the maximum number of elements that are mapped to any bin, denoted max_b, is a non-trivial problem and has been subject to extensive research [24, 38, 48]. When hashing m elements to $b = m$ bins, [24] showed that $max_b = \frac{\ln m}{\ln\ln m}(1+o(1))$ w.h.p. In this case, there is a difference between the expected and the maximum number of elements mapped to a bin, which are 1 and $O(\frac{\ln m}{\ln\ln m})$, respectively. When decreasing the number of bins to a value b satisfying $c \cdot b \ln b = m$ for some constant c, it was shown in [48] that $max_b = (d_c - 1 + \alpha)\ln b$, where d_c is the largest solution to $f(x) = 1 + x(\ln c - \ln x + 1) - c = 0$, and α is a parameter for adjusting the conservativeness of the approximation, and should be set to be slightly larger than 1. In this case the expected and maximum number of elements mapped to a bin are of the same order $O(\ln b) \approx O(\ln m)$. This is preferable for our purposes, since even though privacy requires that we set each bin to be as large as the most populated bin, this size is of the same order as the expected size of a bin when no privacy is needed.

Balanced Allocations The balanced allocations hashing scheme [2] uses two uniformly random hash functions $h_1, h_2 : \{0,1\}^\sigma \mapsto [1,m]$. An element e is mapped by checking which of the two bins $B_{h_1(e)}$ and $B_{h_2(e)}$ is less occupied, and mapping the element to that bin. A lookup for an element q is then performed by checking both bins, $B_{h_1(q)}$ and $B_{h_2(q)}$, and comparing the elements in these bins to q. The advantage of this scheme, shown in [2], is that when hashing m elements into $b = m$ bins, max_b is only $\frac{\ln\ln m}{\ln 2}(1+o(1))$, i.e., exponentially smaller than in simple hashing.

[4] Otherwise, and since the hash function is public, some information is leaked about the input. For example, if no items of P_1 were mapped to the first bin by the hash function h, then P_2 learns that P_1 has no inputs in the set $h^{-1}(1)$, which covers about $1/n$ of the input range.

Cuckoo Hashing Similar to balanced allocations hashing, Cuckoo hashing [46] uses two hash functions $h_1, h_2 : \{0,1\}^\sigma \mapsto [1,b]$ to map m elements to $b = 2(1+\varepsilon)m$ bins. The scheme avoids collisions by relocating elements when a collision is found using the following procedure: An element e is inserted into a bin $B_{h_1(e)}$. Any prior contents o of $B_{h_1(e)}$ are evicted to a new bin $B_{h_i(o)}$, using h_i to determine the new bin location, where $h_i(o) \neq h_1(e)$ for $i \in \{1,2\}$. The procedure is repeated until no more evictions are necessary, or until a threshold number of relocations been performed. In the latter case, the last element is put in a special stash s. It was shown that for a stash of size $s \leq \ln m$, insertion of m elements fails with probability m^{-s} [33]. A lookup in this scheme is very efficient as it only compares e to the two items in $B_{h_1(e)}$ and $B_{h_2(e)}$ and to the s items in the stash. In exchange for the improved lookup overhead, the size of the hash table is increased to about $2m$ bins.

6.2 Evaluation of Hashing-Based PSI

We evaluate the asymptotic overhead of applying the OT-based PSI protocol that was introduced in §5.3 while using any of the hashing scheme that we described. Also note that P_1 can save communication since instead of sending all masks for each bin (including masks for both dummy and real values), it can send only the masks of its real values (in permuted order, so that P_2 does not know which value was in each bin). P_2 can then simply check every mask received from P_1 against every computed mask. However, in this case the bit-length ℓ of the masks has to be increased to $\ell' = \lambda + \log_2 n_1 + \log_2 n_2$, since P_2 has to perform a total of $n_1 n_2$ comparisons and the overall error probability must be at most $2^{-\lambda}$. In the following, we address the mask length for checking one item against a set of n_1 items as $\ell_1 = \lambda + \log_2 n_1$ and the mask length for checking a set of n_2 items against n_1 items as $\ell_2 = \lambda + \log_2 n_1 + \log_2 n_2$.

PSI based on simple hashing A protocol based on simple hashing allocates the n inputs of P_2 to b bins, such that $n = O(b \ln b)$ and b is approximately $O(n/\ln n)$. Each bin is padded with dummy items to contain the maximum number of items that is expected in a bin, which is $O(\ln b) = O(\ln n)$. For each bin, the parties need to compute the intersection between sets of $O(\ln n)$ items. Each item can be represented using $O(\ln \ln n)$ bits.[5] The protocol requires $O(\ln n \ln \ln n)$ random OTs for each bin. The total number of OTs is therefore $O(n \ln \ln n)$. The length of the values transferred in the OTs (the masks) is $\ell_2 \ln n$ bits.

[5] This holds since the items in a bin can be hashed to a shorter representation, as long as no collisions occurs. The length of the hashed value should be about $\lambda + \log((\ln n)^2) = O(\ln \ln n)$.

PSI based on balanced allocations A major problem occurs when using balanced allocations hashing for PSI: every item can be mapped to one of two bins, and therefore it is unclear with which of P_1's bin should P_2 compare its own input elements e. Furthermore, the protocol must hide from each party the choice of bins made by the other party to store e, since that choice depends on other input elements and might reveal information about them. The solution to this is to use balanced allocations by P_2 alone, whereas P_1 maps each of its input elements to *two* bins using simple hashing with both hash functions h_1 and h_2. When using $b = n$ bins, P_2 has $O(\ln \ln n)$ items in each bin, whereas P_1 has $O(\ln n / \ln \ln n)$ items in every bin (actually, it has twice as many items as with simple hashing, since it maps each item twice). The items can be represented using strings of $O(\ln \ln n)$ bits. The protocol continues as before. P_2 learns the output, but since P_1 does not use balanced allocations, P_1 does not learn P_2's choices in that hashing scheme. The number of OTs is linear in the number of items stored by P_2 multiplied by the representation length, e.g., $O(n \cdot (\ln \ln n)^2)$ OTs on $\ell_2 \ln n / \ln \ln n$ bit strings. This overhead is larger than that of the simple hashing-based scheme.

PSI based on Cuckoo hashing Designing PSI based on Cuckoo hashing encounters the same privacy problem as when using balanced allocations hashing, and therefore the same solution is used. P_2 uses Cuckoo hashing whereas P_1 maps each of its elements using simple hashing with each of the two hash functions. P_2 maps a single item to each of the $2n$ bins, whereas P_1's bins contain $O(\ln n)$ items. In addition, P_2 has a stash of $s \leq \ln n$ elements. Each of these elements must be compared with each of P_1's n elements. An item in a bin can again be represented using $O(\ln \ln n)$ bits, whereas an item in the stash can be represented using $O(\ln n)$ bits. Furthermore, when checking items in the stash, we check one item against n_1, allowing us to reduce the bit-size of the masks in the OTs to ℓ_1 instead of ℓ_2. The protocol therefore performs $O(n \ln \ln n)$ OTs on inputs of length $O(\ell_2 \ln \ln n)$ bits (for the items in the bins), and in addition $O((\ln n)^2)$ OTs of inputs of length $O(\ell_1 \ln n)$ bits (for the items in the stash, which are each compared to all items of P_1's input). Overall, the protocol has the same asymptotic overhead as the protocol that uses simple hashing.

6.3 Maximum Bin Size and Overhead

When using hashing schemes for private set intersection, the number of bins b and the corresponding maximum bin size max_b must be set to values that balance efficiency and security. If max_b is chosen too small, the probability of a party failing to perform the mapping, denoted P_{fail}, increases. As a result, the output might be inaccurate

Parameter	Total # OTs	Comm. [bits] P_1 to P_2	Comm. [MB] total, $n = 2^{18}$
No hashing	nt	$n^2\ell_1$	458,880 / 458,784
Simple Hashing	$3.7nt$	$n\ell_2$	476 / 121
Balanced Alloc.	$2.9nt(\ln\ln n)$	$2n\ell_2$	1,298 / 595
Cuckoo Hashing	$(2(1+\varepsilon)n+s)t$	$sn\ell_1+2n\ell_2$	319 / 89

Table 4: Number of OTs and communication for the different hashing-based protocols. The total communication given in the last column is calculated for $\ell_1 = \lambda + \log_2 n$, $\ell_2 = \lambda + 2\log_2 n$, $\kappa = 128$, $\lambda = 40$, $\varepsilon = 0.2$, $s = 4$. The first value in this column is for $t = \sigma = 32$ $\binom{2}{1}$-OTs per element and the second value is for $t = 32/8$ $\binom{N}{1}$-OTs, $N = 2^8$. It is composed of the total number of OTs in the 2nd column times the communication per OT plus the communication from P_1 to P_2 in the 3rd column.

(since not all items can be mapped to bins), or one of the parties needs to request a new hash function (a request that leaks information about the input set of that party). On the other hand, the number of performed comparisons increases with b and max_b. An asymptotic analysis of the maximum bin size was presented in [19, 21], but leaves the exact choice of b and max_b and the resulting P_{fail} to further work. In the following, we analyze the complexity of the hashing schemes when used in combination with our set inclusion protocol, described in §5. To compare the performance of the hashing schemes on a unified base, we depict in Tab. 4 the overall communication, divided into the number of OTs (where we run t OTs per element) and the number of bits sent from P_1 to P_2.

In the full version [47]we detail the analysis of setting the optimal parameters for usage of the different hashing schemes in our PSI protocol, and of the resulting number of OTs and communication overhead. The results are depicted in Tab. 4 and show that Cuckoo hashing has the lowest communication. In addition, this scheme has a stronger guarantee on the upper bound of P_{fail}, since we achieve rehash probability of n^{-s}. We therefore use this scheme in our implementation and experiments.

A note on approximations When using a hashing scheme with fixed bin sizes it is possible that the number of items mapped to a certain bin, say by P_1, is larger than the capacity of the bin. (This event happens with probability P_{fail}.) In such a case it is possible for P_1 to ask to use a new hash function. This request reveals some information about P_1's input. Another option is for P_1 to ignore the missed item, and therefore essentially compute an approximation to the intersection. This choice, too, might reveal information about P_1's input, albeit in a more subtle way through multiple invocations of the functionality. Similarly, in the Bloom filter-based protocol, the occurrence of a false positive might leak information. The best solution to this issue is to make sure that the probability of these events happening is negligible, so that it is almost certain that these events will not occur in practice. This is the approach that we take in our comparisons. (Another approach would be to allow the computation of an approximation of the original intersection function, while analyzing the privacy leakage effects of this computation, and deciding whether to tolerate them. The result might be a more liberal choice of parameters which will result in a more efficient implementation of the original protocol.)

7 Experimental Evaluation

In the following we experimentally evaluate the PSI protocols described before. We describe our benchmarking environment in §7.1 and then detail the comparison between the protocols in §7.2. Tab. 5 compares the single-threaded runtimes of all protocols over Gigabit LAN, Tab. 6 compares the communication complexities, and Tab. 7 compares the single-threaded runtimes on different networks. In the tables we highlight the protocol with lowest runtime and communication for each type.

7.1 Benchmarking Environment

We ran our experiments on two Intel Core2Quad desktop PCs (**without** AES-NI extension) with 4 GB RAM, connected via Gigabit LAN. In each experiment, P_1 and P_2 held the same number of input elements n and were not allowed to perform any pre-computation. We set n as in [17], i.e., $n \in \{2^{10}, 2^{12}, 2^{14}, 2^{16}, 2^{18}\}$, but omitted $n = 2^{20}$, since many implementations exceeded the available main memory. We use $\sigma = 32$ as the bit length of the elements.[6] We use a statistical security parameter $\lambda = 40$ and a symmetric security parameter $\kappa \in \{80, 128\}$ (other security parameters are chosen according to Tab. 2). For our set-inclusion protocol we set $\eta = 8$, i.e., use 1-out-of-2^8 OT extensions.

In our tables, the asymptotic performance is given for the party with the majority of the workload, and are divided to public-key operations (asym) and symmetric cryptographic operations (sym).

Implementations The implementation of the blind-RSA-based [14] and garbled Bloom-Filter [17] protocols were taken from the authors, but we used a hash-table to compute the last step in the blind-RSA protocol that finds the intersection (the original implemen-

[6] For protocols whose complexity depends on σ, elements from a large domain can be hashed to short representations; cf. full version [47] for details.

tation used pairwise comparisons with quadratic runtime overhead). We implemented a state-of-the-art Yao's garbled circuits protocol (using garbled-row-reduction, point-and-permute, free-XOR, and pipelining, cf [28]) by building on the C++ implementation of [12] and using the fixed-key garbling scheme of [7][7]. For Yao's garbled circuits protocol, we evaluated a size-optimized version of the sort-compare-shuffle circuit (comparison circuits of size and depth σ) while for GMW we evaluated a depth-optimized version (comparison circuits of size 3σ and depth $\log_2 \sigma$) for σ-bit input values [49].

We implemented FFC (finite field cryptography) and IFC (integer factorization cryptography) using the GMP library (v. 5.1.2), ECC using the Miracl library (v. 5.6.1), symmetric cryptographic primitives using OpenSSL (v. 1.0.1e), and used the OT extension implementation of [1] which requires about 3 symmetric cryptographic operations per OT for the asymptotic performance analysis.

We argue that we provide a fair comparison, since all protocols are implemented in the same programming language (C/C++), run on the same hardware, and use the same underlying libraries for cryptographic operations.

For each protocol we measured the time from starting the program until the client outputs the intersecting elements. All runtimes are averaged over 10 executions.

7.2 Performance Comparison

We divide the performance comparison into three categories, depending on whether the protocol is based on public-key operations, circuits, or OT. Afterwards, we provide experiments for different networks and give a comparison between the best protocols in each category.

Public-Key-Based PSI For the public-key-based PSI protocols, we observe that the DH-based protocol of [29] outperforms the RSA-based protocol of [14] when using finite field cryptography (FFC). Similarly to [1], we also obtain the somewhat surprising result that for 80-bit security elliptic curve cryptography (ECC) using the Miracl library is slower than FFC using the GMP library. For larger security parameters, however, ECC becomes more efficient and outperforms FFC by a factor of 3 for 128-bit security for the DH-based protocol. (The reason for this phenomenon might be better implementation optimizations in the GMP library.) The advantage of the ECC-based protocol is its communication complexity, which is lowest among all PSI protocols, cf. Tab. 6. We note that a major advantage of these protocols is their simplicity, which makes them comparably easy to implement.

[7]The security of the fixed-key garbling scheme is somewhat controversial but we included it for performance reasons.

Circuit-Based PSI Here we tested Yao- and GMW-based implementations, as well as an implementation of our optimized vector multiplication-triple-based GMW protocol (§3.2). Following is a summary of the results:

- Both the computation complexity and the communication complexity of the circuit-based PSI protocols are the highest among all protocols that we tested.
- The basic GMW protocol has the highest overall runtime and communication complexity.
- Our vector multiplication triple optimization reduces the runtime and communication of GMW by approximately 40%. For security parameter $\kappa = 80$, this implementation is slightly faster than Yao's protocol, but it is slightly slower for $\kappa = 128$. Communication-wise, the vector multiplication triple GMW is more efficient than Yao's protocol.
- The runtime of Yao's protocol hardly increases with the security parameter, since we use AES-128 for both versions. Note, however, that our implementation of Yao's protocol exceeded the main memory when processing 2^{18} elements.
- Our Yao implementation does not use the AES-NI hardware support. Using AES-NI is likely to improve the runtime of the Yao implementation.

We give a more detailed performance comparison for GMW and Yao's protocol in the full version [47].

OT-Based PSI The random garbled Bloom filter protocol of §4.3 improves the original garbled Bloom filter protocol of [17] by more than a factor of two in runtime and by factor of 2-3 in communication.

We also implemented our protocol of §5, where we used Cuckoo hashing with parameters $\varepsilon = 0.2$ and $s = 4$, cf. §6. This protocol had the best runtime, and was about 5 times faster than the random garbled Bloom filter protocol for $\kappa = 128$. In terms of communication, our set inclusion protocol uses less than 20% of the communication of the random garbled Bloom filter protocol for $\kappa = 80$ and less than 10% communication for $\kappa = 128$.

The main difference between the set inclusion protocol and the random garbled Bloom filter protocol is the dependency of the performance on the symmetric security parameter κ. In the random garbled Bloom filter protocol, the number of OTs is independent of the bit-length σ but scales linearly with κ. On the other hand, the number of OTs for the set inclusion protocol is independent of κ but linear in σ. As a result, the runtime of the Bloom filter protocol (but not of the set inclusion protocol) is greatly affected when κ is increased.

Experiments for Different Networks For each protocol type (public-key-based, circuit-based, and OT-based), we benchmark the best performing PSI protocol in different network scenarios: Gigabit LAN, 802.11g WiFi, intra-country WAN, inter-country WAN, and mobile Internet (HSDPA) and depict our results in Tab. 7. We characterize each network scenario by its bandwidth and latency. By latency we mean one-way latency, i.e., the time from source to sink, and we used the same bandwidth for up- and downlink. We simulated these network types using the Linux command `tc` and ran the protocols on $n = 2^{16}$ elements for $\kappa = 128$ and with one thread.

The only protocol that is nearly unaffected by the change in network environment and for which the network has not become the bottleneck is the DH-based ECC protocol. In this protocol computation is the bottleneck which can be improved by using multiple threads.

For the other protocols we observe how the main bottleneck transitions from computation to communication:

For Yao's protocol this transition happens very early, already when changing from Gigabit LAN to WiFi (factor 6 in runtime).[8] Our vector-MT GMW protocol and our random garbled Bloom filter protocol suffer less drastically from the decreased bandwidth (factor 2.3 in runtime). However, from the WiFi connection on, the performance of all three protocol decreases approximately linear in the bandwidth. Note that, although our vector-MT GMW protocol has only 66% of the communication complexity of Yao's protocol, it is more than two times faster in slower networks. This can be explained by the direction of the communication. In Yao's protocol, the large garbled circuit is sent in one direction, whereas the communication in GMW can be evenly distributed in both directions s.t. it uses both up- and downlink.

For our set inclusion protocol, the network saturation happens when using intra-country WAN. From this point on, the performance also decreases linearly with the bandwidth. Still, this protocol is the fastest of all protocols in all network settings.

Experiments with Multiple Threads Tab. 8 shows the runtimes with four threads. Of special interest is the last column, which shows the ratio between the runtimes with four threads and a single thread for $n = 2^{18}$ elements and security parameter $\kappa = 128$. The DH-based protocol, which is very simple and easily parallelizable, achieves almost the optimal speedup of 4x as computation is the performance bottleneck. The GMW protocol achieves only a speedup of about 2x, possibly due to the gate-by-gate evaluation of the circuit resulting in multiple rounds of communication as the bottleneck. The OT-based protocols achieve a very good speedup of about 3x.

[8] The performance advantage of using fixed-key AES garbling instead of SHA-1/SHA-256 already diminished in the WiFi setting.

Type	Network (Bandwidth (Mbit/s) / Latency (ms))	Gigabit LAN (1,000 / 0.2)	802.11g WiFi (54 / 0.2)	Intra-country WAN (25 / 10)	Inter-country WAN (10 / 50)	HSDPA (3.6 / 500)
Public-Key	DH-based ECC [29]	104.2	104.8	107.6	111.8	115.9
Circuit [27]	Yao [7, 28]	129.1	779.5	1,735.5	4,631.8	11,658.6
	Vector-MT GMW §3.2	168.9 (11.3)	370.5 (18.1)	770.4 (27.5)	1,936.5 (67.2)	5,310.9 (170.2)
OT	Random Garbled Bloom Filter §4.3	16.6	37.2	70.8	164.9	445.0
	Set Inclusion §5 + Hashing §6	**3.7**	**5.0**	**8.8**	**22.8**	**77.5**

Table 7: Runtimes in seconds for PSI protocols with one thread in different network scenarios for $n = 2^{16}$ elements, $\sigma = 32$: bit size of elements, and $\kappa = 128$-bit security (cf. Tab. 2); online time for Vector-MT GMW in ().

Type	Symm. Security Parameter κ	80-bit					128-bit					Speedup
	Set Size n	2^{10}	2^{12}	2^{14}	2^{16}	2^{18}	2^{10}	2^{12}	2^{14}	2^{16}	2^{18}	
Public-Key	DH-based FFC [29]	0.1	0.5	1.8	6.7	26.9	1.3	5.2	20.8	80.1	320.1	**3.82x**
Circuit [27]	Vector-MT GMW §3.2	0.8	3.6	15.9	71.3	288.1	1.1	5.6	23.4	96.1	400.9	1.90x
OT	Random Garbled Bloom Filter §4.3	0.08	0.2	0.8	3.2	13.1	0.14	0.5	1.7	6.4	25.9	2.61x
	Set Inclusion §5 + Hashing §6	**0.04**	**0.16**	**0.4**	**1.2**	**4.7**	**0.04**	**0.2**	**0.5**	**1.4**	**4.9**	2.81x

Table 8: Runtimes in seconds for PSI protocols with four threads and $\sigma = 32$; speedup for $n = 2^{18}$ and $\kappa = 128$.

Comparison From the results we observe that OT-based protocols have the lowest runtime on a fast network. The public-key-based protocols require costly public-key operations, which scale very poorly with increasing security parameter, but need less communication than the OT- or circuit-based protocols. The circuit-based protocols have a smaller runtime than the public-key-based protocols using FFC or RSA for $\kappa = 128$, but by far the highest communication complexity.

Our set inclusion protocol achieves both the most efficient runtime and a very low communication overhead. Compared to the second fastest protocol, namely our optimized random garbled Bloom-filter protocol, the set inclusion protocol is at least 5 times faster and uses 10 times less communication (for 128 bit security). Moreover, this protocol has the second best communication overhead, requiring only 3 times the communication of the DH-ECC-based protocol of [29], but running faster in all network environments that we tested.

We stress that the choice of the preferable PSI protocol depends on the application scenario. For instance,

- If communication is the bottleneck and computation is vast, then the DH-based PSI protocol using ECC is the most favorable. That protocol is also the simplest protocol to implement.
- The circuit-based protocols are unique in that they are based on generic secure computation techniques and can therefore be easily modified to compute more complex variants of PSI.
- While our set inclusion protocol performs very efficiently for $\sigma = 32$, it would require twice the runtime for $\sigma = 64$, while the random garbled Bloom filter protocol would have approximately the same runtime (which would still be greater).

Abstract

Generally speaking, malicious code leverages *hooks* within a system to divert the control flow. Without them, an attacker is blind to the events occurring in the system, rendering her unable to perform malicious activities (e.g., hiding of files or capturing of keystrokes). However, while hooks are an integral part of modern attacks, they are at the same time one of their biggest weaknesses: Even the most sophisticated attack can be easily identified if one of its hooks is found. In spite of this fact, hooking mechanisms have remained almost unchanged over the last years and still rely on the *persistent* modification of *code* or *control data* to divert the control flow. As a consequence, hooks represent an abnormality within the system that is *permanently evident* and can in many cases easily be detected as the hook detection mechanisms of recent years amply demonstrated.

In this paper, we propose a novel hooking concept that we refer to as *dynamic hooking*. Instead of modifying persistent control data permanently, this hooking mechanisms targets *transient* control data such as return addresses at run-time. The hook itself will thereby reside within *non-control data* and remains hidden until it is triggered. As a result, there is no *evident* connection between the hook and the actual control flow change, which enables dynamic hooks to successfully evade existing detection mechanisms. To realize this idea, dynamic hooks make use of exploitation techniques to trigger vulnerabilities at run-time. Due to this approach, dynamic hooks cannot only be used to arbitrarily modify the control flow, but can also be applied to conduct *non-control data* attacks, which makes them more powerful than their predecessors. We implemented a prototype that makes uses of static program slicing and symbolic execution to automatically extract paths for dynamic hooks that can then be used by a human expert for their realization. To demonstrate this, we used the output provided by our prototype to implement concrete examples of dynamic hooks for both modern Linux and Windows kernels.

1 Introduction

Over the last decade, the sophistication and technical level of malicious software (*malware*) has increased dramatically. In the early 2000s, we saw malware such as the *I Love You* [29] and *Blaster* worms [3] that generally operated in user space with very little in the way of defensive mechanisms. In contrast, we nowadays see complex kernel level malware such as *Stuxnet*, *Duqu*, and *Flame* [6] that show an increase in sophistication in the target of their attack, the exploitation methods used to deliver them, and their ability to evade detection. By targeting kernel space, modern malware effectively runs at the same privilege level as the operating system (OS), enabling it to attack and modify any part of the system including the kernel itself. In addition, malware can take advantage of stealth techniques that were originally only used by kernel rootkits to hide itself deep within the system. This makes the detection of malware increasingly difficult, especially as malware continues to evolve, enabling it to stay one step ahead of the defenders. Currently, one the most sophisticated methods employed is data-only malware [16, 41].

However, even very sophisticated malware such as data-only malware has an Achilles' heel: in general, malware needs to intercept events within the system to be able to fulfill its purpose [27, 44]. Without this capability, malware would be unable to react to events or provide fundamental functionality such as key logging and file hiding, which would severely limit its possibilities. Event interception, however, requires malware to divert the control flow of the infected system at run-time. To achieve this, malware must install *hooks* in the system that facilitate the required control flow transfer on behalf of the malware whenever the desired event occurs. While malware might manage to hide itself, these hooks represent an abnormality that will be *permanently* visible within the system and thus lends itself well to becoming the basis of detection mechanisms. This insight led to a wide range of research that enable the monitoring of malware hooking behavior for the purpose of signature

generation [47] or detecting malware based on control flow modifications [15, 20, 43].

Although existing systems are not yet able to detect all hooks that are placed by malware, the remaining possibilities for malware to install hooks are constantly dwindling. Hooks that are based on code modifications are usually no longer an option, since changes to code areas can be easily detected due to their static nature. This leaves attackers only with the option of data hooks [43, 47], but even here the options are increasingly restricted by modern detection mechanisms. The reason for this development is that, in contrast to malware where one can observe a constant evolution of techniques and mechanisms used, hooking techniques have not significantly changed over the course of recent years.

In this paper, we present a novel hooking concept that we refer to as *dynamic hooking*. In contrast to existing hooking mechanisms which *persistently* modify control data, our hooking approach targets *transient* control data such as return addresses at run-time. As a consequence, the resulting control flow change that is introduced by the hook only becomes visible when the hook is actually triggered. This significantly complicates the detection of dynamic hooks as security mechanisms can no longer focus on persistent control data, but must also take transient control data into account. What is even more, the hook itself will thereby reside in *non-control* data, which is much more difficult to analyze and verify [4, 15] when compared to *control* data that traditional hooks target. Despite the fact that dynamic hooks reside purely in non-control data, they are able to reliably intercept the execution flow of functions similar to traditional hooks. Furthermore, they can be used in pure data-only attacks, which are by themselves a realistic and dangerous threat [3, 5]. Thus they are not only harder to detect, but also more powerful than their predecessors.

To provide these capabilities, dynamic hooks modify data in such a way that they will trigger vulnerabilities at run-time. Through this approach, they are able to arbitrarily modify the control flow, while the hook itself only consists of the data that triggers and exploits the vulnerability. This makes them quite similar to traditional exploitation techniques with the exception that they target applications that are *already* controlled by the attacker. Due to this fact, the attack surface for dynamic hooks is much broader compared to traditional exploitation, since an attacker can not only attack external functions, but also *internal* functions.

Furthermore, dynamic hooks can be obtained automatically in a manner comparable to automated exploit generation [2]. To demonstrate this, we implemented a prototype that leverages static program slicing [40, 45] and symbolic execution [34] to automatically extract satisfiable, exploitable paths for dynamic hooks. The prototype thereby provides detailed information about each jump condition in the path and the actual vulnerability in an intuitive format, which makes the output suitable for exploit generation frameworks or a human expert. We used this prototype to automatically identify dynamic hooks for recent Linux and Windows kernels. Additionally, we implemented proof of concepts (POCs) of dynamic hooks that demonstrate how they can be used in practice to intercept events such as system calls or to implement backdoors. This proves that the suggested hooking mechanism is not only powerful, but also realistic.

In summary, we make the following contributions:

- We present a novel hooking concept called *dynamic hooking* that targets transient control data at runtime instead of persistent control-data. This approach bypasses existing hook detection techniques proposed in the last few years.
- We show how dynamic hooks for OS kernels can be automatically found by leveraging binary analysis techniques and implemented a prototype.
- We provide detailed POC implementations of dynamic hooks for both Linux and Windows kernels that demonstrate their capabilities and possibilities.

2 Technical Background

Before presenting our approach to realize dynamic hooks, we first review background information that is essential for the understanding of the remainder of the paper. We begin by defining important terms and then discuss why malware in general requires hooks within the system to function. Finally, we cover existing hooking mechanisms and their countermeasures.

2.1 Definitions

We first introduce important terms that we will use throughout the paper. In particular, we highlight the differences between control data and non-control data as well as transient and permanent control data.

Control data and non-control data. *Control data* specifies the target location of a branch instruction. By changing control data, an attacker can arbitrarily change the control flow of an application. Examples of control data are return addresses and function pointers.

In contrast, *non-control data* never contains the target address for a control transfer. In certain cases, however, it may influence the control flow of an application. For instance, a conditional branch may depend on the value of non-control data.

Transient and persistent control data. We consider control data to be *transient* when it cannot be reached through a pointer-chain originating from a global variable. This essentially implies that there is no lasting connection between the application and the control data. Instead, the control data is only visible in the current scope of the execution such as a return address which is only valid as long as a function executes.

By extension, we consider all control data that is reachable through a global variable as *persistent*, since the control data is permanently connected to the application and can thus always be accessed independent of the current scope.

2.2 Malware and Hooking

Petroni et al. [27] estimated that about 96% of all rootkits require *hooks* within the system to function. Intuitively, this makes sense: since the sole purpose of rootkits is to provide stealth, they have to hide all signs of an infection. While existing structures can be hidden using techniques such as *direct kernel object manipulation (DKOM)* [38], hooks enable rootkits to react to changes occurring at *run-time*. Consider, for instance, that a hidden process creates a new network connection or a child process. Naturally, a rootkit must also hide such newly created objects to achieve its goal. This, however, requires a rootkit to be notified of the occurrence of such events. Hooks solve this problem by enabling a rootkit to install callback functions in the system. This makes them an integral part of rootkit functionality.

In practice, rootkit functionality is often mixed with a variety of malicious payloads. According to a report by Microsoft released in 2012 [13], "some of the most prevalent malware families today consistently use rootkit functionality". The primary reason for this is that the single purpose of a rootkit is to avoid detection. Consequently, it is not a big surprise that the techniques formerly only found in rootkits are increasingly being adapted by malware. Since rootkits require hooks to function, this, however, also implies that any malware based on rootkit functionality will require the same.

2.3 Existing Hooking Mechanisms

In general, we distinguish between two different types of hooks: *code* hooks and *data* hooks [11, 43, 47]. Code hooks work by directly patching the application's code regions: wherever the attacker wants to redirect the control flow of the application, she overwrites existing instructions with a branch instruction. As a result, the control flow of the application is diverted every time the execution passes through the modified instructions.

The main problem with code hooks is that code regions are usually static. Therefore, it is generally sufficient to identify modifications to code regions to detect this type of hook. Various techniques have been proposed that leverage such an approach [22, 27, 31]. As a result, adversaries resorted to a different hooking form referred to as data hooks. Instead of modifying code directly, data hooks target *persistent* control data within the application. By modifying control data, the attacker is able to divert every control transfer that makes use of the modified data. For example, the most straightforward method for intercepting the execution of system calls is to modify function pointers within the system call table.

To counter the threat of data hooks, researchers proposed various systems that aim to protect control data within an application [9, 20, 27, 43]. However, the main focus of these systems thereby lies in the protection of function pointers that are allocated on the heap or reside within the data region of the application. This is achieved by ensuring that each function pointer points to a valid function according to its control flow graph (CFG). *Transient* control data on the other side is generally ignored by these approaches or they merely consider the protection of return addresses, which is not the only kind of transient control data. Instead transient function pointer may also exist as we will discuss in Section 5.1.

While researchers acknowledge that malware could potentially also target transient control data to modify the control flow [20, 27, 43], these attacks are usually only considered in the context of exploitation or return-oriented rootkits [16], but are not deemed to be relevant for hooking. The reasoning behind this assumption is that malware generally wants to change the control flow of the target application indefinitely in order to be continuously able to intercept events. Consequently, the malware must *permanently* redirect the control flow and thus target persistent control data as transient control data is, by definition, only used by the system for a limited amount of time. In this paper, we demonstrate that this assumption is false and can be used to circumvent existing defense mechanisms against hooking.

3 Dynamic Hooks

In the following, we introduce our novel hooking concept that we refer to as *dynamic hooking*. For this purpose, we provide an overview of the concept, discuss the vulnerabilities that can be used to implement dynamic hooks, and cover the types of dynamic hooks that exist and their properties. Before doing so, however, we first state the attacker model that we assume throughout this paper.

3.1 Attacker Model & Scope

In the following, we assume that the attacker's goal is to install persistent kernel malware such as a rootkit on the victim's system. For this purpose, we assume that the attacker has the ability to manipulate the kernel's memory arbitrarily either through a vulnerability or the ability to load a kernel module (or driver). To avoid detection, the attacker wishes to hide all the hooks of the malware. That is, we are not concerned with the stealth of the malware itself, but instead solely focus on its hooks. Consequently, we consider all malware detection mechanisms that do not detect malware based on its hooks to be out of scope for the remainder of the paper. Furthermore, we assume the target system leverages common protection mechanisms such as Address Space Layout Randomization (ASLR), stack canaries, and $W \oplus X$.

3.2 High-Level Overview

The main problem with existing hooking mechanisms is that they require the *permanent* change of code or function pointers. Consequently, the desired control flow change of the malware is *permanently* evident within the system [27]. The fundamental idea behind dynamic hooks is to solve this problem by hiding the desired control flow change within *non-control data* such that there is no clear connection between the changes that the malware conducts and the actual control flow change. This is accomplished with the help of *exploitation techniques*.

To exploit a vulnerable application, an attacker makes use of specially crafted input data that—when processed by the application—will eventually trigger a vulnerability. If the vulnerability enables the attacker to overwrite important control structures such as a return address, she will be able to modify and often control the execution flow of the application using techniques such as return-oriented programming (ROP) [35].

With dynamic hooks, we apply the same concepts that are used in traditional exploitation scenarios to hooking. That is, we manipulate the input data of the functions we want to hook in such a way that we will trigger a control flow modifying vulnerability when the data is used. This effectively allows us to overwrite control data (e.g., a return address) at run-time and enables us to control the execution flow of the application similar to a traditional hook. The main difference, however, is that such a dynamic hook will reside somewhere within the data structures of the application unnoticed until its malicious payload is eventually used by the target function.

For this approach to work, we need to identify a control flow modifying vulnerability in every function that we want to hook. At first glance this seems unlikely. However, there is a key difference between the exploitation of traditional vulnerabilities and vulnerabilities that are used to realize dynamic hooks: the attacker *already* controls the application at the time she installs a hook. In a traditional exploit, the attacker's goal is to *gain* control over an application. To achieve this, she needs to find an input to the application that will trigger a vulnerability. That is, the attacker can only control the *external* data which is provided to the application. In the case of a dynamic hook, however, this restriction does not apply. As the attacker controls the application, she is free to access and modify *any* internal data structure of the application. This results in a much stronger attacker model when compared to traditional exploitation.

Finding and exploiting vulnerabilities in such a scenario becomes much easier for several reasons. First, many existing protection mechanisms such as ASLR, stack canaries, or $W \oplus X$ only protect against an *external* attacker, but can be easily circumvented by an attacker that controls the application. Second, the attacker can *prepare* the code (or ROP chain) she wants to execute when the vulnerability is triggered beforehand and does not have to provide it during the exploitation process. This enables the attacker to exploit vulnerabilities for which traditional methods would be difficult due to space constraints of the vulnerability. Third, the attack surface for dynamic hooks is much broader. The attacker cannot only attack functions that handle user input, but can also target internal functions that cannot be influenced by the user. In fact, by manipulating internal data structures, the attacker can create new vulnerabilities that would not occur during normal operation of the application, because the targeted data structures are normally only accessed and modified by the program itself. This may even allow the attacker to circumvent checks and filters within the application as the manipulated data structures may contain values that could never occur during normal operation and may thus not have been expected by the programmer. Finally, to hook a specific event, the hook may be placed anywhere within the control flow of the handling code, it is not restricted to a single function.

Example. To illustrate the concept of dynamic hooks at a concrete example, consider the following code from the `list_del` function in the Linux kernel (version 3.8):

```
1  struct list_head {
2          struct list_head *next;
3          struct list_head *prev;
4  };
5
6  static void list_del(struct list_head *entry)
7  {
8            entry->next->prev = entry->prev;
9            entry->prev->next = entry->next;
10 }
```

This function essentially removes the given entry from its list. If the attacker controls the `next` and the `prev`

field from the entry to be deleted, she essentially can trigger an arbitrary 8-byte write on a 64-bit architecture. In particular, she can write the value of `prev` into the memory address `[next + 8]` (Line 8) and the value of `next` into the memory address `[prev]` (Line 9). To use this code fragment for a dynamic hook, the attacker could, for instance, modify a specific entry within the system and set its `prev` pointer to point to the return address of the `list_del` function and its `next` pointer to point to attacker-controlled code. When the entry is deleted, the `list_del` function will then, while processing the malicious pointers, overwrite its own return address and activate the code of the attacker on its return.

The example code above was selected as the `list_del` function is used throughout the Linux kernel and demonstrates the arguments stated above. In general, this function is not exploitable by an external attacker, as the entries that are used by the function are created by other internal functions within the kernel. While these functions initialize the values of the pointers correctly, an attacker that controls the kernel can modify them arbitrarily, thus creating a new vulnerability. The `list_del` function does not expect the manipulated values and uses them without checks. This enables an attacker to conduct an arbitrary 8-byte write, which is not enough to introduce shellcode into the system, but is sufficient to transfer the control flow to a previously prepared code region. In addition, the attacker is not hindered by any of the protection mechanisms used by the Linux kernel, since she can disable $W \oplus X$ for her code[1], does not need to overwrite the stack canary, and knows the address of her code or can calculate the address of the location of the return address[2]. Finally, since the `list_del` function is invoked by many other functions within the kernel, a dynamic hook within this function is very effective.

3.3 Suitable Vulnerabilities

In principle, any kind of vulnerability can be used to implement a dynamic hook. In this paper, however, we will, for the sake of simplicity, focus on *n-byte* writes, sometimes also referred to as *write-what-where* primitives, such as the one presented in the previous example. Such n-byte writes enable an attacker to modify *n* bytes at an arbitrary memory location. In our example, the attacker controls an *8*-byte write to an arbitrary memory address. In x86-assembly, n-byte writes are essentially a memory `mov` instruction for which the source and the destination operand can be controlled by an attacker. An example of a potential 8-byte write vulnerability in Intel assembly syntax is the following instruction:

```
mov [rax], rbx
```

If the attacker can control the contents of `rax` and `rbx` at the time the instruction is executed, she can misuse it for a dynamic hook. It goes without saying that such instructions appear frequently within software. In the Linux 3.8 kernel binary, for instance, we found more than 103,000 `mov` instructions similar to the one shown above that can potentially be abused for an 8-byte write. This corresponds to about 5% of all instructions (1,976,441) within the tested Linux kernel binary (Linux 64-bit 3.8 kernel). Note that this does not include the approximately 58,000 one, two, or four byte write instructions. Together, this equates to a total of 8% of all instructions that can potentially be used to realize a dynamic hook.

3.4 Types of Dynamic Hooks

Generally speaking, there are two different types of dynamic hooks: *dynamic control hooks* and *dynamic data hooks*. The former target the control flow of the victim application and can be used as an alternative to traditional hooks since they enable an attacker to intercept events within the application. Dynamic data hooks, on the other side, do not target control data, but rather other critical data structures within an application. As an example, consider that an attacker wants to install a backdoor. For this purpose, she places a dynamic hook into a control path that can be triggered from userland such as a specific system call. However, instead of changing control data, this dynamic hook will upon invocation directly overwrite the credentials of a predefined process and elevate its privileges to *root*. Since the task credentials are usually a data value, this can be achieved with a single memory write. Thus, instead of overwriting a return address, the attacker simply sets her hook to overwrite the memory location where the task credentials reside. As pointed out by Chen et al. [10], such non-control data attacks can be quite powerful.

While dynamic data hooks do not modify the control flow directly, they can be used to influence the control flow at a later point in time. Consider for instance data that resides in memory and is processed by a just-in-time compiler. If an attacker manages to overwrite this data with dynamic hooks before it gets compiled, she can influence the instructions that are introduced into the system, which can lead to arbitrary code execution [7].

[1] Note that this is necessary since the first write (Line 8) of the example will write the return address (`prev`) into the code (`[next + 8]`) of the attacker. However, this is not a problem in practice, as the attacker can set her code to be writable and executable. In fact, this is even the default for memory allocated in the Linux kernel via `kmalloc`.

[2] The location of the return address depends solely on the address of the kernel stack and the size of the current function's stack frame. Both values are known to the attacker as we will describe in Section 4.2.

3.5 Properties of Dynamic Hooks

Components. Dynamic hooks always consist of two integral components. On the one hand, there is the instruction that activates the hook, which we refer to as the *trigger*. In the case of an 8-byte write, the trigger is the `mov` instruction that conducts the write on behalf of the attacker. Every path that leads to the execution of the trigger is referred to as a *trigger path*. On the other hand, there is the data that was manipulated by the attacker and encodes the malicious action that the attacker wants to conduct. This is the *payload* of the hook. For n-byte writes, the payload usually consists of two manipulated pointers: the *destination pointer*, which contains the address that will be written to and the *source pointer*, which specifies the value that will be written.

Binding. While the same trigger can be shared among different dynamic hooks, each hook in general requires its own payload. The reason for this is that the payload contains the actual data that specifies the control transfer. This data, however, will only be valid in a particular *context*. To overwrite a specific return address, for example, we must first be able to predict its exact location. This requires us to know the exact path leading to the use of the payload by the trigger. In practice, this means that a payload and thus the dynamic hook is usually closely *bound* to a specific execution path. The closer the connection between an execution path and a dynamic hook, the better the control of the attacker over the hook.

In an ideal situation, a dynamic hook is *exclusively* bound to a specific execution path. In this case, the payload of the hook is *only* processed in the execution path that leads to its trigger. This enables the attacker to predict possible modifications applied to the payload before its use in addition to the state of the machine at the time of the exploitation with high probability, since she must only consider a single execution path. Similar to traditional exploits, this is essential information that is required to be able to setup a dynamic hook correctly. After all, the attacker needs to correctly predict the exact address of the control data, which should be overwritten and overwrite it with the precise address of the target code region. Without knowing the exact layout of the stack as well as the transformations that may be applied to the payload before its use, this is a hard task.

If there are multiple paths that use the payload, the dynamic hook is only *loosely* bound to the path leading to the trigger instruction. The more execution paths the payload affects, the more difficult it will become for an attacker to control the hook. On the one hand, this is due to the fact that it will become increasingly difficult to predict the necessary memory addresses and transformations as has been described above. On the other hand, the more functions access the actual payload that the attacker modified, the more likely it will be that the hook introduces side effects into the application that may lead to unexpected behavior and crash the application. Consider, for instance, that an entry that is used by the `list_del` function has been modified to act as payload for a dynamic hook. If the same entry is used by a different function to iterate through all elements within the list, this will most likely lead to a crash of the system as the `prev` and the `next` pointer do not point to the previous and next element, respectively, as would have been expected.

Coverage. Another important property of a dynamic hook is coverage: as dynamic hooks should be closely bound to the execution path containing the trigger, it is essential that this triggering path is *always* executed when the target event that should be hooked is invoked. In this case, the dynamic hook provides *full* coverage. Otherwise, the hook may only be able to intercept *some* execution paths of the target event, but not all. In that case, the hook has only *partial* coverage and must thus be combined with other dynamic hooks to be able to achieve *full* coverage of the target function. Note that while binding is a property of the payload of the hook, coverage is a property of the trigger instruction.

3.6 Automated Path Extraction

So far we have discussed the concept of dynamic hooks and provided an overview of the different types of dynamic hooks and their properties. However, the creation of a dynamic hook still remains a manual process, which can—as in the case of traditional exploitation—be very time-consuming and error-prone especially for complex binaries such as modern OS kernels. We now describe how paths for dynamic hooks can be obtained automatically for a given binary. This is essentially a two-step process: In the first step, we make use of static program slicing [40, 45] to extract potential paths that could be used for a dynamic hook. In the second step, we then employ symbolic execution [17, 34] to verify the satisfiability of the paths and to generate detailed information for their exploitation.

3.6.1 Program Slicing

To find possible locations for dynamic hooks within an application, an attacker has to find triggers that make use of a payload that she can control. Since trigger instructions can be as simple as a memory move, there usually exist many triggering instructions in many paths of the application. To identify whether a particular trigger instruction can be used for a dynamic hook, it is necessary

to analyze the data flow that leads to the particular instruction. One technique that can be used for this purpose is static program slicing [40, 45].

The basic idea behind static program slicing is to traverse back through the control flow graph (CFG) of an application starting from a *sink* node and to extract each node that directly or indirectly influences the values used at the sink. Applied to the problem of finding dynamic hooks, static program slicing thus allows us to determine where the values of the *source* and the *destination* pointer in an n-byte write originate. To achieve this, we first identify all potentially vulnerable `mov` instructions within a given binary. These are essentially all `mov` instructions which move a value contained within a register to a memory location specified by another register. In the next step, we then traverse the CFG of the binary backwards at the assembler level until we encounter the first instruction that modifies the source register of the move. We record this instruction and continue with our backward traversal. Instead of looking for instructions that modify the source register of the original move, however, we will from here on search for instructions that modify the source register of the last instruction we recorded. If we continue this process, we eventually obtain the register or memory location where the value that is later on contained within the source register originates. We then repeat the process for the destination register. All the instructions that we recorded using this method form a *slice* of the binary. Each slice contains all the instructions that affect a given vulnerable `mov` instruction.

We implemented a *slicer* which is capable of extracting potential paths that could be used for n-byte writes from a 64-bit Linux or Windows kernel binary. The implementation of the slicer is based on the disassembler *IDA Pro* [14]. In particular, we make use of the CFG that IDA provides to perform the above described *static interprocedural def-use analysis*. Starting from each trigger, we perform a breadth-first search in a backwards direction. We hereby make use of a register set to conduct the actual analysis. Initially, this register set consists of the source and destination register. Whenever we encounter an instruction that modifies a register included within the register set, we add the source register of the instruction to the set and remove the modified register. Since we walk backwards through the instruction stream, this effectively allows us to record and track the *def-use chains* for the source and destination register. In addition, we record all instructions that we visit along the way, in order to be able to reconstruct the path that we explored in case we consider it to be potentially exploitable.

The challenge that remains to be solved is to determine whether a slice can be used for a dynamic hook or not. To address this problem, we must know whether the registers in the vulnerable move can be controlled by an attacker. We consider this to be the case if the values of the source and destination register originate from a *global* variable. The reasoning behind this approach is that the data used within the move in this case stems from a persistent location. Consequently, to control the final `mov` instruction, an attacker can modify the pointer chain starting from the global variable.

To identify global variables in the kernel, we assume that each access to a fixed address or the *Global Segment register (GS)* constitutes an access to a global variable. The reason for the latter is that both the Linux and Windows kernels store important global variables that are valid for a particular CPU within a memory region pointed to by this register. For instance, both Linux and Windows store the address of the `task_struct` (`gs:0xc740`) or the `_ETHREAD` (`gs:188`) structure of the process that is currently executing in this memory region.

If both the source *and* the destination register originate from a fixed address or the memory region pointed to by GS, we consider the path to be potentially exploitable and record it such that it can later on be used as input for the symbolic execution engine.

3.6.2 Symbolic Execution

Symbolic Execution is a well-known program analysis method that has been proposed over three decades ago [8, 17]. The basic idea of symbolic execution is to treat input data of interest as symbols rather than concrete values. These symbols can represent any possible value and as we walk over the code of a program, the values become constrained. Branches, for instance, set up conditions that constrain symbolic variables. Each of these conditions can be represented as a logical formula which can then be fed into an SMT solver to obtain concrete values that satisfy the path conditions. A profound introduction is available in the literature [25, 34].

We use forward symbolic execution to verify the satisfiability of our sliced paths and to produce detailed information for the creation of the dynamic hooks. In the process, we utilize the VEX IR, which is a RISC like intermediate representation with single static assignment (SSA) properties, deeply connected to the popular Valgrind toolkit [24]. Due to space limitations, we refrain from discussing this intermediate language in detail.

To verify satisfiability, we transform each basic block of the sliced path into VEX IR code and execute the code symbolically. The translation to VEX IR is achieved by utilizing a python framework called *pyvex* [36]. We dismantle every VEX statement that we obtain from *pyvex* and link the components of the statements into our own data structures. These data structures are used to walk over the VEX code and by doing so, we semantically map the statements to Z3 expressions. Z3 is a theorem

prover developed at Microsoft Research that we use to solve our formulas [23].

As we walk over the VEX code of our sliced paths, we also keep track of three global contexts, i.e., a memory context, CPU context, and the current jump condition. Each context consists of Z3 expressions that semantically mirror the current state of the execution. Additionally, each basic block also keeps track of temporary VEX IR variables in SSA form. By constant propagation, we use these variables to resolve source and destination. Each store, load, and register set statement updates the corresponding context in form of Z3 expressions. Once we hit a jump condition, we ask the solver whether we can take the jump according to our context. If no solution exists, we can filter out the path. An unsatisfiable set of formulas stops execution of the current path, and we move on with the next slice.

At this point it is worth mentioning that we do not use symbolic execution in the traditional sense to achieve code coverage. Our main goal is to check whether we can walk down our paths and to determine what value sets lead us to the end of the slice. We use the symbolic formulas to generate detailed information about the controlled registers at the time the vulnerability is triggered as well as the jump conditions that must be fulfilled to actually reach the trigger. By processing over the VEX code, the solver also gives us possible values to set.

4 Experiments

Based on the slicer and the symbolic execution engine, we created a prototype that we used to automatically extract paths for dynamic hooks in a fully patched Windows 7 SP1 64-bit kernel and a Linux 64-bit 3.8 kernel. We chose this approach for three main reasons. First and foremost, since malware nowadays generally attacks the kernel, this approach allowed us to test the prototype in a realistic scenario. Second, kernel binaries are especially complex, which makes them well suited for a thorough test of our implementation. Finally, by targeting Windows and Linux, the experiments show that the proposed mechanism is applicable to two of the most popular OSs.

In the following, we first discuss the results that we obtained by providing detailed statistics about the automatically extracted paths for both kernels. To demonstrate how useful the prototype is when it comes to the actual creation of the hooks, we also describe three concrete POCs for dynamic hooks that we created based on the information that the prototype provided.

4.1 Automated Path Extraction

As stated above, we tested our prototype with a fully patched Windows 7 SP1 64-bit kernel and a Linux 64-bit 3.8 kernel. The goal of the experiment was to automatically extract trigger paths that could then either be used by a human expert to manually design dynamic hooks or to automatically generate exploits. Table 1 provides an overview of the obtained results.

At first, we determined the number of instructions contained within both kernel binaries for reference. In the next step, we obtained the number of potentially exploitable 8-byte `mov` instructions. In the process, we only counted those `mov` instructions that move data from one general purpose register into a memory location specified by another general purpose register with the condition that the involved registers were neither `rbp` nor `rsp`. The reason for this restriction is that our prototype implementation currently does not support a memory model, meaning that we cannot track memory store and load operations in our slicer, which is why we currently ignore any path that requires this functionality. We will cover this limitation in more detail in Section 5.3. As Table 1 shows, about 2 % of all instructions within the tested kernels are `mov` instructions that fulfill this criteria.

Next, we used the slicer to extract potentially exploitable slices for each of the identified moves. In case of Linux, the slicer considered about 4% of the `mov` instructions as potentially exploitable, while on the Windows side about 20% of the `mov` instructions were marked as possibly exploitable. We assume that the significant difference between Windows and Linux stems from the fact that Linux has substantially more `mov` instructions that store or load data from memory (61,651 vs 37,272). Since the slicer does not support a memory model, it will abort whenever such a `mov` instruction is part of a def-use chain. Due to their number, this scenario is more likely to occur on Linux than on Windows.

Finally, we symbolically executed each of the obtained slices. In total, this led to 566 exploitable paths for Linux and 379 exploitable paths for Windows. The symbolic execution engine thereby produced the required value for each conditional jump within the path and detailed information of the vulnerable `mov` instruction. In particular, the output[3] specifies exactly which memory addresses must be modified in what way to pass the conditional jumps and where the source and destination values are located, respectively. This information can directly be applied to generate exploits or to manually create a dynamic hook as we will show in the next section.

4.2 Prototypes

We now present three concrete examples of dynamic hooks to illustrate the capabilities and properties which have been discussed throughout the paper. We created

[3] An example of the output is shown in Section 4.2.3.

OS	*Size*	*Instructions*	*8-byte moves*	*Slices*	*Paths*
Linux 3.8 64-bit (`vmlinux`)	18.8 MB	1,976,441	42,130 (2.1%)	1753 (4%)	**566 (32%)**
Windows 7 SP1 64-bit (`ntoskrnl.exe`)	5.3 MB	1,330,791	26,694 (2.0%)	5450 (20%)	**379 (07%)**

Table 1: Overview of the 8-byte moves, the potentially exploitable slices, and the exploitable paths according to the symbolic execution engine for the analyzed Linux and Windows kernels.

these examples based on the output provided by our prototype. The first and the third example focus on a dynamic control hook, while the second example demonstrates a dynamic data hook. To ease the understanding of the examples, all hooks leverage a trigger instruction within the `list_del` function (as explained in Section 3.2) or its Windows equivalent. The first two hooks were implemented for Linux 3.8 and an Intel Core i7-2600 3.4 GHz CPU. To demonstrate that the proposed concept is similarly applicable to Windows, the third hook was implemented on a fully patched version of Windows 7 SP1 running on the same CPU.

4.2.1 Dynamic Control Hook: Intercepting Syscalls

A common functionality that kernel level malware requires is the possibility to intercept system calls. In this example, we show how a single dynamic hook can be used to intercept *all* system calls for a particular process. To achieve this, the hook is placed into the execution flow of the *system call handler*, which is—independent of the system call mechanism that is used (i.e., interrupt-based, sysenter-based, or syscall-based)—invoked whenever a system call on the x86 architecture is executed. The main purpose of the syscall handler is to invoke the actual system call by using the system call number as an index into the system call table.

Similar to other functions within the kernel, the system call handler can be audited for debugging reasons. Auditing can be enabled or disabled within the flags field of the `thread_info` struct associated with each process. By setting the `TIF_SYSCALL_AUDIT` flag, every system call conducted by a process will also lead to the invocation of the auditing functions. In particular, the function `__audit_syscall_entry` will be executed before the invocation of a system call and the function `__audit_syscall_exit` will be executed after the system call, but before the system call handler hands control back to user space. In our POC, the dynamic hook is set within the `__audit_syscall_exit` function.

When syscall auditing is enabled, the `__audit_syscall_entry` function records information about the system call such as the syscall number and the arguments of the syscall within the audit context of the process. The purpose of the `__audit_syscall_exit` function is to reset the audit context of the task before the system call returns. In the process of resetting the audit context, this function invokes the inline function `audit_free_names`, which resets the `names_list` within the audit context:

```
1 static inline void audit_free_names(
2         struct audit_context *context) {
3     ...
4     list_for_each_entry_safe(n, next,
5           &context->names_list, list) {
6             list_del(&n->list);
7     }
8     ...
9 }
```

The `audit_free_names` function essentially iterates over the `names_list` of the audit context (Line 4) and deletes every entry within the list (Line 6). Consequently, if we control the `names_list`, we can control the entry that is passed to the `list_del` function, which in turn allows us to exploit its vulnerability. As the `names_list` is not modified by the `__audit_syscall_entry` function or anywhere else in the kernel[4], the attacker is free to modify it in any way she wants. That is, the `names_list` structure is exclusively bound to the execution path within the syscall handler that we use for our dynamic hook.

While the `names_list` structure seems to be perfectly suited for a dynamic hook, the triggering path places additional constraints on the hook. The problem arises due to the fact that the `list_del` function is contained within a loop that iterates over all entries within the `names_list` list (Line 4). To iterate through the list, the loop will essentially follow the `next` pointer in every entry until one of them points back to the first element in the list, which is `&context->names_list`. Since we want to modify the `next` and the `prev` pointer of an entry within the list to conduct an arbitrary 8-byte write, we have to take this problem into account and assure that the list iteration will eventually terminate. To achieve this we initialize the audit context as shown in Figure 1.

The basic idea behind this setup is to make use of a special address, referred to as a "magic address", that is a valid memory address, but at the same time contains valid x86 instructions. Due to little-endian byte order, these valid instructions must be contained in re-

[4]While there are other functions in the kernel that try to access the `names_list`, these attempts can be blocked by setting the first member within the audit context (`dummy`) to one.

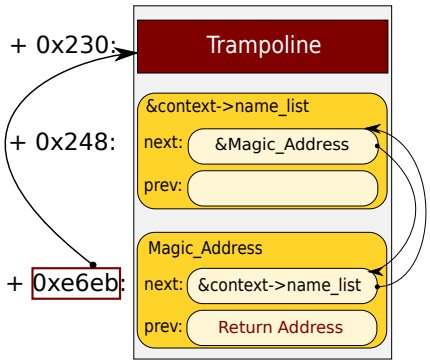

Figure 1: The audit context structure that the attacker uses to set a dynamic hook within `audit_free_names`.

verse order within the address. In Figure 1, the instruction encoded into the address is a negative relative jump (0xe6eb (address) $\Rightarrow$ 0xebe6 (instruction)) that will upon execution transfer control to a trampoline, that then transfers control to an arbitrary address. Initially when the loop begins iterating over the `names_list`, it follows the `next` pointer to the first entry within the list, which is located at the magic address. The `next` pointer stored at the magic address will in turn point back to the `names_list`, thus fulfilling the loop condition. However, before the loop exits, the first entry in the list (located at the magic address) is processed by the `list_del` function. Since the `prev` pointer of this entry points to the location of a return address, the `list_del` function will overwrite this return address with the value stored in the `next` pointer ($prev \rightarrow next = next$), which points to `&context->names_list`. Consequently, as soon as the return address is used, control will be transferred to the address of `&context->names_list` where the magic address is stored, leading to the execution of the magic address and the activation of the trampoline code. Note that the hook requires the audit context region created by the attacker to be writable and executable, since the `list_del` function conducts *two* write operations as has been described in Section 3.2. This is not a big problem in practice, since every memory region allocated with `kmalloc` is by default writable and executable.

The final problem that remains is which return address we are actually going to overwrite and how we can predict its location. As previously stated, the syscall handler is invoked before every system call and it will invoke the actual function handling the syscall. Thus, if we know the stack frame size of the syscall handler and the location of the kernel stack, we can predict where the return address of the function that is invoked by the syscall handler resides. The stack frame size can be obtained from the assembler code of the syscall handler, while the location of kernel stack can be obtained from a kernel variable (`get_cpu_var(kernel_stack)`). The target return address will then reside at `stack_frame_size + get_cpu_var(kernel_stack)`.

Summary. A dynamic control hook for intercepting all system calls for a particular process can be placed in the `audit_free_names` function. To ensure that execution passes through this function, we set the `TIF_SYSCALL_AUDIT` flag within the `thread_info` struct of the target process. In the next step, we modify the audit context of the target process in the way described above and use a trampoline to control the execution flow. This enables us to reliably divert the control flow at run-time. The resulting dynamic hook will have full coverage and be exclusively bound to the execution path leading to the `audit_free_names` function.

4.2.2 Dynamic Data Hook: Installing a Backdoor

In the second example, we demonstrate the possibilities of dynamic data hooks. In particular, we show how a dynamic data hook can be used to install a backdoor within a Linux system that is capable of elevating the task rights of a predefined process to *root*. For this purpose, we leverage the `ptrace` system call, which enables one process to attach to another process for debugging reasons. To install the backdoor, we simulate that a process used the `ptrace_attach` system call to attach to the target process (i.e. the process that will contain the hook). This is achieved by manually applying the changes that the `ptrace_attach` function conducts to the internal data structures of the target process. Most importantly, the `state` field of the task must be updated to include `__TASK_TRACED`, the `ptrace` field within the task must be set to 1, and the `parent` field must be set to the process which will later trigger the backdoor. We will defer the discussion of this last change for the moment and explain it in more detail later on.

Once the changes of the `ptrace_attach` function have been simulated, it is possible to invoke the `ptrace_detach` function on the so prepared process. The execution of this function eventually leads to the invocation of the `__ptrace_unlink` function, which in turn invokes the `list_del` function using the `ptrace_entry` pointer within the target process as argument:

```
1 void __ptrace_unlink(
2       struct task_struct *child) {
3       ...
4       list_del(&child->ptrace_entry);
5       ...
6 }
```

To use this code fragment for a dynamic data hook, we modify the $ptrace\_entry \rightarrow next$ pointer and the

ptrace_entry → *prev* pointer of the target process. This enables us to conduct an arbitrary 8-byte write when the `list_del` function is invoked during the execution of `ptrace_detach`. In particular, we set the `prev` pointer to point to the task credentials that we want to override and the `next` pointer to an address that is writable and ends with four zero bytes. To understand this, we have to take a look at the Linux task credential structure, which defines the access rights of a process:

```
1  struct cred {
2      ...
3      kuid_t  uid;  /* real UID */
4      kgid_t  gid;  /* real GID */
5      kuid_t  suid; /* saved UID */
6      kgid_t  sgid; /* saved GID */
7      kuid_t  euid; /* effective UID */
8      kgid_t  egid; /* effective GID */
9      ...
10 };
```

Each task contains three pairs of access rights and each access right pair consists of a user id and a group id. Most important for us is the effective user id (`euid`), which specifies the effective access rights of a process. Since the root user in Linux generally has the user id zero, our goal is to overwrite the `euid` field, which has a size of 4 bytes, with zeroes. If we choose an address for the `next` pointer that has its lower 32-bits set to zero and additionally set the `prev` pointer to point to the `euid` field of the process whose privileges we want to elevate, we will—due to the little endian byte order—overwrite the `euid` (*prev* → *next* = *next*) field with zeroes and thus set the access rights of the process to root. However, because the `list_del` function will also write the `prev` pointer into the address of `[next + 8]` (*next* → *prev* = *prev*), we have to ensure that the address used within the `next` pointer points to a writable memory region that does not contain crucial data. A possible address that can be used for this purpose is `0xffff880000000000` since this address usually points to the first 8-bytes of the physical memory of the machine, which is not used by the Linux kernel. Finally, note that we will also override the `egid` of the process with the upper 32-bits of the address in the next pointer. This will, however, not affect the process as long as it has a valid `euid`.

We can now set up a dynamic hook as follows: First, we need to select a target process that remains running on the system as it will contain the above described dynamic hook. Good candidates are therefore background daemons such as the SSH daemon. Second, we need to specify the victim process whose privileges we want to elevate and setup the dynamic hook within the target process. Since we need to know the address of the task struct of the victim process in order to be able to set the `prev` pointer to its `euid` field, this process also needs to remain running. A good choice in this case could, for instance, be a shell process within a screen session.

To activate the backdoor, we need to call the `ptrace` syscall with the `PTRACE_DETACH` argument on the target process. However, the backdoor cannot be activated by any process because only the tracing process can detach from the traced process. Since we simulate the changes conducted by `ptrace_attach`, the process which can execute the `ptrace_detach` call, is the process that we specify as `parent` during the setup of the dynamic hook. While this ensures that the backdoor cannot be triggered by accident, this requires us to specify the process that triggers the backdoor when we setup the dynamic hook. The easiest way to solve this problem is to specify the victim process as parent of the target process. In this case the victim, whose privileges will be elevated, can trigger the backdoor itself.

Summary. A dynamic data hook can be used to implement a backdoor that can be triggered from user space with arbitrary access rights. In our example, the backdoor is closely bound to the process that was specified as the tracing process and to the execution path within `ptrace_detach`. In addition, the hook only provides partial coverage as only the detach call to a specific process will trigger it, which is desired behavior in the case of a backdoor.

4.2.3 Dynamic Control Hook: Process Termination

To show that the proposed hooking concept can be applied to other OSs as well, we will in our final example present a dynamic control hook that we implemented on a fully patched version of Windows 7. In particular, the hook is capable of intercepting the termination of an arbitrary process, which can, for instance, be useful in situations where a malicious process on the system is found and terminated by a security application or the user. Due to the hook, the malware would be notified of this event and could react to it.

When a process is exiting on Windows 7, the function `NtTerminateProcess` is invoked which in turn invokes various cleanup functions that prepare the termination of the process. One of these functions is `ExCleanTimerResolutionRequest`. To support a wide range of applications, Windows provides processes with the possibility to request a change to the system's clock interval [32]. This enables programs that have a demand for a faster response time to decrease the clock interval and thus to increase the number of clock-based interrupts. When a process emits such a request, the process is added to the `TimerResolutionLink` list, which is used by the OS to manage all timer resolution changes. As the name suggests, the purpose of the `ExCleanTimerResolutionRequest` function is to remove processes from the man-

agement list once they exit. Our automated path extraction tool discovered the following path within this function:

```
1  ———SLICE———
2  0x000000014042c396   mov      rax, gs:188h
3  0x000000014042c39f   mov      rbx, [rax+70h]
4  0x000000014042c3c6   mov      rcx, [rbx+4A8h]
5  0x000000014042c3cd   mov      rax, [rbx+4B0h]
6  0x000000014042c3d4   mov      [rax], rcx
7  0x000000014042c3d7   mov      [rcx+8], rax
8
9  ———SYMBOLIC———
10 Jump Condition in: BB_0x14042c390
11 Concat(0x0, Extract(0x1f, 0x0,
12 MEM[RBX+0x440])) >> Concat(0x0, 0xc) &1 == 0
13
14 CPU CONTEXT/CONTROLLED REGISTERS
15 RCX -> MEM[MEM[MEM[0x188+GS]+0x70]+0x4a8]
16 RAX -> MEM[MEM[MEM[0x188+GS]+0x70]+0x4b0]
```

To remove a process from the TimerResolutionLink list, the ExCleanTimerResolutionRequest function obtains the forward and the backward pointer (Line 4 and Line 5) from the EPROCESS structure of the process and performs the discussed list delete operation (Line 6 and Line 7). The only prerequisite for this path is that the 13th least significant bit of the memory word at location EPROCESS+0x440 is not set (Line 11). By manipulating this memory word and the pointers, which are located within in the EPROCESS struct of the process at offset 0x4A8 (Line 4) and offset 0x4B0 (line 5) respectively, we can thus perform an arbitrary 8-byte write and change the control flow. In our POC we set the forward pointer (rcx) to point to our shellcode and the backward pointer (rax) to point to the return address of ExCleanTimerResolutionRequest. Just as in the case of our first example, the location of the latter can be obtained by subtracting the sum of the stack frames of the invoking functions from the start address of the kernel stack, which is stored within the InitalStack variable contained within the KTHREAD structure of the thread of the process. Similarly, the area where the shellcode resides must be writable *and* executable. On Windows, we can allocate such a memory region by invoking the ExAllocatePoolWithTag function with the argument NonPagedPoolExecute.

One last problem that remains, however, is that the TimerResolutionLink entry structure of a process is unfortunately not exclusively bound to the path of our dynamic hook, since the TimerResolutionLink list is also used by other functions such as ExpUpdateTimerResolution. The solution to this problem is quite simple, though: since the TimerResolutionLink list is not critical for the execution of a process and the ExCleanTimerResolutionRequest function does on top of that not iterate through the list, but rather accesses the forward and backward pointers directly, we can simply remove the entry from the linked list. As a result, the manipulated entry will no longer be processed by other management functions, which will bind the TimerResolutionLink entry structure exclusively to our trigger path. In our experiments, removing processes from the TimerResolutionLink list did not affect their execution in any way. The proposed dynamic hook therefore serves as an example that an exclusive binding of a hook payload must not be given by the target application, but can also be manually enforced by the creator of the hook.

Summary. By manipulating the TimerResolutionLink entry structure of a process in the way described above we can install a dynamic hook and intercept the termination of an arbitrary process on Windows. While the manipulated structure is by default not exclusively bound to the trigger path, the creator of the hook can enforce an exclusive binding manually by removing the manipulated entry from its linked list. In addition, the presented dynamic hook had full coverage in our experiments. It was even triggered if we forcefully terminated the process using the task manager.

5 Discussion

Up to this point, we have not discussed what kinds of transient control data exist. This is why it may seem to the reader that dynamic control hooks could be mitigated by protecting return addresses alone. In this section, we cover this topic in more detail and show that this is not the case. In addition, we cover possible countermeasures against dynamic hooks and review the limitations of the proposed hooking concept and our current prototype.

5.1 Transient Control Data

Instead of targeting *persistent* control data such as function pointers in the system call table, dynamic control hooks change *transient* control data at run-time. While return addresses are a popular example of *transient* control data, it is not the only kind of transient control data that exists. For instance, if a function allocates a local function pointer, this pointer will reside on the stack and not in the data segment or the heap. Instead of overwriting the return address, an attacker can in such a case similarly target the function pointer. While this is a rather unlikely scenario, it demonstrates a very important class of attacks where a local variable on the stack is changed to achieve the desired control flow change. This class of attacks is not restricted to function pointers alone. Consider, for example, the following code from the read sys-

tem call in the Linux kernel[5]:

```
1  struct fd {
2      struct file *file;
3      int need_put;
4  };
5
6  SYSCALL_DEFINE3(read, unsigned int, fd, char
7                  __user *, buf, size_t, count) {
8      struct fd f = fdget(fd);
9      ...
10     ret = f.file->f_op->read(f.file, buf,
11                              count, pos);
12     ...
13 }
```

In this case, a local structure (`struct fd f`) is allocated on the stack (Line 8). The structure contains a pointer to another structure (`struct file *file`), which in-turn contains a function pointer that is called in Line 10. With the help of a dynamic hook, an attacker could modify the pointer within the local structure (Line 2) and point it to an attacker-controlled structure instead. If she manages this before the function call in Line 10 is executed, this will effectively allow her to control the function call and thus enable her to arbitrarily change the control flow.

Instead of targeting a return address or a function pointer directly, the attacker in this scenario modifies a local pointer on the stack. This approach enables her to control any data that the local function accesses using this pointer. In the kernel, where objects in general are accessed through pointer chains, this represents a powerful attack vector, which effectively provides control over *any* object that the pointer references. Since similar code exists in many other functions within the kernel, this attack vector must be taken into account when one considers countermeasures against dynamic hooks.

5.2 Countermeasures

Dynamic hooks are installed by an attacker that already controls the application, which renders many of the existing defense mechanisms against exploits ineffective. However, while dynamic hooks are a powerful attack vector, there are, of course, countermeasures that can be used to reduce the attack surface. In the following, we first discuss possible countermeasures against dynamic control hooks, before we present defense mechanisms for dynamic data hooks.

Dynamic control hooks. What makes dynamic control hooks difficult to detect is that they do not permanently modify control data. Instead, their payload is hidden within non-control data and the actual control flow modification only occurs at run-time. This enables them to evade popular hook detection mechanisms such as HookSafe [43] or SBCFI [27], which only protect *persistent* control data, but ignore *transient* control data on the stack. However, at some point during the execution, dynamic control hooks must override control data in order to divert the control flow. Thus while a dynamic hook may be hidden at first, it will become visible when it is triggered. The resulting control flow change can potentially be detected using control flow integrity (CFI) and related approaches [1, 15, 20, 39, 42, 46, 48].

In order to detect dynamic control hooks with CFI, it is crucial that *every* control transfer of an application is verified. If a single control transfer is missed, this can potentially be abused by an attacker to install a dynamic hook. However, finding all possible control transfer instructions within complex software such as an OS kernel is a difficult problem. This is especially true if we consider attacks on transient control data such as the one present in the last section. Even worse, control transfer instructions can often have more than a single target. Consequently, one must not only identify all control transfer locations, but also all the possible targets of these transfers to avoid false positives. Additionally, if there are multiple possible targets for a given control transfer instruction, an attacker can still launch return-to-libc like attacks [37], which is a general problem of CFI mechanisms [48]. Finally, every check of a control transfer comes at a cost [39]: the more instructions we verify, the higher the overhead will be and for applications that are optimized for performance such as an OS kernel, even a small overhead can have a huge impact.

While current CFI approaches are not yet able to solve all of these problems, they certainly reduce the attack surface and make it more difficult to install dynamic control hooks. The results presented in this paper can help to further improve these mechanisms by using the discussed techniques to automatically extract possible triggers from a given application and adding additional checks to verify them. To increase the performance, one could make use of lazy control flow verification as proposed by Bletsch et al. [7]. This could result in an effective and efficient detection system, which might not be able to eliminate dynamic control hooks entirely, but will significantly raise the bar for an attacker.

Dynamic data hooks. The defense mechanisms discussed above make use of the fact that dynamic control hooks have to eventually modify the control flow. That is, the detection mechanisms do not focus on the hook itself, but rather target the *effects* of the hook's invocation. The idea behind dynamic data hooks is to complicate detection even further by modifying non-control data instead of control data. As a result, defenders can no

[5]For better readability we directly included the `vfs_read` function into the `read` system call. In the actual code the function call in Line 10 will occur in the `vfs_read` function.

longer concentrate on the control flow of the application alone, but rather have to detect integrity violations within the data of the application.

Verifying the integrity of data structures is a difficult problem. Petroni et al. [26] were the first to propose a general architecture for the detection of kernel data integrity violations. Since then various systems have been proposed that try to detect or prevent malicious modification of kernel data structures [9, 15, 19, 30, 33]. What is common to all these approaches, however, is that they only *enforce* integrity checks, but leave the *creation* of the actual integrity constraints to a human expert. To the best of our knowledge, the only approach that tries to generate integrity constraints for kernel data structures automatically is Gibraltar [4]. While this approach provides a good starting point and could support a human expert in the creation of integrity constraints, the authors acknowledge that the generated invariants are "neither sound nor complete" [4]. Creating reliable and evasion-resistant integrity constraints is, however, the basis for the detection of dynamic data hooks.

To be able to effectively protect kernel data structures, additional research in the field of automatic integrity constraint generation is required. Techniques that are able to generate signatures for kernel data structures such as the ones presented by Lin et al. [21] or Dolan-Gavitt et al. [12], could thereby provide a good starting for further research, as the generated signatures could potentially be used to infer integrity invariants. In the meanwhile, initial defense mechanism could use systems such as HookMap [43] or K-Tracer [18] in combination with the techniques presented in this paper to generate integrity constraints for known dynamic hooks that can then be enforced by one of the systems mentioned above.

Summary. While the threat of dynamic control hooks can potentially be reduced with the help of (kernel-level) CFI mechanisms, dynamic data hooks pose a difficult problem that cannot be easily solved. To detect dynamic data hooks, reliable integrity constraints are required that allow the automatic verification of the kernel data regions. Until these constraints are available, one could reduce the attack surface with the help of manual integrity specifications or by automatically creating integrity constraints for known attacks.

5.3 Limitations

Dynamic Hooks. Dynamic hooks essentially face two limitations. First and foremost, not every function may contain a vulnerability that can be used to implement a dynamic hook. In contrast, it is likely that there are functions which are immune against the attack. However, this is not a big problem in practice: if a particular function cannot be hooked directly, it may still be possible to intercept calls to the function by hooking a function that immediately precedes or follows the function in the execution flow. After all, not every function contains a function pointer either. Function pointer hooks have nevertheless been proven to be very effective in practice.

Second, similar to traditional exploits, a dynamic hook may face restrictions that are caused by the vulnerability it is exploiting. For instance, specific hooks such as the one presented in our first prototype (see Section 4.2.1) may require that certain memory areas are writable and executable. Depending on its restrictions, a dynamic hook may therefore not be suitable for every scenario. This, however, heavily depends on the particular hook.

Automated Path Extraction. While our prototype already produces very valuable paths that can be used to implement powerful dynamic hooks as we have shown in Section 4.2, it also faces some limitations. First, our slicer does not yet support a detailed memory model. As a result, we are unable to find dynamic hooks on paths where registers, which are currently monitored, are loaded with values from the stack. This situation frequently occurs when subfunctions are called. In this case, the calling function often stores register values temporarily on the stack to guarantee that they are not overwritten by the subfunction. During our experiments, the slicer ignored 79,853 such paths due to this restriction.

Second, the symbolic execution engine currently only handles a subset of the available x86 instructions. Most importantly, it is unable to handle some instructions that are a ring-0 privilege. This is, however, a restriction in the VEX intermediate language. In the experiments we conducted, this led to 949 (55%, Linux) and 4,908 (90%, Windows) paths that could not be verified.

Finally, the slicer and the symbolic execution engine currently do not consider the properties of *binding* and *coverage*, while determining whether a path could be used for a dynamic hook or not. Consequently, not all of the paths extracted by our prototype will be suited for the implementation of a dynamic hook. As described in Section 3.5, especially the property of binding can be a limiting factor. If a payload is only loosely bound, it is likely that the hook will introduce side effects that can lead to a crash of the system. Determining automatically whether a path has exclusive binding or full coverage is difficult though. As the discussed POCs show, even payloads that initially seem unsuited for the implementation of a dynamic hook can through subtle manipulations of the involved data structures yield very reliable hooks. To designate the binding of a payload, we thus not only have to identify whether a payload is used in multiple locations, but we also have to establish how many of those usages can be controlled by the attacker. This requires

a profound semantic understanding of the data structures and functions involved.

6 Related Work

To the best of our knowledge, Petroni et al. [27] were the first to consider the hooking of transient control data. However, their work is primarily focused on the detection of *persistent* control flow modifications. Attacks on transient control data are thereby only mentioned as a limitation of their system. Hofmann et al. [15] presented a "return to schedule" rootkit that overwrites return addresses of sleeping processes to periodically invoke itself and evade hook detection mechanisms. While related to our work, this approach does not leverage exploitation techniques to change the control of an application at runtime. As a consequence, the technique only enables the rootkit to reschedule itself, but it does not allow it to intercept events within the system, which is the actual goal of a hooking mechanism.

In addition, there has also been a lot of work concerned with the possibilities of non-control data attacks. Chen et al. [10] were the first to demonstrate that non-control data attacks are indeed a dangerous and realistic threat. Sparks and Butler [38] presented DKOM as a general mechanism to hide objects within kernel space. Baliga et al. [5] extended this work and presented another class of stealthy attacks that do not have the goal of hiding objects, but rather target crucial kernel data structures to subvert the integrity of the system. Finally, Prakash et al. [28] discussed the manipulation of semantic values in the kernel to evade virtual machine introspection (VMI).

7 Conclusion

In this paper, we presented a novel hooking concept that we coined dynamic hooks. The main insight behind this concept is that existing hooking mechanisms are based on the permanent modification of *persistent* control data. As a consequence, the resulting hooks are constantly evident within the system and can be detected by verifying persistent control data alone.

Dynamic hooks solve this problem by targeting *transient* control data at *run-time*. This is achieved by applying exploitation techniques to the problem of hooking. To install a dynamic hook, an attacker will modify the internal data structures of an application in such a way that its usage will trigger a vulnerability at run-time. The hook thereby only consists of the modified data as well as the exploitation logic. This results in a powerful attack model with a wide range of possibilities as the attacker can make use of the entire arsenal of exploitation mechanisms to achieve her goal. At the same time, the hook will remain hidden in non-control data until it is triggered, which makes dynamic hooks not only powerful, but also difficult to detect in practice.

To show the applicability of the approach, we implemented a prototype that is capable of automatically extracting paths for dynamic hooks from recent Linux and Windows kernels. The experiments that we conducted prove that dynamic hooks are not only a dangerous, but are also a realistic threat that can be applied to practical scenarios such as system call hooking and backdooring. In future work, we plan to further improve our prototype implementation and to make use of it to generate integrity constraints instead of attack vectors that can then be used for the reliable detection of dynamic hooks.

Abstract

This paper introduces X-Force, a novel binary analysis engine. Given a potentially malicious binary executable, X-Force can force the binary to execute requiring no inputs or proper environment. It also explores different execution paths inside the binary by systematically forcing the branch outcomes of a very small set of conditional control transfer instructions. X-Force features a crash-free execution model that can detect and recover from exceptions. In particular, it can fix invalid memory accesses by allocating memory on-demand and setting the offending pointers to the allocated memory. We have applied X-Force to three security applications. The first is to construct control flow graphs and call graphs for stripped binaries. The second is to expose hidden behaviors of malware, including packed and obfuscated APT malware. X-Force is able to reveal hidden malicious behaviors that had been missed by manual inspection. In the third application, X-Force substantially improves analysis coverage in dynamic type reconstruction for stripped binaries.

1 Introduction

Binary analysis has many security applications. For example, given an unknown, potentially malicious executable, binary analysis helps construct its human inspectable representations such as control flow graph (CFG) and call graph (CG), with which security analysts can study its behavior [40, 23, 50, 46, 6, 33]. Binary analysis also helps identify and patch security vulnerabilities in COTS binaries [10, 14, 31, 51, 11]. Valuable information can be reverse-engineered from executables through binary analyses. Such information includes network protocols [44, 12, 7, 47, 28, 32], input formats [27, 29, 13], variable types, and data structure definitions [30, 25, 39]. They can support network sniffing, exploit generation, VM introspection, and forensic analysis.

Existing binary analysis can be roughly classified into static, dynamic, and symbolic (concolic) analysis. Static analysis analyzes an executable directly without executing it; dynamic analysis acquires analysis results by executing the subject binary; symbolic (concolic) analysis is able to generate inputs to explore different paths of a binary. These different styles of analyses have their respective strengths and limitations. Static analysis has difficulty in handling packed and obfuscated binaries. Memory disambiguation and indirect jump/call target analysis are known to be very challenging for static analysis.

Dynamic binary analysis is based on executing the binary on a set of inputs. It is widely used in analyzing malware. However, dynamic analysis is incomplete by nature. The quality of analysis results heavily relies on coverage of the test inputs. Moreover, modern malware [16, 26, 19] has become highly sophisticated, posing many new challenges for binary analysis: (1) For a zero-day binary malware, we typically do not have any knowledge about it, especially the nature of its input, making traditional execution-based analysis [15, 50, 4, 43, 49] difficult; (2) Malware binaries are increasingly equipped with anti-analysis logic [37, 5, 17, 18, 35] and hence may refuse to run even if given valid input; (3) Malware binaries may contain multi-staged, condition-guarded, and environment-specific malicious payloads, making it difficult to reveal all payloads, even if one manages to execute them.

Symbolic [8] and concolic analysis [38, 20, 40, 10] has seen much progress in recent years. Some handle binary programs [40, 10, 33, 6] and can explore various paths in a binary. However, difficulties exist when scaling them to complex, real-world binaries, as they operate by modeling individual instructions as symbolic constraints and using SMT/SAT solvers to resolve the generated constraints. Despite recent impressive progress, SMT/SAT remains expensive. While symbolic and concrete executions can be performed simultaneously so that concrete execution may help when symbolic analysis encounters difficulties, the user needs to provide concrete inputs, called *seed inputs*, and the quality of seed inputs is critical to the execution paths that can be explored. With no or little knowledge about malware input, creating such seed inputs is difficult. Moreover, many existing techniques cannot handle obfuscated or self-modifying binaries.

In this paper, we propose a new, practical execution engine called X-Force. The core enabling technique behind X-Force is *forced execution* which, as its name suggests, *forces an arbitrary binary to execute along different paths without any input or environment setup.* More specifically, X-Force monitors the execution of a binary through dynamic binary instrumentation, systematically forcing a small set of instructions that may affect the execution path (e.g., predicates and jump table ac-

cesses) to have specific values, regardless of their computed values, and supplying random values when inputs are needed. As such, the *concrete* program state of the binary can be systematically explored. For instance, a packed/obfuscated malware can be forced to unpack/deobfuscate itself by setting the branch outcomes of self-protection checks, which terminate execution in the presence of debugger or virtual machine. X-Force is able to tolerate invalid memory accesses by performing on-demand memory allocations. Furthermore, by exploring the reachable state of a binary, X-Force is able to explore different aspects or stages of the binary behavior. For example, we can expose malware's data exfiltration operations, without the presence of the real data asset being targeted.

Compared to manual inspection and static analysis, X-Force is more accurate as many difficulties for static analysis, such as handling indirect jumps/calls and obfuscated/packed code, can be substantially mitigated by the concrete execution of X-Force. Compared to symbolic/concolic analysis, X-Force trades precision slightly for *practicality* and *extensibility*. Note that X-Force may explore infeasible paths as it forces predicate outcomes; whereas symbolic analysis attempts to respect path feasibility through constraint solving[1]. The essence of X-Force will be discussed later in Section 6. Furthermore, executions in X-Force are all concrete. Without the need for modeling and solving constraints, X-Force is more likely to scale to large programs and long executions. The concrete execution of X-Force makes it suitable for analyzing packed and obfuscated binaries. It also makes it easy to port existing dynamic analysis to X-Force to leverage the large number of executions, which will mitigate the incompleteness of dynamic analyses.

Our main contributions are summarized as follows:

- We propose X-Force, a system that can force a binary to execute requiring no inputs or any environment setup.
- We develop a crash-free execution model that could detect and recover from exceptions properly. We have also developed various execution path exploration algorithms.
- We have overcome a large number of technical challenges in making the technique work on real world binaries including packed and obfuscated malware binaries.
- We have developed three applications of X-Force. The first is to construct CFG and CG of stripped binaries, featuring high quality indirect jump and call target identification; the second is to study hidden behavior of advanced malwares; the third one is to apply X-Force in reverse engineering variable types and data structure definitions of executables. Our results show that X-Force substantially advances the state-of-the-arts.

[1]However, due to the difficulty of precisely modeling program behavior, even state-of-the-art symbolic analysis techniques [8, 10, 40] cannot guarantee soundness.

2 Motivation Example

Consider the snippet in Figure 1. It shows a hidden malicious payload that hijacks the name resolution for a specific domain (line 14), which varies according to the current date (in function *genName()*). In particular, it receives some integer input at line 2. If the input satisfies condition *C* at line 3, a *DNSentry* object will be allocated. In lines 5-8, if the input has the *CODE_RED* bit set, it populates the object by calling *genName()* and stores the input and the generated name as a (key, value) pair into a hash table. In lines 12-14, the pair is retrieved and used to guide domain name redirection. Note that the hash table is used as a general storage for objects of various types. In line 10, an irrelevant object *o* is also inserted into the table.

This example illustrates some of the challenges faced by both static and symbolic/concolic analysis. *In static analysis*, it is difficult to determine that the object retrieved at line 12 is the one inserted at line 7 because the abstract domain has to precisely model the behavior of the hash table put/get operations and the condition that `y==x`, which requires context-sensitive and path-sensitive analysis, and disambiguating the memory `bucket[i]` and `bucket[i+4]` in *table_get()* and *table_put()*. The approximations made by many static analysis techniques often determine the object at line 12 could be the one put at line 7 or 10. Performed solely at the binary level, such an analysis is actually much more challenging than described here. *In symbolic/concolic analysis*, one can model the input at line 2 as a symbolic variable such that, by solving the symbolic constraints corresponding to path conditions, the hidden payload might be reached. However, the dictionary read at line 21 will be difficult to handle if the file is *unavailable*. Modeling the file as symbolic often causes scalability issues if it has nontrivial format and size, because the generated symbolic constraints are often complex and the search space for acquiring syntactically correct inputs may be extremely large.

In X-Force, the binary is first executed as usual by providing random inputs. Note that X-Force does not need to know the input format *a priori* as its exception recovery mechanism prevents any crashes/exceptions. In other words, the supply of random input values is merely to allow the execution to proceed, not to drive the execution along different paths. In the first normal run, assume that the false branches of the conditionals at lines 3, 5 and 13 are taken, yielding an uninteresting execu-

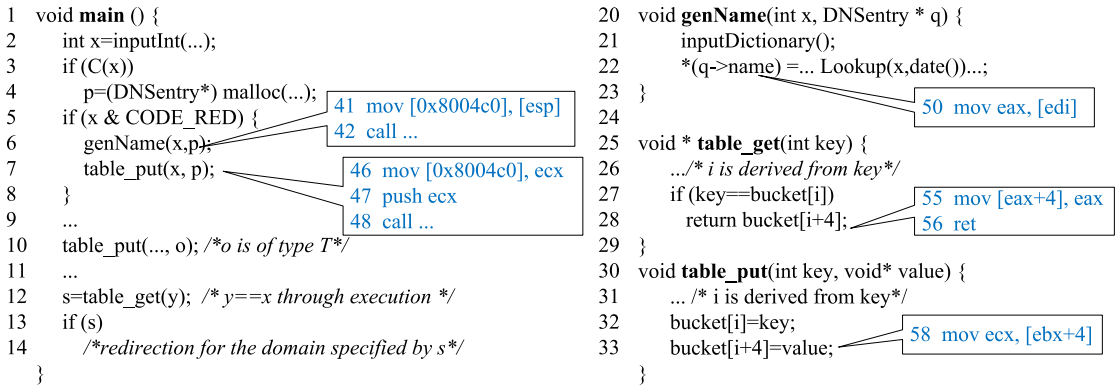

Figure 1: Motivating Example.

tion. X-Force will then try to *force-set* branch outcomes at a small number (say, 1 or 2) of predicates by performing systematic search. Assume that the branch outcome at line 5 is force-set to "true". The malicious payload will be forced to activate. Note that pointer p has a null value at line 6, which will normally crash the execution at line 22. X-Force tolerates such invalid accesses by *allocating memory on demand*, right before line 22. Also, even if the dictionary file at line 21 is absent, X-Force will force it through by supplying random input values. As such, some random integer and domain are inserted into the table (line 7) and retrieved later (line 12). Eventually, the random domain name is redirected at line 14, exposing the DNS hijacking operation. We argue that the domain name itself is not important as long as the hidden hijacking logic is exposed.

3 High Level Design

3.1 Forced Execution Semantics

This section explains the basics of how a single forced execution proceeds. The goal is to have a non-crashable execution. For readability, we focus on explaining how to detect and recover from memory errors in this subsection, and then gradually introduce the other aspects of forced execution such as path exploration and handling libraries and threads in later sections.

Program	P	$::= s$
Stmt	s	$::= s_1; s_2 \mid \texttt{nop} \mid r :=^{\ell} e \mid r :=^{\ell} \texttt{R}(r_a) \mid \texttt{W}^{\ell}(r_a, r_v) \mid \texttt{jmp}^{\ell}(\ell_1) \mid \texttt{if}\ (r^{\ell})\ \texttt{then jmp}(\ell_1) \mid \texttt{jmp}^{\ell}(r) \mid r := \texttt{malloc}^{\ell}(r_s) \mid \texttt{free}^{\ell}(r) \mid \texttt{call}^{\ell}(\ell_1) \mid \texttt{call}^{\ell}(r) \mid \texttt{ret}^{\ell}$

PC	ℓ	$::= \{\ell_1, \ell_2, \ell_3, \ldots\}$

Figure 2: Language.

Language. Due to the complexity of the x86 instruction set, we introduce a simple low-level language that models x86 binary executables to facilitate discussion. We only model a subset that is sufficient to illustrate the key ideas. Fig. 2 shows the syntax.

Memory reads and writes are modeled by $\texttt{R}(r_a)$ and $\texttt{W}(r_a, r_v)$ with r_a holding the address and r_v the value. Since it is a low-level language, we do not model conditional or loop statements, but rather guarded jumps; `malloc()` and `free()` represent heap allocation and deallocation. Function invocations and returns are modeled by `call()` and `ret`. In our language, stack/heap memory addresses are modeled as a range of integers and a special value 0 to denote the null pointer value. Program counters (or instruction addresses) are explicitly modeled by the *PC* set. Observe that each instruction is labeled with a *PC*, denoting its instruction address. Direct jumps/calls are parameterized with explicit *PC* values whereas indirect jumps/calls are parameterized with a register.

LSet	::=	$\mathcal{P}(Addr)$
$SR \in RegLinearSet$	::=	$Register \mapsto \&LSet$
$SM \in MemLinearSet$	::=	$Addr \mapsto \&LSet$
$accessible \in AddrAccessible$	::=	$Addr \mapsto boolean$

1. The occurrence“r” denotes the symbolic name of register r, the occurrence of r denotes the value stored in r.
2. Operator “=” means set update, “$\rightarrow$” means pointer update.

able by allocating memory on-demand. However, when we replace a pointer pointing to an invalid address *a* with the allocated memory, *we need to update all the other pointer variables that have the same address value or a value denoting an offset from the address*. We achieve this through the *linear set tracing semantics*, which is also the basic semantics for forced executions[2]. Its goal is to identify the set of variables (i.e. memory locations and registers at the binary level), whose values have *linear correlations*. In this paper, *we say two variables are linearly correlated if the value of one variable is computed from the value of the other variable by adding or subtracting a value.* Note that it is simpler than the traditional definition of linear correlation, which also allows a scaling multiplier. It is however sufficient in this work as *the goal of linear set tracing is to identify correlated pointer variables, which are induced by address offsettings that are exclusively additions and subtractions*.

The semantics is presented in Table 1. The corresponding definitions are presented in Fig 3. Particularly, linear set *LSet* denotes a set of addresses such that *the values stored in these addresses are linearly correlated*. Mapping *SR* maps a register to the reference of a *LSet*. Intuitively, one could interpret that it maps a register to a pointer pointing to a set of addresses such that the values stored in the register and those addresses are linearly correlated. Two registers map to the same reference (of a *LSet*) implies that the values of the two registers are also linearly correlated. Similarly, mapping *SM* maps an address to the reference of a *LSet* such that the values in the address and all the addresses in *LSet* are linearly correlated. The essence of linear set tracing is to maintain the *SR* and *SM* mappings for all registers and addresses that have been accessed so that at any execution point, we can query the set of linearly correlated variables of any given variable.

[2]We will explain the predicate switching part of the semantics in Section 3.2
